Intermediate-Level Visual Processing and Visual Primitives

We have seen in Chapters 21 and 22 that the eye is not a mere camera, but instead contains sophisticated retinal circuitry that decomposes the retinal image into signals representing contrast and movement. These data are conveyed through the optic nerve to the primary visual cortex, which uses this information to analyze the shape of objects. It first identifies the boundaries of objects, represented by numerous short line segments, each with a specific orientation. The cortex then integrates this information into a representation of specific objects, a process referred to as *contour integration.*

These two steps, local analysis of orientation and contour integration, exemplify two distinct stages of visual processing. Computation of local orientation is an example of low-level visual processing, which is concerned with identifying local elements of the light structure of the visual field. Contour integration is an example of intermediate-level visual processing, the first step in generating a representation of the unified visual field. At the earliest stages of analysis in the cerebral cortex, these two levels of processing are accomplished together.

A visual scene comprises many thousands of line segments and surfaces. Intermediate-level visual processing is concerned with determining which boundaries and surfaces belong to specific objects and which are part of the background (see Figure 21–4). It is also involved in distinguishing the brightness and color of a surface from the intensity and wavelength of light reflected from that surface. The physical characteristics of reflected light result as much from the intensity and color balance of the light that illuminates a surface as from the color of that surface. Determining the actual surface color of a single object requires comparison of the wavelengths of light reflected from multiple surfaces in a scene.

Intermediate-level visual processing thus involves assembling local elements of an image into a unified percept of objects and background. Although determining which elements belong together in a single object is a highly complex problem with an astronomical number of potential solutions, each relay in the visual circuity of the brain has built-in logic that

allows assumptions to be made about the likely spatial relationships between elements. In certain cases, these inherent rules can lead to the illusion of contours and surfaces that do not actually exist in the visual field (Figure 23–1).

Three features of visual processing help overcome ambiguity in the signals from the retina. First, the way in which a visual feature is perceived depends on everything that surrounds it. The perception of a point, line, or surface, for example, depends on the relationship between that feature and what else is present in the scene. That is, the response of a neuron in the visual cortex is context-dependent: It depends as much on the presence of contours and surfaces outside the cell's receptive field as on the attributes within it. Second, the functional properties of neurons in the visual cortex can be altered by visual experience or perceptual learning. Finally, visual processing in the cortex is subject to the influence of cognitive functions, specifically attention, expectation, and "perceptual task" (the active engagement in visual discrimination or detection). The interaction between these three factors—the context or entire set of signals representing a scene, experience-dependent changes in cortical circuitry,

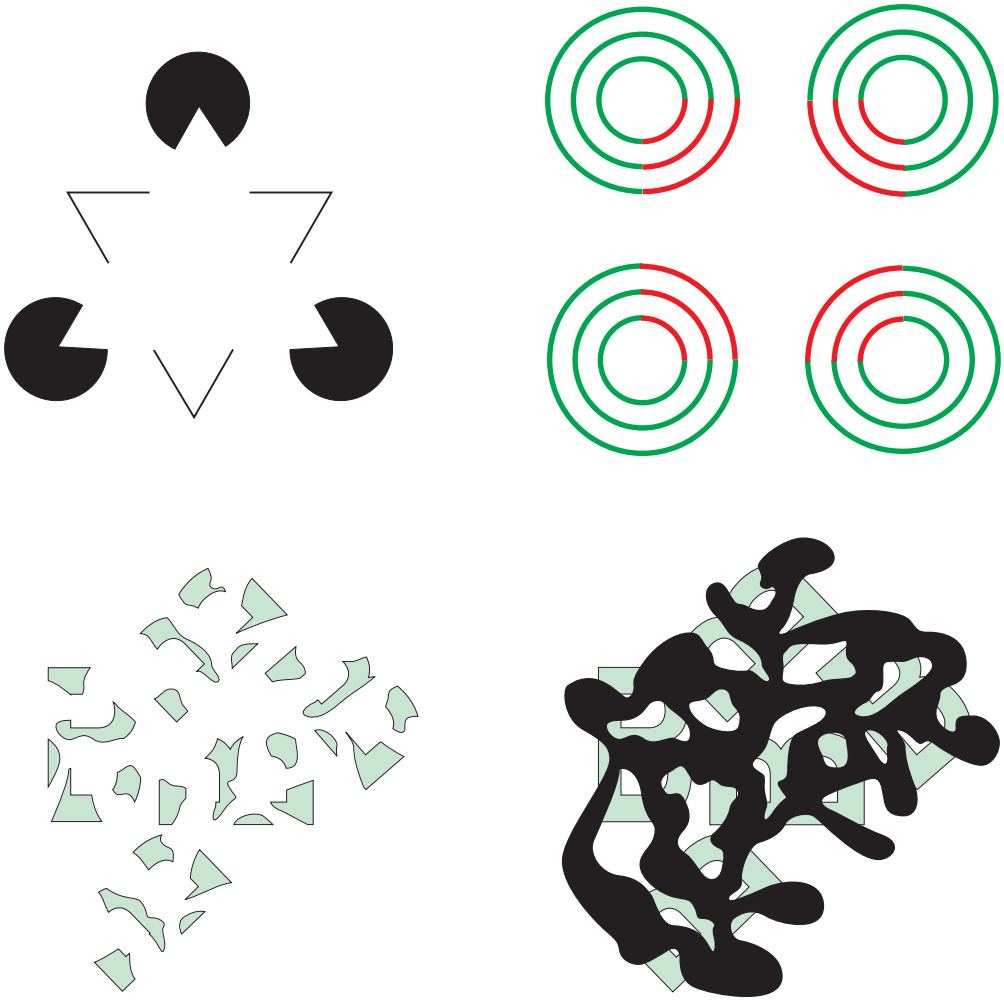

Figure 23–1 Illusory contours and perceptual fill-in. The visual system uses information about local orientation and contrast to construct the contours and surfaces of objects. This constructive process can lead to the perception of contours and surfaces that do not appear in the visual field, including those seen in illusory figures. **Top left:** In the Kanizsa triangle illusion, one perceives continuous boundaries extending between the apices of a white triangle, even though the only real contour elements are those formed by the Pac-Man–like figures and the acute angles. **Top right:** The inside and outside of the illusory pink square are the same white color as the page, but a continuous transparent pink surface within the square is perceived. **Bottom:** Occluding surfaces can also facilitate contour integration and surface segmentation. The irregular shapes on the left appear to be unrelated, but when they are partially occluded by black shapes (right), they are easily seen as fragments of the letter B.

and expectation—is vital to the visual system's analysis of complex scenes.

In this chapter, we examine how the brain's analysis of the local features in a visual scene, or *visual primitives,* proceeds in parallel with the analysis of more global features. Visual primitives include contrast, line orientation, brightness, color, movement, and depth. Each type of visual primitive is subject to the integrative action of intermediate-level processing. Lines with particular orientations are integrated into object contours, local contrast information into surface brightness and surface segmentation, wavelength selectivity into color constancy, and directional selectivity into object motion.

The analysis of visual primitives begins in the retina with the detection of brightness and color and continues in the primary visual cortex with the analysis of orientation, direction of movement, and stereoscopic depth. Properties related to intermediate-level visual processing are analyzed together with visual primitives in the visual cortex starting in the primary visual cortex (V1), which plays a role in contour integration and surface segmentation. Other areas of the visual cortex specialize in different aspects of this task: V2 analyzes properties related to object surfaces, V4 integrates information about color and object shape, and V5—the middle temporal area or MT—integrates motion signals across space (Figure 23–2).

Internal Models of Object Geometry Help the Brain Analyze Shapes

A first step in determining an object's contour is identification of the orientation of local parts of the contour. This step commences in V1, which plays a critical role in both local and global analysis of form.

Neurons in the visual cortex respond selectively to specific local features of the visual field, including orientation, binocular disparity or depth, and direction of movement, as well as to properties already analyzed in the retina and lateral geniculate nucleus, such as contrast and color. Orientation selectivity, the first emergent property identified in the receptive fields of cortical neurons, was discovered by David Hubel and Torsten Wiesel in 1959.

Neurons in both the retina (Chapter 22) and the lateral geniculate nucleus (Chapter 21) have circular receptive fields with a center-surround organization. They respond to the light–dark contrasts of edges or lines in the visual field but are not selective for the orientations of those edges (see Figure 21–9). In the visual cortex, however, neurons respond selectively to lines of particular orientations. Each neuron responds to a narrow range of orientations, approximately 40°, and different neurons respond optimally to distinct orientations. Hubel and Wiesel proposed that this orientation selectivity reflects the arrangement of the inputs

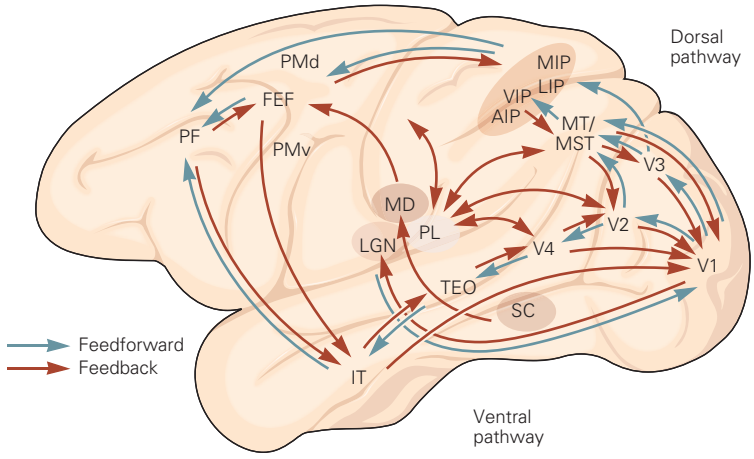

Figure 23–2 Cortical areas involved with intermediate-level visual processing. Many cortical areas in the macaque monkey, including V1, V2, V3, V4, and middle temporal area (**MT**), are involved with integrating local cues to construct contours and surfaces and segregating foreground from background. The shaded areas extend into the frontal and temporal lobes because cognitive output from these areas, including attention, expectation, and behavioral task, contributes to the process of scene segmentation. (Abbreviations: **AIP**, anterior intraparietal cortex; **FEF**, frontal eye fields; **IT**, inferior temporal cortex; **LGN**, lateral geniculate nucleus; **LIP**, lateral intraparietal cortex; **MD**, medial dorsal nucleus of thalamus; **MIP**, medial intraparietal cortex; **MST**, medial superior temporal cortex; **MT**, middle temporal cortex; **PF**, prefrontal cortex; **PL**, pulvinar; **PMd**, dorsal premotor cortex; **PMv**, ventral premotor cortex; **SC**, superior colliculus; **TEO**, occipitotemporal cortex; **VIP**, ventral intraparietal cortex; **V1**, **V2**, **V3**, **V4**, primary, secondary, third, and fourth visual areas.)

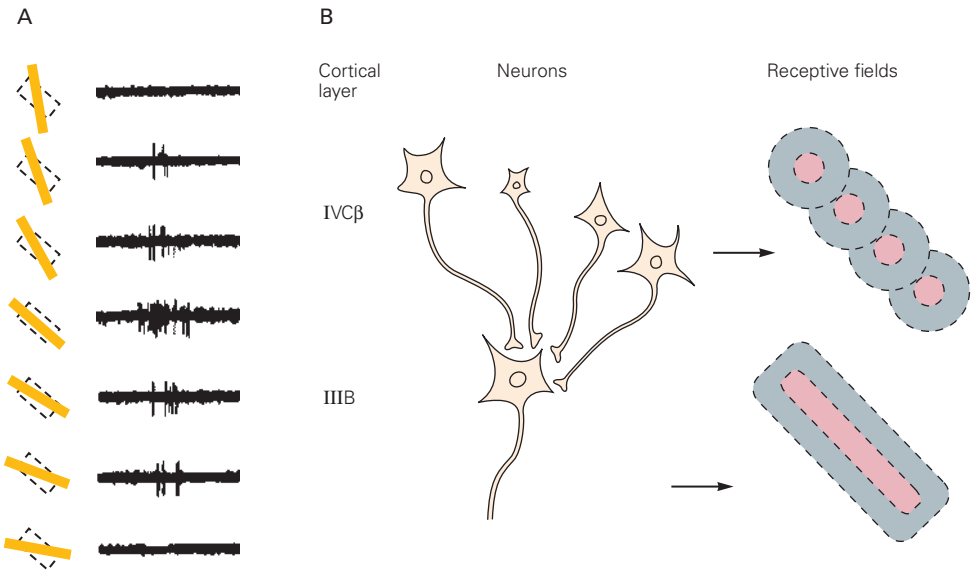

Figure 23–3 Orientation selectivity and mechanisms.

A. A neuron in the primary visual cortex responds selectively to line segments that fit the orientation of its receptive field. This selectivity is the first step in the brain's analysis of an object's form. (Reproduced, with permission, from Hubel and Wiesel 1968. Copyright © 1968 The Physiological Society.)

B. The orientation of the receptive field is thought to result from the alignment of the circular center-surround receptive fields of several presynaptic cells in the lateral geniculate nucleus. In the monkey, individual neurons in layer IVCβ of V1 have unoriented receptive fields. However, when several neighboring IVCβ cells project to a neuron in layer IIIB they create a receptive field with a specific orientation for that postsynaptic cell.

from the lateral geniculate nucleus, and there is now a body of supportive evidence for the idea. Each V1 neuron receives input from several neighboring geniculate neurons whose center-surround receptive fields are aligned so as to represent a particular axis of orientation (Figure 23–3). Two principal types of orientation-selective neurons, simple and complex, have been identified.

Simple cells have receptive fields divided into ON and OFF subregions (Figure 23–4). When a visual stimulus such as a bar of light enters the receptive field's ON subregion, the neuron fires; the cell also responds when the bar leaves the OFF subregion. Simple cells have a characteristic response to a moving bar; they discharge briskly when a bar of light leaves an OFF region and enters an ON region. The responses of these cells are therefore highly selective for the position of a line or edge in space.

Complex cells are less selective for the position of object boundaries. They lack discrete ON and OFF subregions (Figure 23–4) and respond similarly to light and dark at all locations across their receptive fields. They fire continuously as a line or edge stimulus traverses their receptive fields. Hubel and Wiesel proposed that the complex cells are a second stage of the elaboration of receptive fields after simple receptive fields and are built by overlapping simple receptive fields.

As one considers the range of receptive field properties that have been described in the early visual cortical areas, it is important to point out phylogenetic differences, with different species differing in the location in which these properties are first expressed and in the kinds of properties that are represented. In the cat, the target layer of the visual cortex for lateral geniculate neurons has oriented simple cells; it had been presumed that these cortical cells represent an obligatory first stage in the cortical processing of visual information, between the center-surround circularly symmetric receptive fields in the lateral geniculate nucleus and the receptive fields of complex cells in the superficial cortical layers. In primates, however, the geniculate target layers, 4Cα and β, have circularly symmetric, unoriented receptive fields. The postsynaptic target of the layer 4C cells, predominantly the superficial layers of the cortex, is populated with complex cells, therefore skipping a simple cell stage. In the mouse, orientation selectivity is seen in the lateral geniculate nucleus. The preceding comparison points out a few characteristics of the evolution of visual processing. One is the encephalization of function, where properties such as orientation are shifted to later stages of processing over stages of evolution. Another is the development of new pathways. It has been suggested that the

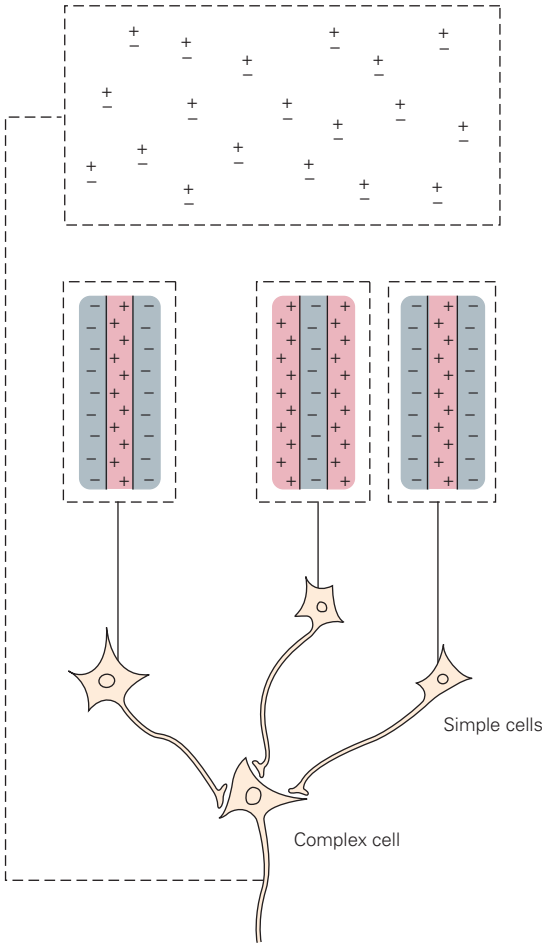

Figure 23–4 Simple and complex cells in the visual cortex. The receptive fields of simple cells are divided into subfields with opposite response properties. In an ON subfield (indicated by +), the onset of a light triggers a response in the neuron; in an OFF subfield (indicated by –), the extinction of a bar of light triggers a response. Complex cells have overlapping ON and OFF regions and respond continuously as a line or edge traverses the receptive field along an axis perpendicular to the receptive-field orientation.

magnocellular pathway in the monkey is equivalent to the entire geniculostriate pathway in the cat, whereas the parvocellular pathway, which mediates higher-resolution vision and color vision, is new to the primate.

Moving stimuli are often used to study the receptive fields of visual cortex neurons, not only to simulate the conditions under which an object moving in space is detected but also to simulate the conditions produced by eye movements. As we scan the visual environment, the boundaries of stationary objects move across the retina. In fact, visual perception requires eye movement. Visual cortex neurons do not respond to an image that is stabilized on the retina. These neurons require transient stimulation (moving or flashing stimuli) in order to be activated.

Some visual cortex neurons have receptive fields in which an excitatory center is flanked by inhibitory regions. Inhibitory regions along the axis of orientation, a property known as *end-inhibition*, restrict a neuron's responses to lines of a certain length (Figure 23–5). End-inhibited neurons respond well to a line that does not extend into the inhibitory flanks but lies entirely within the excitatory part of the receptive field. Because the inhibitory regions share the orientation preference of the central excitatory region, end-inhibited cells are selective for line curvature and also respond well to corners.

To define the shape of the object as a whole, the visual system must integrate the information on local orientation and curvature into object contours. The way in which the visual system integrates contours reflects the geometrical relationships present in the natural world (Figure 23–6). As originally pointed out by Gestalt psychologists early in the 20th century, contours that are immediately recognizable tend to follow the rule of good continuation (curved lines maintain a constant radius of curvature and straight lines stay straight). In a complex visual scene, such smooth contours tend to "pop out," whereas more jagged contours are difficult to detect.

The responses of a visual cortex neuron can be modulated by stimuli that themselves do not activate the cell and therefore lie outside the receptive field's core. This *contextual modulation* endows a neuron with selectivity for more complex stimuli than would be predicted by placing the components of a stimulus at different positions in and around the receptive field. The same visual features that facilitate the detection of an object in a complex scene (Figure 23–6A) also apply to contextual modulation. The properties of the features that confer perception of contours, even illusory ones, are reflected in the responses of neurons in the primary visual cortex, which are sensitive to the global characteristics of contours, even those that extend well outside their receptive fields.

Contextual influences over large regions of visual space are likely to be mediated by connections between multiple columns of neurons in the visual cortex that have similar orientation selectivity (Figure 23–6B). These connections are formed by pyramidal-cell axons that run parallel to the cortical surface (see Figure 21–16). The extent and orientation dependency of these horizontal connections provide the interactions that could mediate contour saliency (see Figure 21–14).

Central to the process of contour integration is the idea of the association field. The association field refers

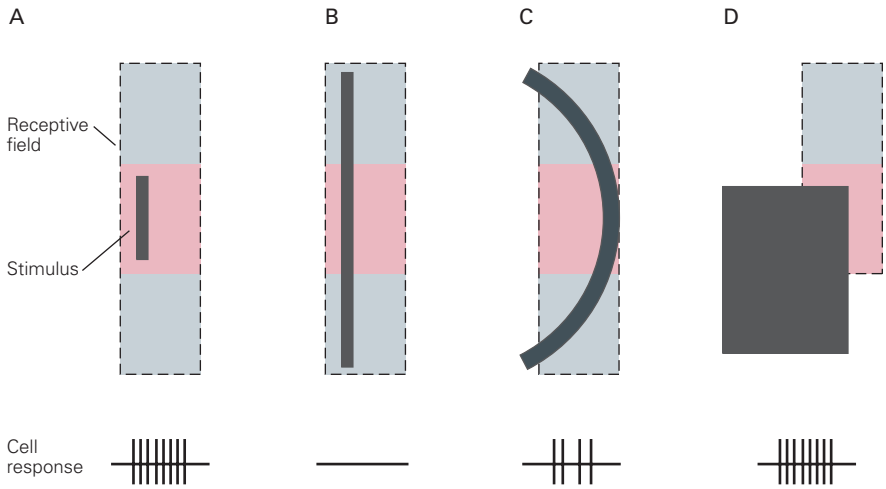

Figure 23–5 End-inhibited receptive fields. Some receptive fields have a central excitatory region flanked by inhibitory regions that have the same orientation selectivity. Thus, a short line segment or a long curved line will activate the neuron (**A** and **C**), but a long straight line will not (**B**). A neuron with a receptive field that displays only one inhibitory region in addition to the excitatory region can signal the presence of corners (**D**).

to the interactions across visual space required to perceptually link contour elements into global contours. It underlies the Gestalt principle of good continuation and the perceptual saliency of smooth contours embedded in complex scenes. Physiologically, it underlies the facilitation of neuronal responses by contour elements extending outside their "classical" receptive fields. Anatomically, it is mediated in part by the relationship between long-range horizontal connections and cortical functional architecture. Though it has been investigated most extensively in primary visual cortex, because of the ubiquity of horizontal connections across all areas of cortex, it is likely to be a strategy for associating bits of information that are mapped within every cortical area. The functional role of the association field in cortical areas outside of V1 depends on how information is mapped across the cortical surface and the relationship between these maps and the plexus of horizontal connections.

Depth Perception Helps Segregate Objects From Background

Depth is another key feature in determining the perceived shape of an object. An important cue for the perception of depth is the difference between the two eyes' views of the world, which must be computed and reconciled by the brain. The integration of binocular input begins in the primary visual cortex, the first level at which individual neurons receive signals from both eyes. The balance of input from the two eyes, a property known as ocular dominance, varies among cells in V1.

Binocular neurons in many visual cortical areas are also selective for depth, which is computed from the relative retinal positions of objects placed at different distances from the observer. An object that lies in the *plane of fixation* produces images at corresponding positions on the two retinas (Figure 23–7). The images of objects that lie in front of or behind the plane of fixation fall on slightly different locations in the two eyes, a property known as binocular disparity. Individual neurons can be selective for a narrow range of disparities and therefore positions in depth. Some are selective for objects lying on the plane of fixation (tuned excitatory or inhibitory cells), whereas others respond only when objects lie in front of the plane of fixation (near cells) or behind that plane (far cells).

Depth plays an important role in the perception of object shape, in surface segmentation, and in establishing the three-dimensional properties of a scene. Objects that are placed near an observer can partially occlude those situated farther away. A surface passing behind an object is perceived as continuous even though its two-dimensional image on each retina represents two surfaces separated by the occluder. When the brain encounters a surface interrupted by gaps that have appropriate alignment and contrast, and lying in the near-depth plane, it fills in the gaps to create a continuous surface (Figure 23–8).

Although the depth of a single object can be established easily, determining the depths of multiple objects within a scene is a much more complex problem that requires linking the retinal images of all objects in the two eyes. The disparity calculation is therefore a global one: The calculation in one part of the visual image influences the calculation for other parts. When the assignment of depth is unambiguous in one part of an image, that information is applied to other parts of the image where there is insufficient information to

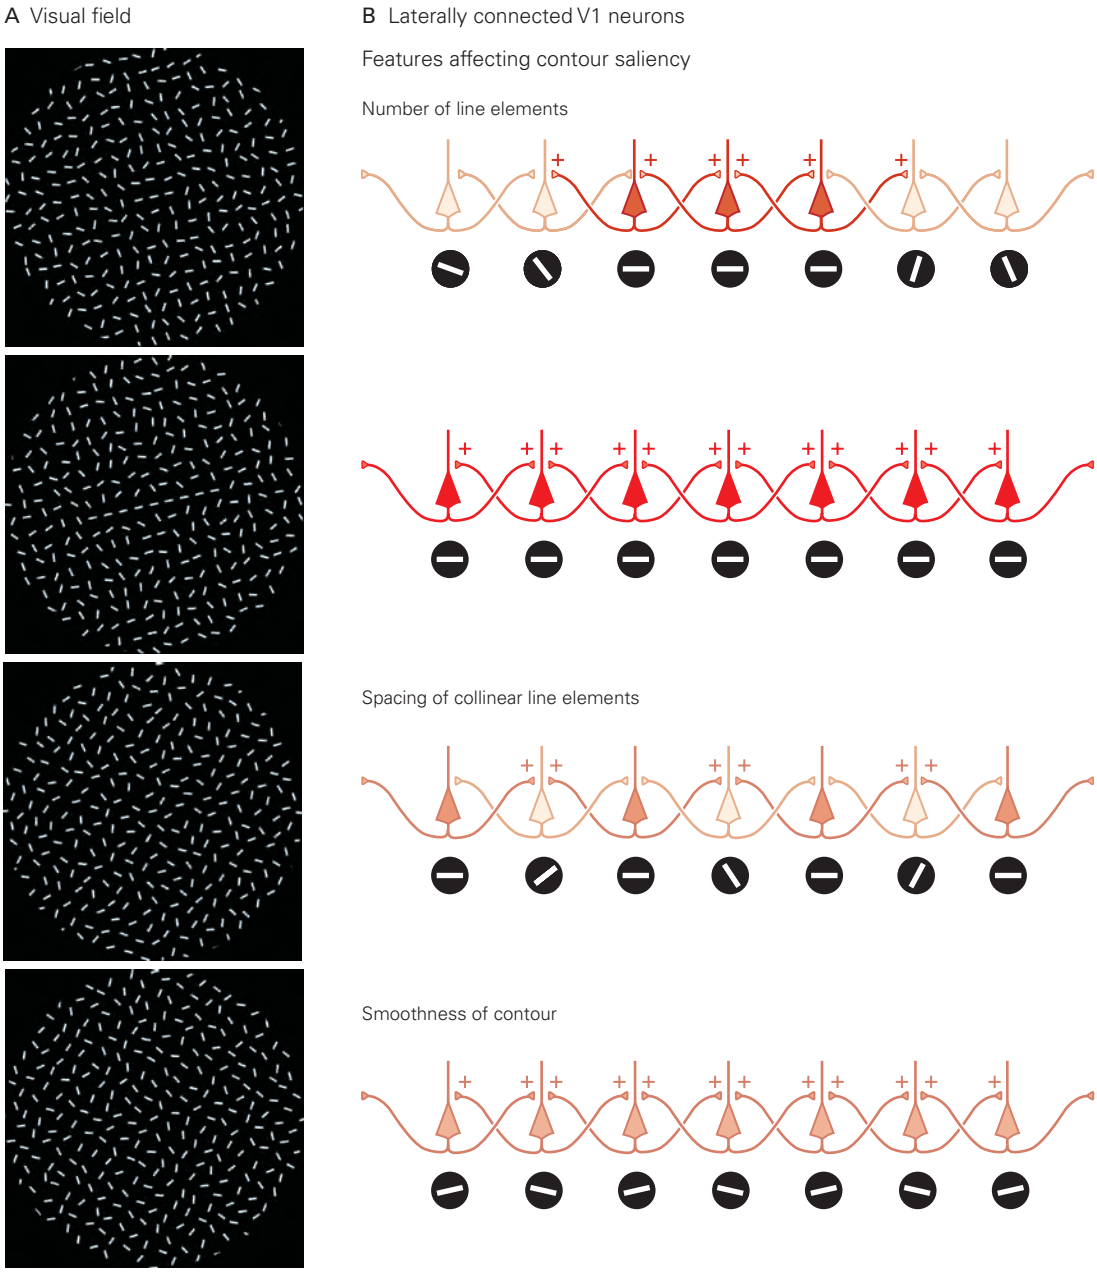

Figure 23–6 Contour integration reflects the perceptual rules of proximity and good continuation. (Adapted, with permission, from Li and Gilbert 2002.)

A. A straight line composed of one or more contour elements with the same oblique orientation appears in the center of each of the four images here. In some images, the line pops out more or less immediately, without searching. Factors that contribute to contour saliency include the number of contour elements (compare the first and second frames), the spacing of the elements (third frame), and the smoothness of the contour (bottom frame). When the spacing between elements is too large or the orientation difference between them too great, one must search the image to find the contour.

B. These perceptual properties are reflected in the horizontal connections between columns of V1 neurons with similar orientation selectivity. As long as the visual elements are spaced sufficiently close together, excitation can propagate from cell to cell, thus facilitating the responses of V1 neurons. Each neuron in the network then augments the responses of neurons on either side, and the facilitated responses propagate across the network.

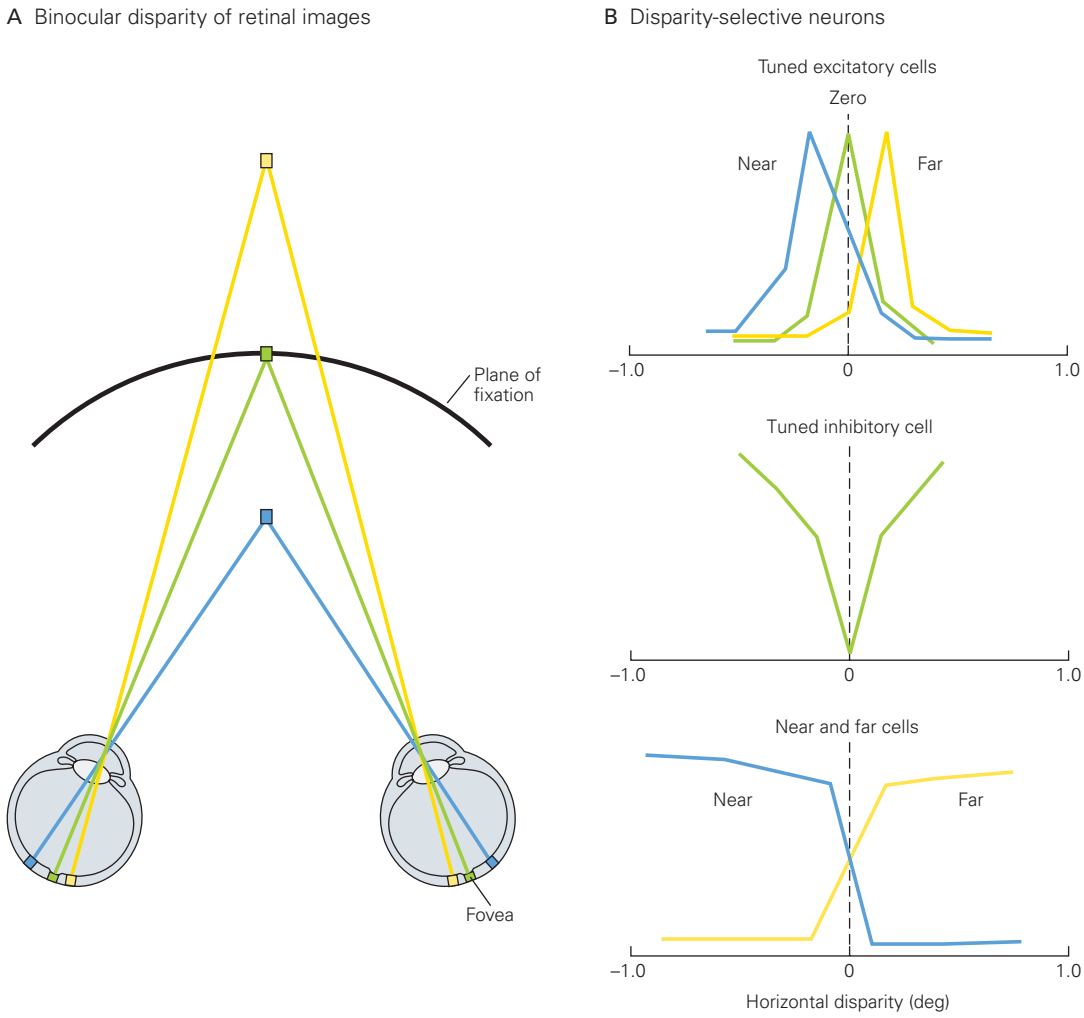

Figure 23–7 Stereopsis and binocular disparity.

A. Depth is computed from the positions at which images occur in the two eyes. The image of an object lying in the plane of fixation (**green**) falls on corresponding points on the two retinas. Images of objects lying in front of the plane of fixation (**blue**) or behind it (**yellow**) fall on noncorresponding locations on the two retinas, a phenomenon termed *binocular disparity*.

B. Neurons in many visual cortical areas are selective for particular ranges of disparity. Each plot shows the responses of a neuron to binocular stimuli with different disparities (abscissa). Some neurons are tuned to a narrow range of disparities and thus have particular disparity preferences (tuned excitatory or tuned inhibitory neurons), whereas others are tuned broadly for objects in front of the fixation plane (near cells) or beyond the plane (far cells). (Adapted, with permission, from Poggio 1995. Copyright © 1995 Oxford University Press.)

determine depth, a phenomenon known as disparity capture.

Random-dot stereograms provide a dramatic demonstration of the global scope of disparity analysis. The visual information presented to each eye appears to be incoherent, but when the stereogram is viewed binocularly, the disparity between the random array of dots in the two images allows an embedded shape to become visible (Figure 23–8C). The calculation underlying this percept is not simple, but requires determining which features shown to the left eye correspond to features seen by the right eye and propagating local disparity information across the image.

Neurons in area V2 display sensitivity to global disparity cues. Distant depth cues can be used to link contour elements that belong to an object, and to separate them from the object background (Figure 23-B).

In addition to binocular disparity, the visual system also uses many monocular cues to discriminate depth. Depth determination through monocular

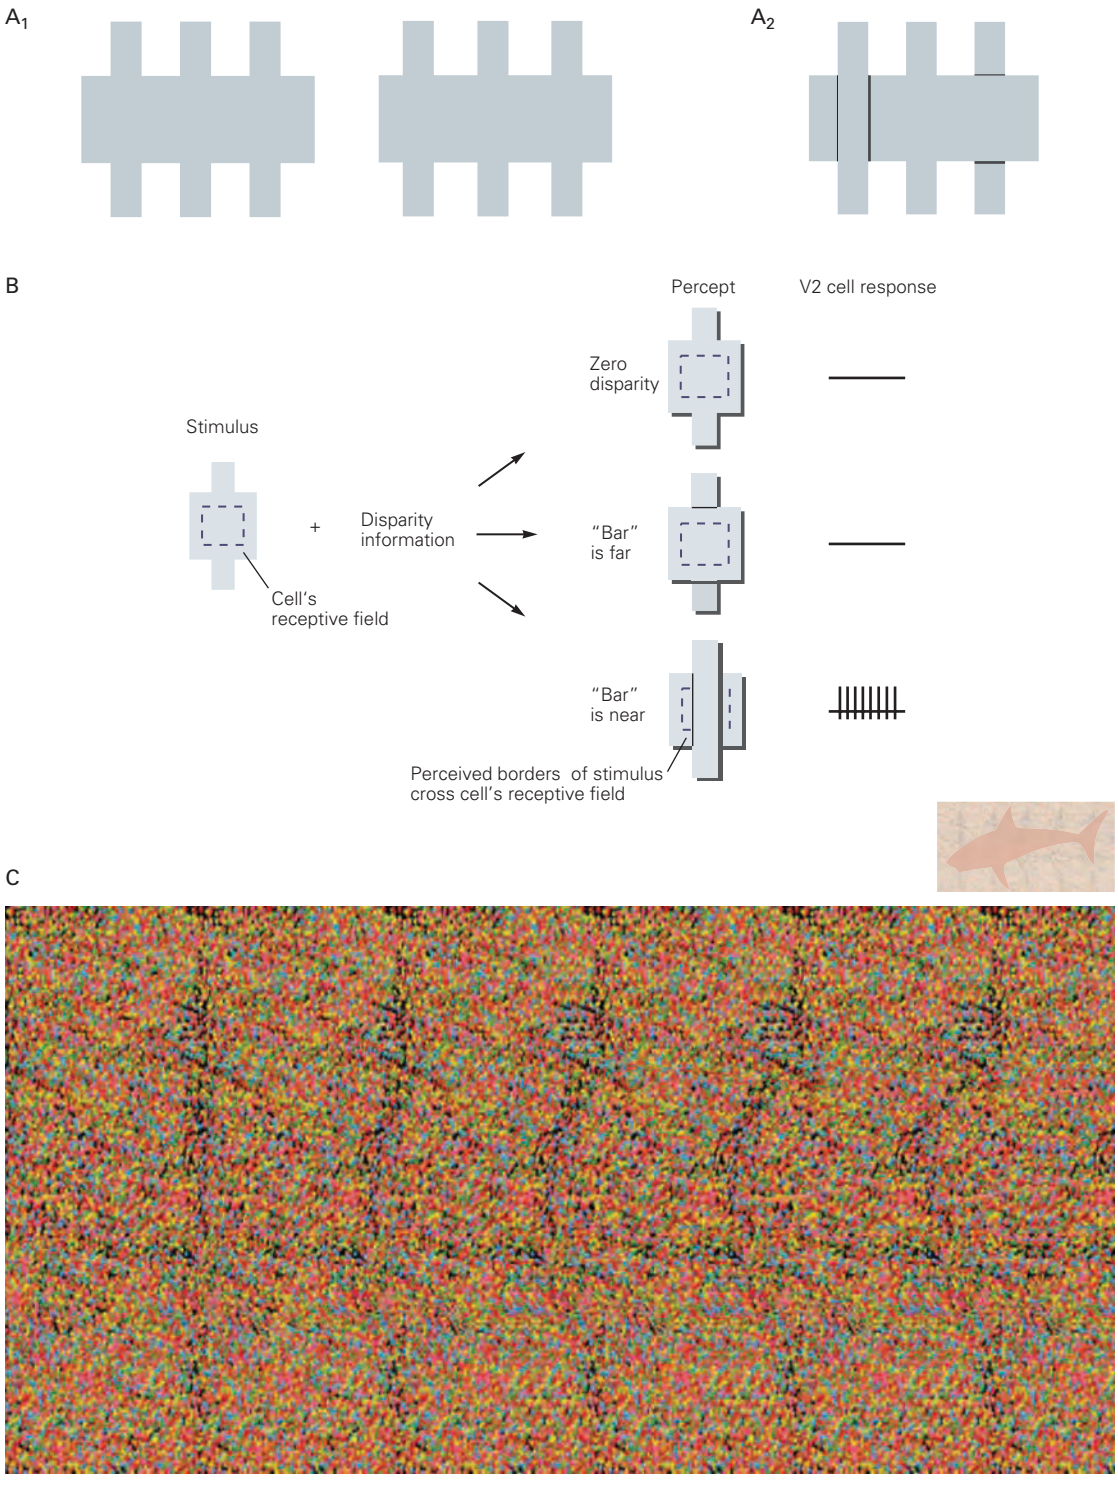

Figure 23–8 Global analysis of binocular disparity.

A. 1. Depth cues contribute to surface segmentation. If you view one of the images of three gray vertical bars crossing a gray horizontal rectangle, you see a uniform gray area within the rectangle. 2. However, if you fuse the two rectangles with diverged eyes, the three vertical bars fall on the two retinas with near, zero, and far disparity. Seen this way, the bar at the left appears to hover in front of the rectangle with an illusory vertical edge crossing the rectangle, whereas the bar at the right appears to lie behind the edges of the horizontal rectangle.

B. A neuron in area V2 responds to illusory edges formed by binocular disparity cues. When the cell's receptive field is centered in the gray square, the cell does not respond to a vertical bar that has far disparity or the same disparity as the square. When the vertical bar has near disparity, the cell responds as the illusory vertical edge crosses its receptive field. (Reproduced, with permission, from Bakin, Nakayama, and Gilbert 2000. Copyright © 2000 Society for Neuroscience.)

C. A random-dot stereogram is seen as a random array of colored dots until you diverge or converge your eyes to bring the adjacent dark vertical stripes into register, producing a three-dimensional image of a shark that emerges from the background. This effect stems from systematic disparity for selected sets of dots. (© Fred Hsu/ Wikimedia Commons/CC-BY-SA-3.0.)

cues, such as size, perspective, occlusion, brightness, and movement, is not difficult. Another cue that originates outside the visual system is vergence, the angle between the optical axes of the two eyes for objects at varying distances. Yet another binocular cue, known as DaVinci stereopsis, is the presence of features visible to one eye but occluded in the other eye's view.

Neurons in areas V1 and V2 also signal foreground–background relationships. A cell with its receptive field in the center of a pattern within a larger surface may respond even when the boundary of that surface is distant from the receptive field. This response helps differentiate the object from its background. In making sense of an image, the brain must identify which edge belongs to which object and differentiate the edge of each object from the background. Some cells in area V2 have the property of "border ownership," firing only when a figure but not the background is to one side of the edge, even when the local edge information is identical in both instances (Figure 23–9).

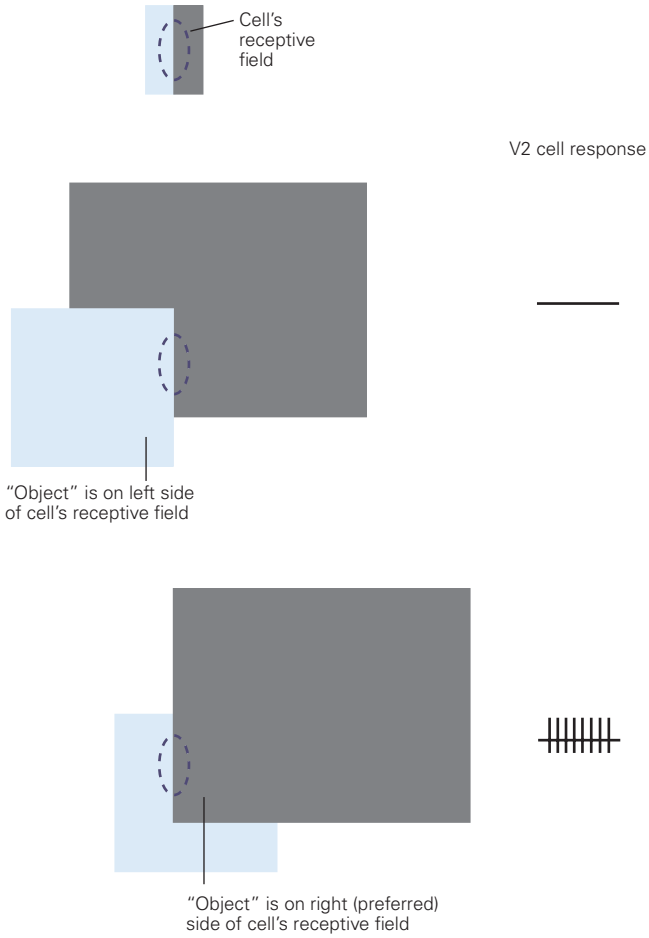

Figure 23–9 Border ownership. Cells in area V2 are sensitive to the boundaries of whole objects. Even though the local contrast is the same for the two rectangles within a cell's receptive field, the cell responds only when the boundary is part of the full rectangle that lies on the preferred side of the receptive field. (Adapted, with permission, from Zhou, Friedman, and von der Heydt 2000. Copyright © 2000 Society for Neuroscience.)

Local Movement Cues Define Object Trajectory and Shape

The primary visual cortex determines the direction of movement of objects. Directional selectivity in neurons likely involves sequential activation of regions on different sides of the receptive field.

If an object moving at an appropriate velocity first encounters a region of a neuron's receptive field with long response latencies and then passes into regions with progressively shorter latencies, signals from throughout the receptive field will arrive at the cell simultaneously and the neuron will fire vigorously. If the object moves in the opposite direction, signals from the different regions will not summate and the cell may never reach the threshold for firing (Figure 23–10).

Early in the visual pathways, analysis of the movement of an object is limited by the size of the receptive fields of the sensory neurons. Even in the initial cortical areas V1 and V2, the receptive fields of neurons are small and might encompass only a fraction of an object. Eventually, however, information about the direction and speed of movement of discrete aspects of an object must be integrated into a computation of the movement of a whole object. This problem is more difficult than one might expect.

If one observes a complex shape moving through a small aperture, the part of the object's boundary within the aperture appears to move in a direction perpendicular to the boundary's orientation (Figure 23–11A). One cannot detect a line's true direction of movement if the line's ends are not visible. The image of a line appears the same if it is moving slowly along an axis perpendicular to its orientation or more quickly along an oblique axis. This is the quandary presented by the receptive field of a V1 neuron. The visual system's solution is to assume that the movement of a contour is perpendicular to its orientation. Thus, an object is first presented to the visual system in countless small pieces with boundaries of different orientations, all of which appear to be moving in

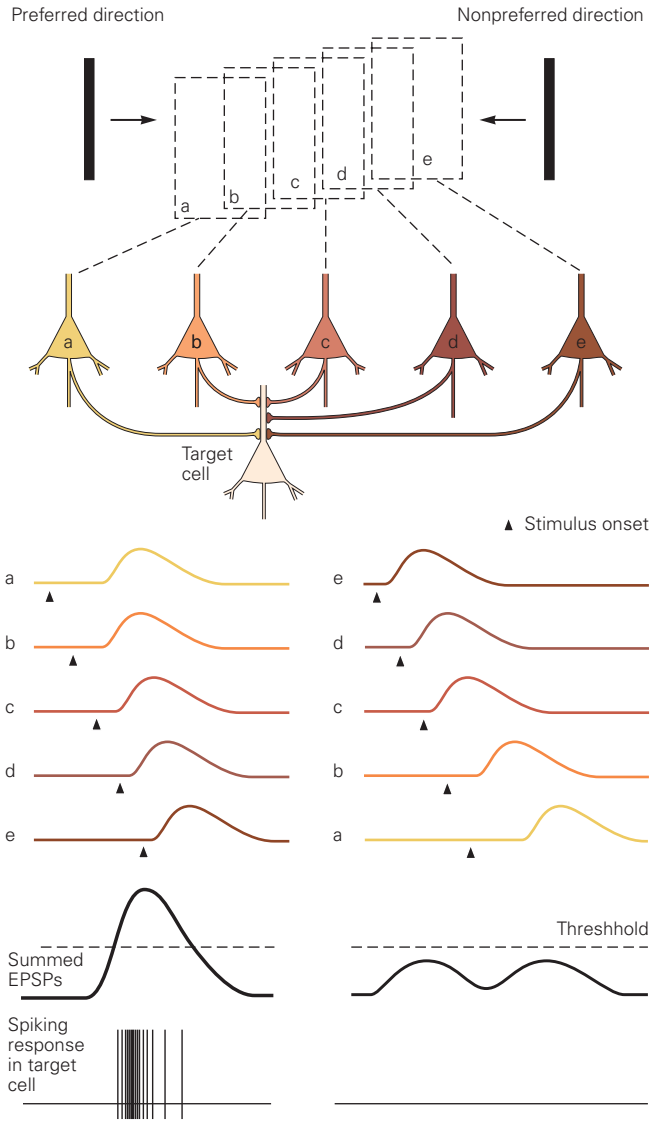

Figure 23–10 Directional selectivity of movement. A neuron's selectivity for direction of movement depends on the response latencies of presynaptic neurons relative to the onset of a stimulus. The response latencies of presynaptic neurons *a* and *b* are somewhat longer than those of neurons *d* and *e*. When a stimulus moves from left to right, neurons *a* and then *b* are activated first, but because their response latencies are longer, their inputs arrive at the target neuron superimposed with the inputs from neurons *d* and *e*, and the summated inputs cause the neuron to fire. In contrast, stimuli moving leftward produce signals that arrive in the target neuron at different times and therefore do not reach the cell's threshold for firing. (Abbreviation: **EPSP**, excitatory postsynaptic potential.) (Adapted, with permission, from Priebe and Ferster 2008. Copyright © 2008 Elsevier.)

different directions and at different velocities (Figure 23–11A).

Determining the direction of motion of an object requires resolving multiple cues. This can be demonstrated readily by placing one grating on top of another and moving the two in different directions. The resulting checkerboard pattern appears to move in an intermediate direction between the trajectories of the individual gratings (Figure 23–11B). This percept depends on the relative contrast of the gratings and the area of grating overlap. With large relative contrasts, the gratings appear to slide across each other, moving in their individual directions rather than together in a common direction.

An important determinant of perceived direction is scene segmentation, the separation of moving elements into foreground and background. In a scene with moving objects, segmentation is not based on local cues of direction; instead, perception of direction depends on scene segmentation. The barber-pole illusion provides another example of the predominance of global relationships over the perception of simple attributes. The rotating stripes are perceived as moving vertically along the long axis of the pole (Figure 23–11C). The perception of motion in the visual field uses a complex algorithm that integrates the bottom-up analysis of local motion signals with top-down scene segmentation.

Integration of local motion signals in monkeys has been observed in the middle temporal area (area MT or V5), an area specializing in motion. The neurons in this area are selective for a particular direction of movement of an overall pattern, rather than individual components of the pattern. This dependency on the overall pattern is also seen in the correspondence of their responses with the perceived direction in the barber-pole effect.

Context Determines the Perception of Visual Stimuli

Brightness and Color Perception Depend on Context

The visual system measures the surface characteristics of objects by comparing the light arriving from different parts of the visual field. As a result, the perception of brightness and color is highly dependent on context. In fact, perceived brightness and color can be quite different from what is expected from the physical properties of an object. At the same time, perceptual constancies make objects appear similar even when the brightness and wavelength distribution of the light

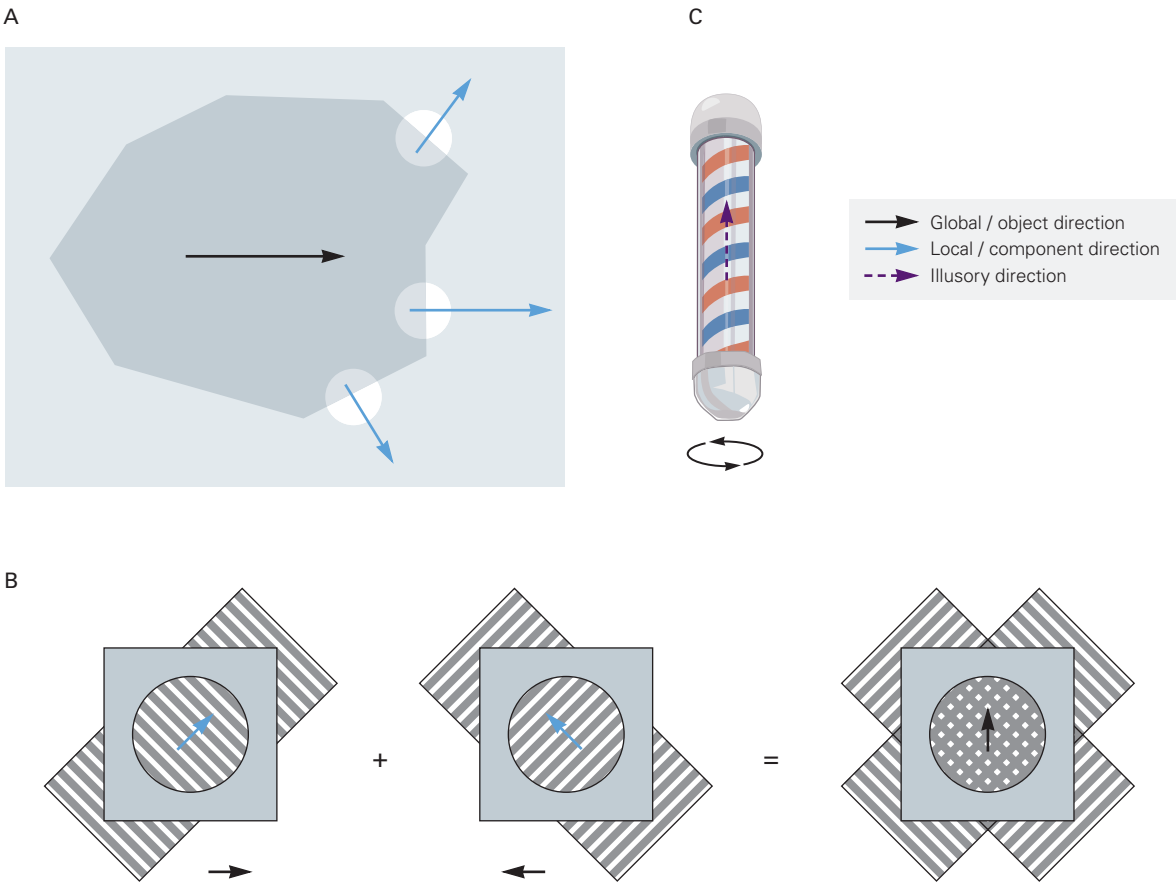

Figure 23–11 The aperture problem and barber-pole illusion.

A. Although an object moves in one direction, each component edge when viewed through a small aperture appears to move in a direction perpendicular to its orientation. The visual system must integrate such local motion signals into a unified percept of a moving object.

B. Gratings are used to test whether a neuron is sensitive to local or global motion signals. When the gratings are superimposed and moved independently in different directions, one does not see the two gratings sliding past each other but rather a plaid pattern moving in a single, intermediate direction. Neurons in the middle temporal area of monkeys are responsive to such global motion rather than to local motion.

C. Motion perception is influenced by scene segmentation cues, as seen in the barber-pole illusion. Even though the pole rotates around its axis, one perceives the stripes as moving vertically, due to the global vertical rectangle surround of the barber pole enclosure.

that illuminates them changes from natural to artificial light, from sunlight to shadow, or from dawn to midday (Figure 23–12A).

As we move about or as the ambient illumination changes, the retinal image of an object—its size, shape, and brightness—also changes. Yet under most conditions, we do not perceive the object itself to be changing. As we move from a brightly lit garden into a dimly lit room, the intensity of light reaching the retina may vary a thousandfold. Both in the room's dim illumination and in the sun's glare, we nevertheless see a white shirt as white and a red tie as red. Likewise, as a friend walks toward you, she is seen as coming closer; you do not perceive her to be growing larger even though the image on your retina does expand. Our ability to perceive an object's size and color as constant illustrates again a fundamental principle of the visual system: It does not record images passively, like a camera, but instead uses transient and variable stimulation of the retina to construct representations of a stable, three-dimensional world.

Another example of contextual influence is color induction, whereby the appearance of a color in one region shifts toward that in an adjoining region. Shape also plays an important role in the perception of surface brightness. Because the visual system assumes that illumination comes from above, gray patches on a folded surface appear very different when they lie on

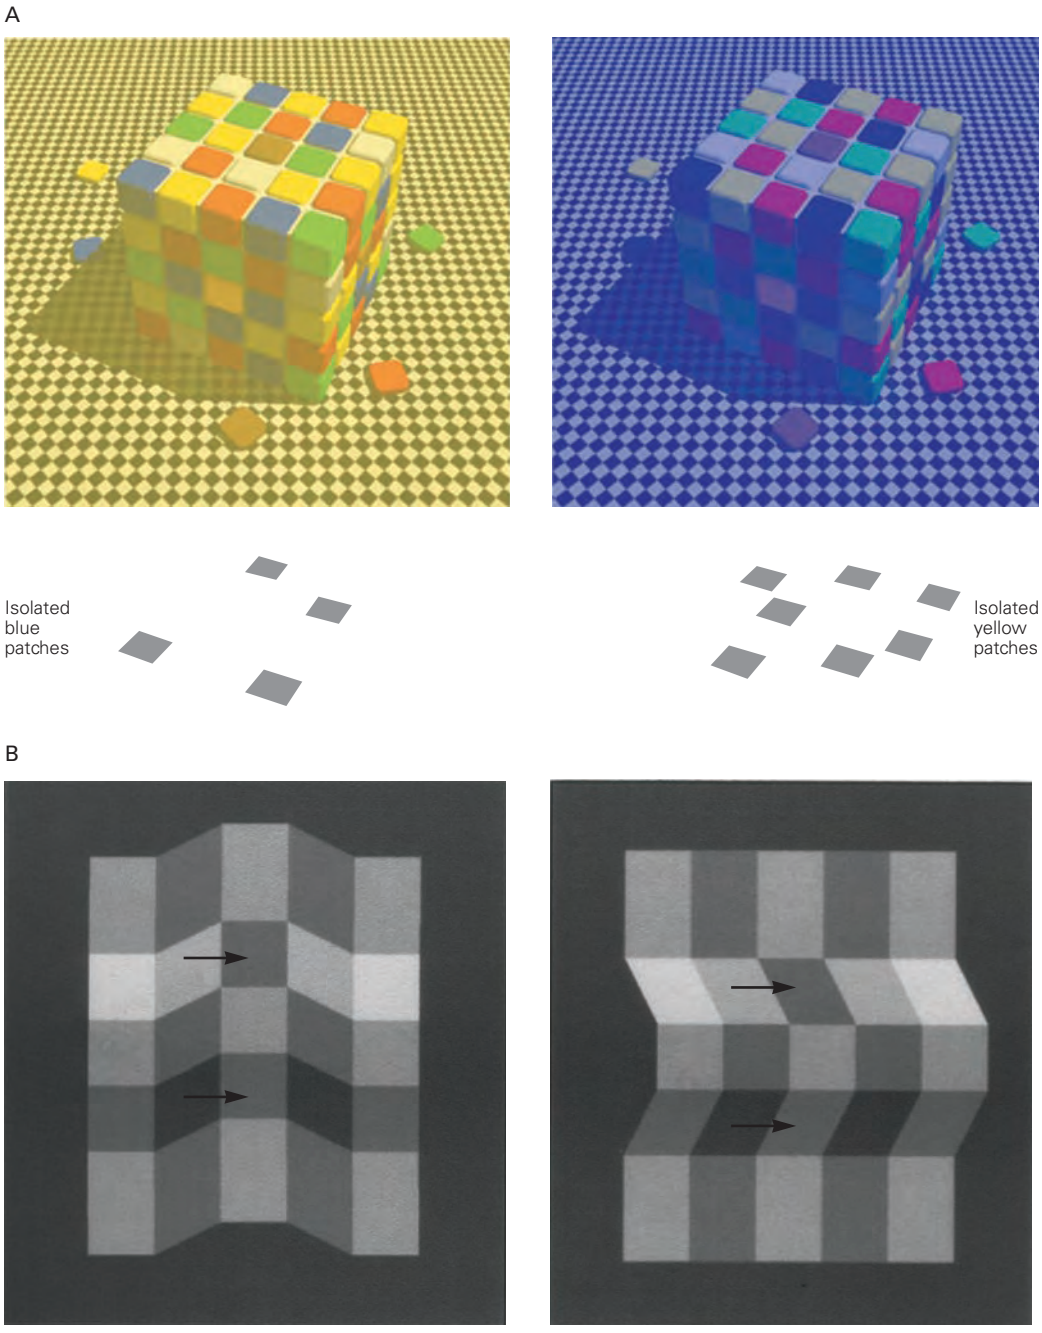

Figure 23–12 Color and brightness perception depend on contextual cues.

A. Perceived surface colors remain relatively stable under different illumination conditions and the consequent changes in wavelength of the light reflected from the surface. The **yellow squares** on the left and right cubes appear similar despite the fact that the wavelengths of light coming from the two sets of surfaces are very different. In fact, if the **blue squares** on the top of the left cube and the **yellow squares** on the top of the right cube are isolated from their contextual squares, their colors appear identical. (Reproduced, with permission, from www.lottolab.org.)

B. Brightness perception is also influenced by three-dimensional shape. The four gray squares indicated by **arrows** all have the same luminance. The apparent brightnesses are similar in the left illustration but different in the right illustration. This is because the visual system has an inherent expectation that illumination comes from above (the position of the sun relative to us), and thus the perception that the surface below the fold in the illustration on the right is brighter than the surface of the same luminance that lies above. (Reproduced, with permission, from Adelson 1993. Copyright © 1993 AAAS.)

the top or bottom of the surface, even when they are in fact the same shade of gray (Figure 23–12B).

The responses of some neurons in the visual cortex correlate with perceived brightness. Most visual neurons respond to surface boundaries; the center-surround structure of the receptive fields of retinal ganglion cells and geniculate neurons is suited to capturing boundaries. Most such cells do not respond to the interior parts of surfaces, for uniform interiors produce no contrast gradients across receptive fields. However, a small percentage of neurons do respond to the interiors of surfaces, signaling local brightness, texture, or color, and the responses of these neurons are influenced by context. The cell's response changes as the brightness of surfaces *outside* a cell's receptive field change, even when the brightness of the surface within the receptive field remains fixed.

Because most neurons respond to surface boundaries and not to areas of uniform brightness, the visual system calculates the brightness of surfaces from information about contrast at the edges of surfaces. The brain's analysis of surface qualities from boundary information is known as perceptual fill-in. If one fixates the boundary between a dark disk and a surrounding bright area for a few seconds, the disk will "fill in" with the same brightness as the surrounding area. This occurs because the cells that respond to edges fire only when the eye or stimulus moves. They gradually cease to respond to a stabilized image and no longer signal the presence of the boundary. Neurons with receptive fields within the disk gradually begin to respond in a fashion similar to those with receptive fields in the surrounding area, demonstrating short-term plasticity in their receptive-field properties.

An object's color always appears more or less the same despite the fact that under different conditions of illumination the wavelength distribution of light reflected from the object varies widely. To identify an object, we must know the properties of its surface rather than those of the reflected light, which are constantly changing. Computation of an object's color is therefore more complex than analyzing the spectrum of reflected light. To determine a surface's color, the wavelength distribution of the incident light must be determined. In the absence of that information, surface color can be estimated by determining the balance of wavelengths coming from different surfaces in a scene. Some neurons in V4 respond similarly to different illumination wavelengths if the perceived color remains constant. By being responsive to the light across an extensive surface, these neurons are selective for surface color rather than wavelength.

Receptive-Field Properties Depend on Context

The distinction between local and global effects—between stimuli that occur within a receptive field and those beyond—poses the problem of how the receptive field itself is defined. Because the original characterization of the receptive fields of visual cortex neurons did not take into account contextual influences, some investigators now distinguish between "classical" and "nonclassical" receptive fields.

However, even the earliest description of the sensory receptive field allowed for the possibility of influences from portions of the sensory surface outside the narrowly defined receptive field. In 1953, Steven Kuffler, in his pioneering observations on the receptive-field properties of retinal ganglion cells, noted that "not only the areas from which responses can actually be set up by retinal illumination may be included in a definition of the receptive field but also all areas which show a functional connection, by an inhibitory or excitatory effect on a ganglion cell. This may well involve areas which are somewhat remote from a ganglion cell and by themselves do not set up discharges."

A more useful distinction contrasts the response of a neuron to a simple stimulus, such as a short line segment, with its response to a stimulus with multiple components. Even in the primary visual cortex, neurons are highly nonlinear; their response to a complex stimulus cannot be predicted from their responses to a simple stimulus placed in different positions around the visual field. Their responses to local features are instead dependent on the global context within which the features are embedded. Contextual influences are pervasive in intermediate-level visual processing, including contour integration, scene segmentation, and the determination of object shape, object motion and surface properties.

Cortical Connections, Functional Architecture, and Perception Are Intimately Related

Intermediate-level visual processing requires sharing of information from throughout the visual field. The relationship of interconnections within the primary visual cortex to the functional architecture of this area suggests that this circuitry mediates contour integration.

Cortical circuits include a plexus of long-range horizontal connections formed by the axons of pyramidal neurons running parallel to the cortical surface. Horizontal connections exist in every area of the cerebral cortex, but their function varies from one area to

the next depending on the functional architecture of each area. In the visual cortex, these connections mediate interactions between orientation columns of similar specificity, thus integrating information over a large area of visual cortex that represents a great expanse of the visual field (see Figure 21–16).

The fact that these horizontal connections link neurons similar in function but representing distant locations in the visual field suggests that these connections have a role in contour integration. Contour integration and the related property of contour saliency reflect the Gestalt principle of good continuation. Both are mediated by the horizontal connections in V1 (see Figure 23–6).

A final feature of cortical connectivity important for visuospatial integration is feedback projections from higher-order cortical areas. Feedback connections are as extensive as the feedforward connections that originate in the thalamus or at earlier stages of cortical processing. Little is known about the function of these feedback projections. They likely play a role in mediating the top-down influences of attention, expectation, and perceptual task, all of which are known to affect early stages in cortical processing.

Perceptual Learning Requires Plasticity in Cortical Connections

The synaptic connections in ocular-dominance columns are adaptable to experience only during a critical period in development (Chapter 49). This suggests that the functional properties of visual cortex neurons are fixed in adulthood. Nevertheless, many properties of cortical neurons remain mutable throughout life. For example, changes in the visual cortex can occur following retinal lesions.

When focal lesions occur in corresponding positions on the two retinas, the corresponding part of the cortical map, referred to as the lesion projection zone, is initially deprived of visual input. Over a period of several months, however, the receptive fields of cells within this region shift from the lesioned part of the retina to the functioning area surrounding the lesion. As a result, the cortical representation of the lesioned part of the retina shrinks while that of the surrounding region expands (Figure 23–13).

The plasticity of cortical maps and connections did not evolve as a response to lesions but as a neural mechanism for improving our perceptual skills. Many of the attributes analyzed by the visual cortex, including stereoscopic acuity, direction of movement, and orientation, become sharper with practice. Hermann von Helmholtz stated in 1866 that "the judgment of the senses may be modified by experience and by training derived under various circumstances, and may be adapted to the new conditions. Thus, persons may learn in some measure to utilize details of the sensation which otherwise would escape notice and not contribute to obtaining any idea of the object." This perceptual learning is a variety of implicit learning that does not involve conscious processes (Chapter 52).

Perceptual learning involves repeating a discrimination task many times and does not require error feedback to improve performance. Improvement manifests itself, for example, as a decrease in the threshold for discriminating small differences in the attributes of a target stimulus or in the ability to detect a target in a complex environment. Several areas of visual cortex, including the primary visual cortex, participate in perceptual learning.

An important aspect of perceptual learning is its specificity: Training on one task does not transfer to other tasks. For example, in a three-line bisection task, the subject must determine whether the centermost of three parallel lines is closer to the line on the left or the one on the right. The amount of offset from the central position required for accurate responses decreases substantially after repeated practice.

Learning of this task is specific to the location in the visual field and to the orientation of the lines. This specificity suggests that early stages of visual processing are responsible, for in the early stages, receptive fields are smallest, visuotopic maps are most precise, and orientation tuning is sharpest. The learning is also specific for the stimulus configuration. Training on three-line bisection does not transfer to a vernier discrimination task in which the context is a line that is collinear with the target line (Figure 23–14A).

The response properties of neurons in the primary visual cortex change during the course of perceptual learning in a way that tracks the perceptual improvement. An example of this is seen in contour saliency. With practice, subjects can more easily detect contours embedded in complex backgrounds. Detection improves with contour length, as do the responses of neurons in V1. With practice, subjects improve their ability to detect shorter contours and V1 neurons become correspondingly more sensitive to shorter contours (Figure 23–14B).

Visual Search Relies on the Cortical Representation of Visual Attributes and Shapes

The detectability of features such as color, orientation, and shape is related to the process of visual search. In a complex image, certain objects stand out or "pop out"

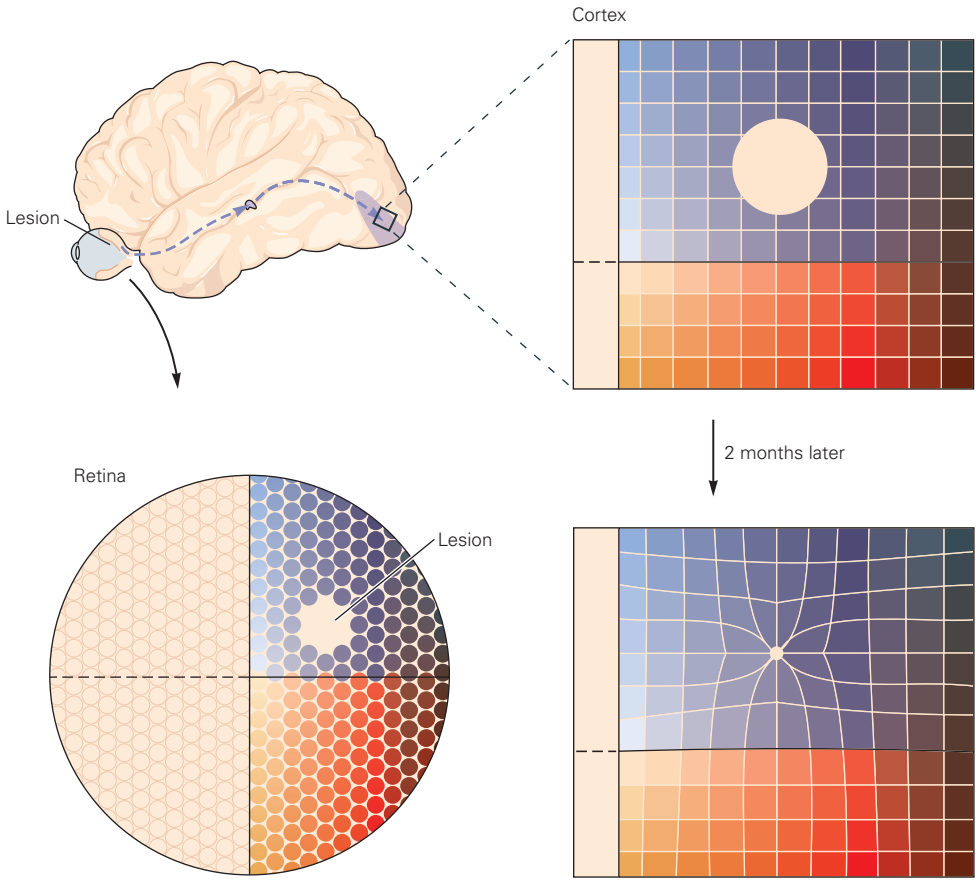

Figure 23–13 Adult cortical plasticity. When corresponding positions in both eyes are lesioned, the cortical area receiving input from the lesioned areas—the lesion projection zone—is initially silenced. The receptive fields of neurons in the lesion projection zone eventually shift from the area of the lesion to the surrounding, intact retina. This occurs because neurons surrounding the lesion projection zone sprout collaterals that form synaptic connections with neurons inside the zone. As a result, the cortical representation of the lesioned part of the retina shrinks while that of the surrounding retina expands.

because the visual system processes simultaneously, in parallel pathways, the features of the target and the surrounding distractors (Figure 23–15). When the features of a target are complex, the target can be identified only through careful inspection of an entire image or scene.

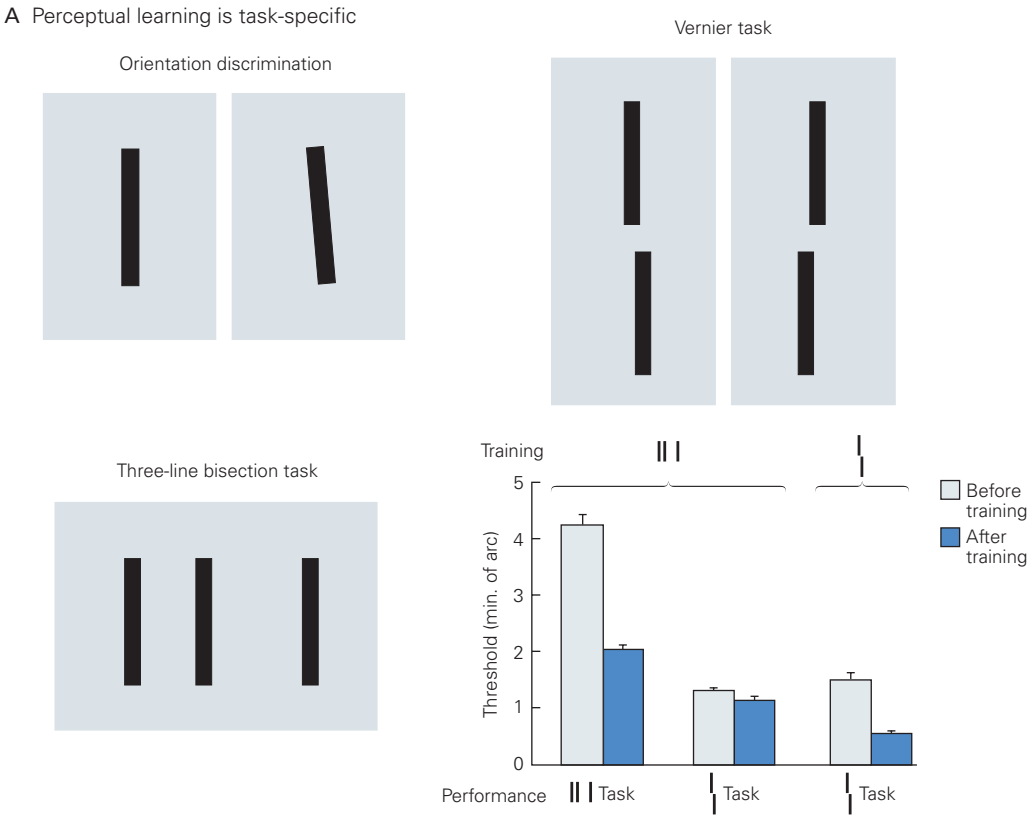
The pop-out phenomenon can be influenced by training. A stimulus that initially cannot be found without effortful searching will pop out after training. The neuronal correlate of such a dramatic change is not certain. Parallel processing of the features of an object and its background is possible because feature information is encoded in retinotopically mapped areas at multiple locations in the visual cortex. Pop-out probably occurs early in the visual cortex. The pop-out of complex shapes such as numerals supports the idea that early in visual processing neurons can represent, and be selective for, shapes more complex than line segments with a particular orientation.

Cognitive Processes Influence Visual Perception

Scene segmentation—the parsing of a scene into different objects—involves a combination of bottom-up processes that follow the Gestalt rule of good continuation and top-down processes that create object expectation.

One strong top-down influence is spatial attention, which can change focus without any movement of an observer's eyes. Spatial attention can be object-oriented in that the focus of attention is distributed over the area occupied by the attended object, allowing the visual cortex to analyze the shape and attributes of objects one at a time.

Attentional mechanisms can solve the superposition problem. Before we can recognize an object in a scene that includes many objects, we must determine which features correspond to which objects. Our sense that we identify all objects in the visual field simultaneously is illusory. Instead, we serially process objects in rapid succession by



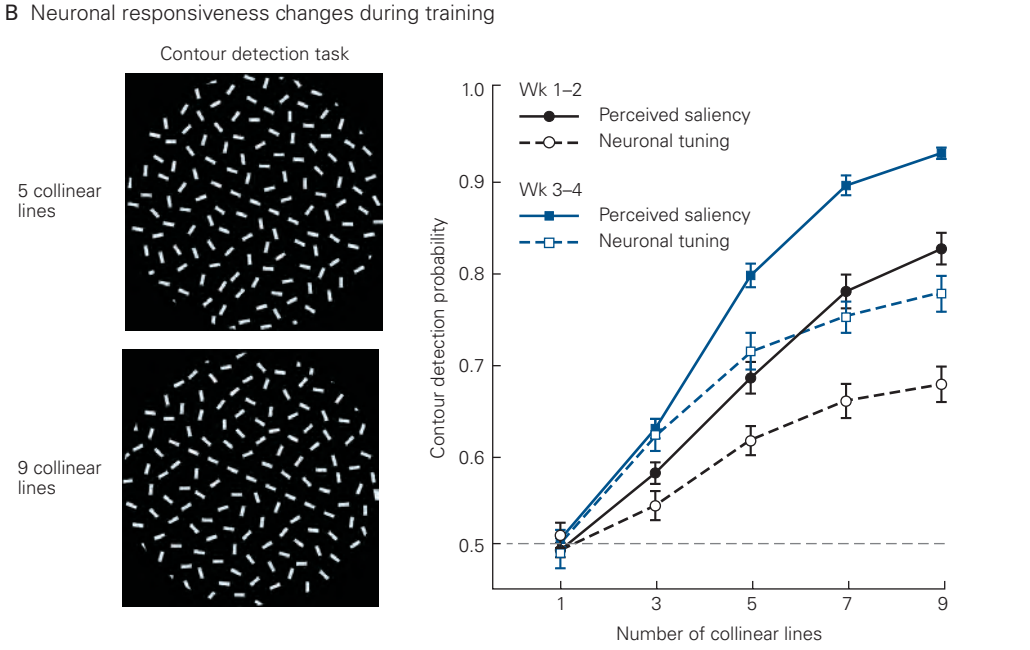


Figure 23–14 **Perceptual learning.** Perceptual learning is a form of implicit learning. With practice, one can learn to discriminate smaller differences in orientation, position, depth, and direction of movement of objects.

A. The improvement is seen as a reduction in the amount of change required to reliably detect a tilted line or one positioned to the left or right of a nearly collinear line (vernier task). Perceptual learning is highly specific, so that training on a three-line bisection task leads to substantial improvement in that task (*left pair of bars* in the bar graph) without affecting performance on the vernier discrimination task (*central pair of bars*). However, training specifically on vernier discrimination does enhance performance on that task (*right pair of bars*).

B. Subjects can detect collinear line segments embedded in a random background more easily as the number of collinear segments is increased. The responses of neurons in V1 grow correspondingly stronger with the increase in the number of line segments. After practice, a line with fewer segments stands out more easily, and with this improvement, the responses in V1 also increase. (Reproduced, with permission, from Crist, Li, and Gilbert 2001; Li, Piech, and Gilbert 2008.)

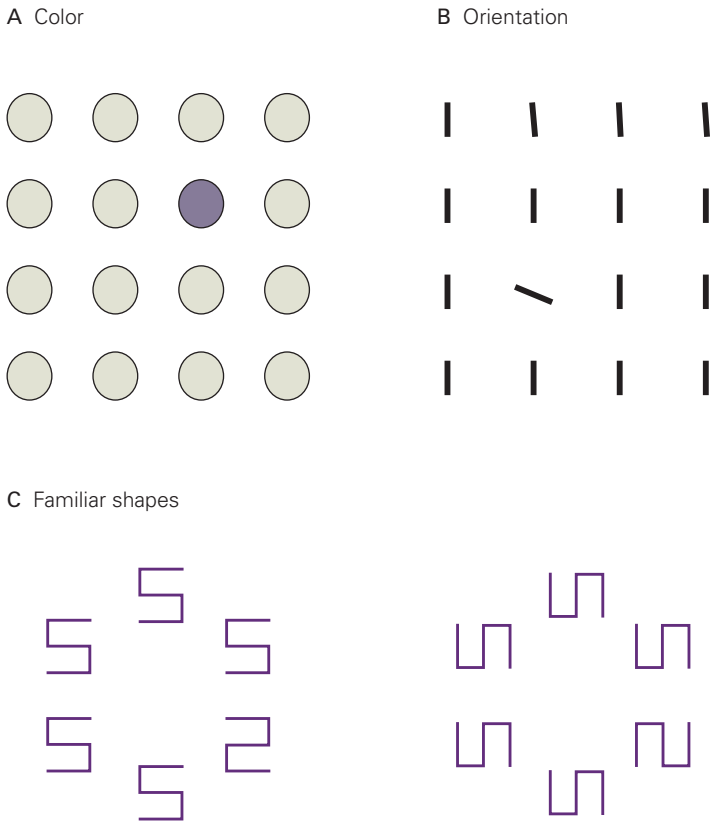

Figure 23–15 One object in a complex image stands out under certain conditions.

A. A differently colored object pops out.

B. A differently oriented line also pops out.

C. More complex shapes can pop out when they are very familiar, such as the numeral 2 embedded in a field of 5s. Rotating the image by 90° renders the elements of the figure less recognizable, making it more difficult to find the one figure that differs from the rest. (Reproduced, with permission, from Wang, Cavanagh, and Green 1994. Copyright © 1994 Springer Nature.)

shifting attention from one to the next. The results of each analysis build up the perception of a complex environment populated with many distinct objects. A dramatic demonstration of the importance of attention in object recognition is *change blindness.* If a subject rapidly shifts between two slightly different views of the same scene, he will not be able to detect the absence of an important component of the scene in one view without considerable scrutiny (see Figure 25–8).

Another top-down influence is perceptual task. At early stages in visual processing, the properties of the same neuron vary with the type of visual discrimination being performed. Object identification involves a process of hypothesis testing in which information arriving from the retina is compared with internal representations of objects. This process is reflected in studies that have shown that early stages in processing, such as the primary visual cortex, are activated when scenes are imagined without visual input.

Highlights

1. Vision requires segregating objects from their backgrounds, a process involving contour integration and surface segmentation.
2. This process is simplified by relying on the statistical properties of natural forms. As recognized by the Gestalt psychologists early in the 20th century, we naturally link scene components based on grouping rules of similarity, proximity, and contour smoothness (referred to as "good continuation").
3. Neurons in visual cortical areas have properties consonant with Gestalt grouping rules. They perform a local and global analysis of scene properties in parallel. The local properties are the visual primitives, which include orientation selectivity, direction selectivity, contrast sensitivity, disparity selectivity, and color selectivity. The corresponding global properties include contour integration, object movement, border ownership, disparity capture, and color constancy.
4. Perception of visual features is dependent on context; similarly, neuronal responses are context dependent. The principle underlying these interactions is the association field, a pattern of interactions between bits of information that are mapped across each cortical area. The association field mediates contour integration in visual cortex but is likely to be a general feature of processing throughout the cerebral cortex. The anatomical

substrate for the association field includes a network of long-range horizontal connections formed by the axons of cortical pyramidal cells, which extend for long distances parallel to the cortical surface.

5. Different visual cortical areas contribute to the various global properties, and interactions between areas, including top-down influences, are required for their development. Though there has been considerable emphasis on selectivity for increasing stimulus complexity as one ascends a hierarchy of cortical areas through feedforward connections extending from the primary visual cortex to areas in the temporal (ventral pathway) and parietal (dorsal pathway) cortex, feedback connections are of equal importance.
6. Future studies will elucidate the relative contributions of intrinsic, feedforward, and feedback cortical connections, and the interactions between them, in cortical processing. Evidence is emerging that rather than having fixed functions, neurons are adaptive processors, taking on different functional roles under different behavioral contexts. Neurons may mediate this functional diversity by input selection, expressing task-relevant inputs and suppressing task-irrelevant inputs. When operating abnormally, these functional and connectivity dynamics may account for perceptual and behavioral phenomena associated with disorders such as autism and schizophrenia.

High-Level Visual Processing: From Vision to Cognition

As we have seen, low-level visual processing is responsible for detecting various types of contrasts in the patterns of light projected onto the retina. Intermediate-level processing is concerned with the identification of so-called visual primitives, such as contours and fields of motion, and the segregation of surfaces. High-level visual processing integrates information from a variety of sources and is the final stage in the visual pathway leading to visual perception.

High-level visual processing is concerned with identifying behaviorally meaningful features of the environment and thus depends on descending signals that convey information from short-term working memory, long-term memory, and executive areas of cerebral cortex.

High-Level Visual Processing Is Concerned With Object Recognition

Our visual experience of the world is fundamentally object-centered. We can recognize the same object even when the patterns of light it casts onto the retina vary greatly with viewing conditions, such as lighting, angle, position, and distance. And this is the case even for visually complex objects, those that include a large number of conjoined visual features.

Moreover, objects are not mere visual entities, but are commonly associated with specific experiences, other remembered objects, and sensations—such as the hum of the coffee grinder or the aroma of a lover's perfume—and a variety of emotions. It is the behavioral significance of objects that guides our action based on visual information. In short, object recognition establishes a nexus between vision and cognition (Figure 24–1).

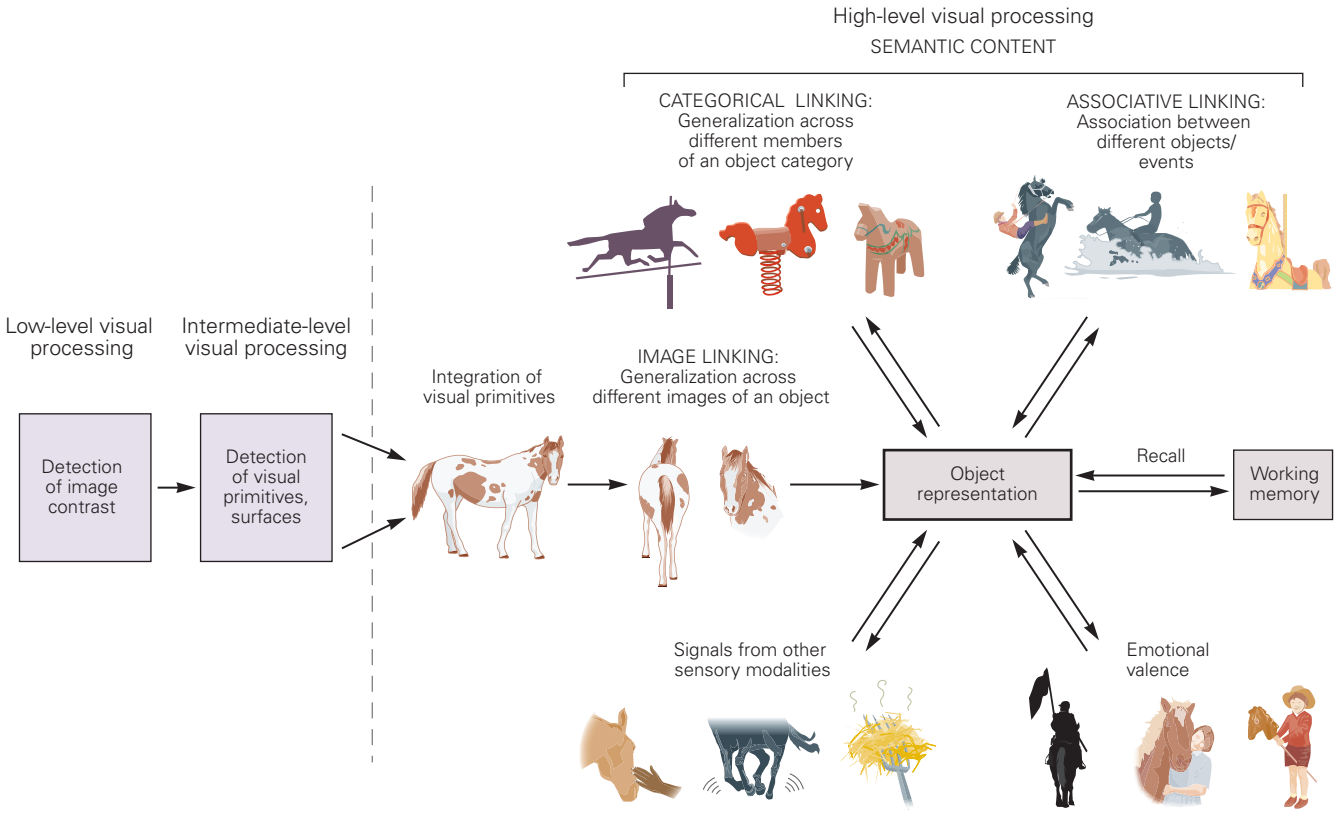

Figure 24–1 Representation of entire objects is central to high-level visual processing. Representation of entire objects involves integration of visual features extracted at earlier stages in the visual pathways. This integration is a generalization of the numerous retinal images generated by the same object and of different members of an object category. The representation also incorporates information from other sensory modalities, attaches emotional valence, and associates the object with the memory of other objects or events. Object representations can be stored in working memory and recalled in association with other memories.

The Inferior Temporal Cortex Is the Primary Center for Object Recognition

Primate studies implicate neocortical regions of the temporal lobe, principally the inferior temporal cortex, in object perception. Because the hierarchy of synaptic relays in the cortical visual system extends from the primary visual cortex to the temporal lobe, the temporal lobe is a site of convergence of many types of visual information.

Neuropsychological studies have found that damage to the inferior temporal cortex can produce specific failures of object recognition. Neurophysiological and functional imaging studies have, in turn, yielded remarkable insights into the ways in which the activity of inferior temporal neurons represents objects, how these representations relate to perceptual and cognitive events, and how they are modified by experience.

Visual signals originating in the retina are processed in the lateral geniculate nucleus of the thalamus before reaching the primary visual cortex (V1). Ascending visual pathways from V1 follow two main parallel and hierarchically organized streams: the ventral and dorsal streams (Chapter 21). The ventral stream extends ventrally and anteriorly from V1 through V2, via V4, into inferior temporal cortex, which, in macaque monkeys, comprises the lower bank of the superior temporal sulcus and the ventrolateral convexity of the temporal lobe (Figure 24–2). Neurons at each synaptic relay in this ventral stream receive convergent input from the preceding stage. At the top of the hierarchy, inferior temporal neurons are in a position to integrate a large and diverse quantity of visual information over a vast region of visual space.

The inferior temporal cortex is a large brain region. The patterns of anatomical connections to and from this region indicate that it comprises at least two main functional subdivisions—the posterior area temporo-occipital cortex and the anterior area temporal cortex—and functional evidence suggests further subdivisions

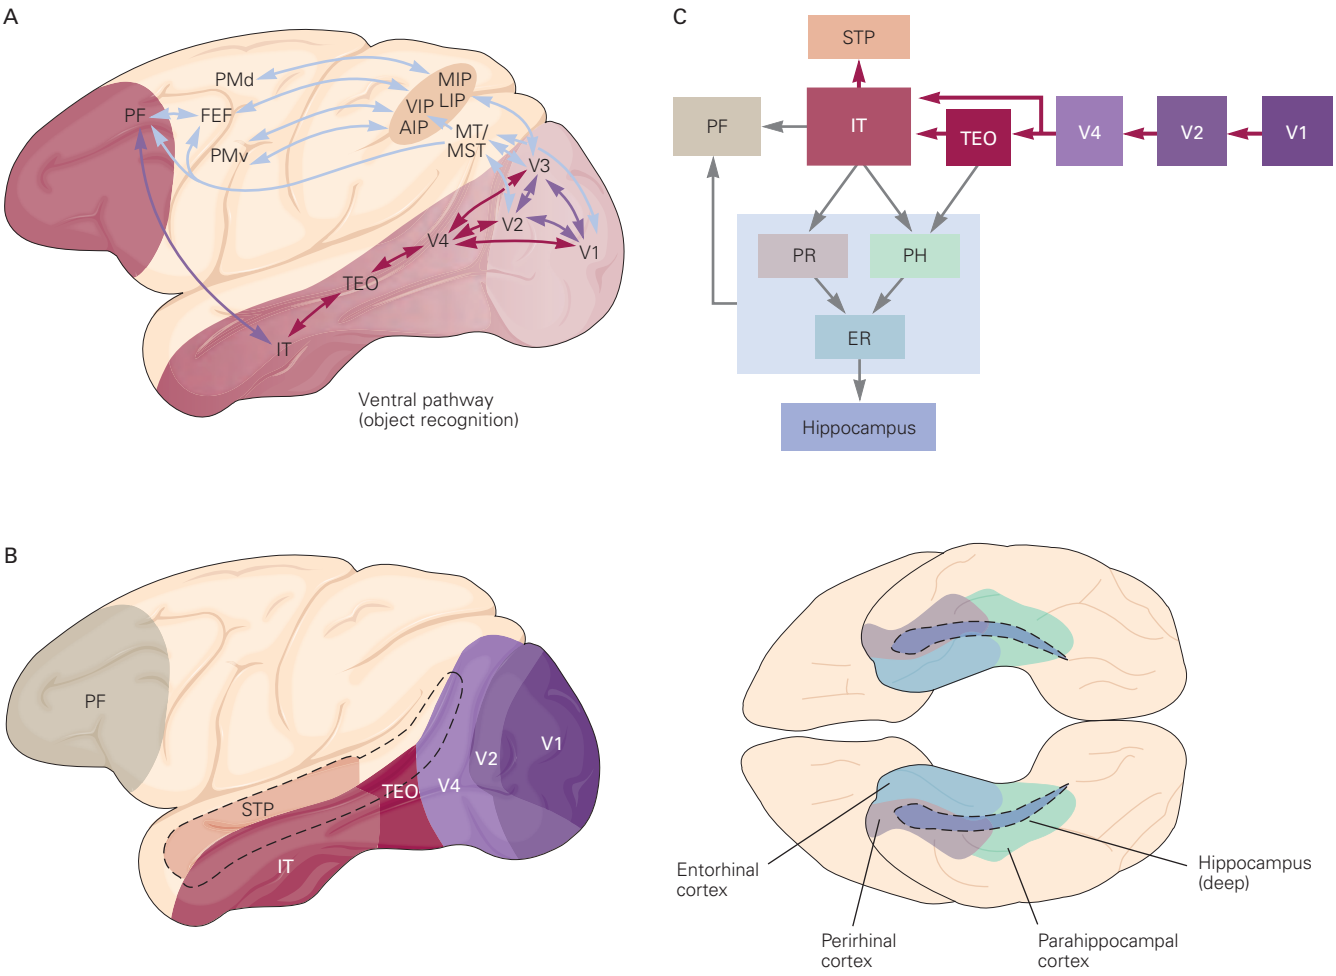

Figure 24–2 Cortical pathway for object recognition.

A. A lateral view of the macaque brain shows the major pathways involved in visual processing, including the pathway for object recognition (**red**). (Abbreviations: **AIP**, anterior intraparietal cortex; **FEF**, frontal eye fields; **IT**, inferior temporal cortex; **LIP**, lateral intraparietal cortex; **MIP**, medial intraparietal cortex; **MST**, medial superior temporal cortex; **MT**, middle temporal cortex; **PF**, prefrontal cortex; **PMd**, dorsal premotor cortex; **PMv**, ventral premotor cortex; **TEO**, temporo-occipital cortex; **VIP**, ventral intraparietal cortex.)

B. Lateral and ventral views of the macaque monkey brain show the cortical areas involved in object recognition. (Abbreviations: **IT**, inferior temporal cortex; **PF**, prefrontal cortex; **STP**, superior temporal polysensory area; **TEO**, temporo-occipital cortex.)

C. The inferior temporal cortex (**IT**) is the end stage of the ventral stream (**red arrows**) and is reciprocally connected with neighboring areas of the medial temporal lobe and prefrontal cortex (**gray arrows**). This chart illustrates the main connections and predominant direction of information flow. (Abbreviations: **ER**, entorhinal cortex; **PF**, prefrontal cortex; **PH**, parahippocampal cortex; **PR**, perirhinal cortex; **STP**, superior temporal polysensory area; **TEO**, temporo-occipital cortex.)

into multiple functionally specialized areas. As we shall see, the distinction between anterior and posterior parts of the inferior temporal cortex is supported by both neuropsychological and neurophysiological evidence.

Clinical Evidence Identifies the Inferior Temporal Cortex as Essential for Object Recognition

The first clear insight into the neural pathways mediating object recognition was obtained in the late 19th century when the American neurologist Sanger Brown and the British physiologist Edward Albert Schäfer found that experimental lesions of the temporal lobe in primates abolished the ability to recognize objects. Unlike the deficits that accompany lesions of occipital cortical areas, temporal lobe lesions do not impair sensitivity to basic visual attributes, such as color, motion, and distance. Because of the unusual type of visual loss, the impairment was originally called psychic blindness, but this term was later replaced by *visual agnosia* ("without visual knowledge"), a term coined by Sigmund Freud.

In humans, there are two basic categories of visual agnosia, apperceptive and associative, the description of which led to a two-stage model of object recognition in the visual system. With apperceptive agnosia, the ability to match or copy complex visual shapes or objects is impaired (Figure 24–3). This impairment results from disruption of the first stage of object recognition: integration of visual features into sensory representations of entire objects. With associative agnosia, the ability to match or copy complex objects remains intact, but the ability to identify objects is impaired. This impairment results from disruption of the second stage of object recognition: association of the sensory representation of an object with knowledge of the object's meaning or function.

Consistent with this functional hierarchy, apperceptive agnosia is most common following damage to the posterior inferior temporal cortex, whereas associative agnosia, a higher-order perceptual deficit, is more common following damage to the anterior inferior temporal cortex. Neurons in the anterior subdivision exhibit a variety of memory-related properties not seen in the posterior area.

More focal lesions within temporal cortex can lead to specific deficits. Damage to a small region of the human temporal lobe results in an inability to

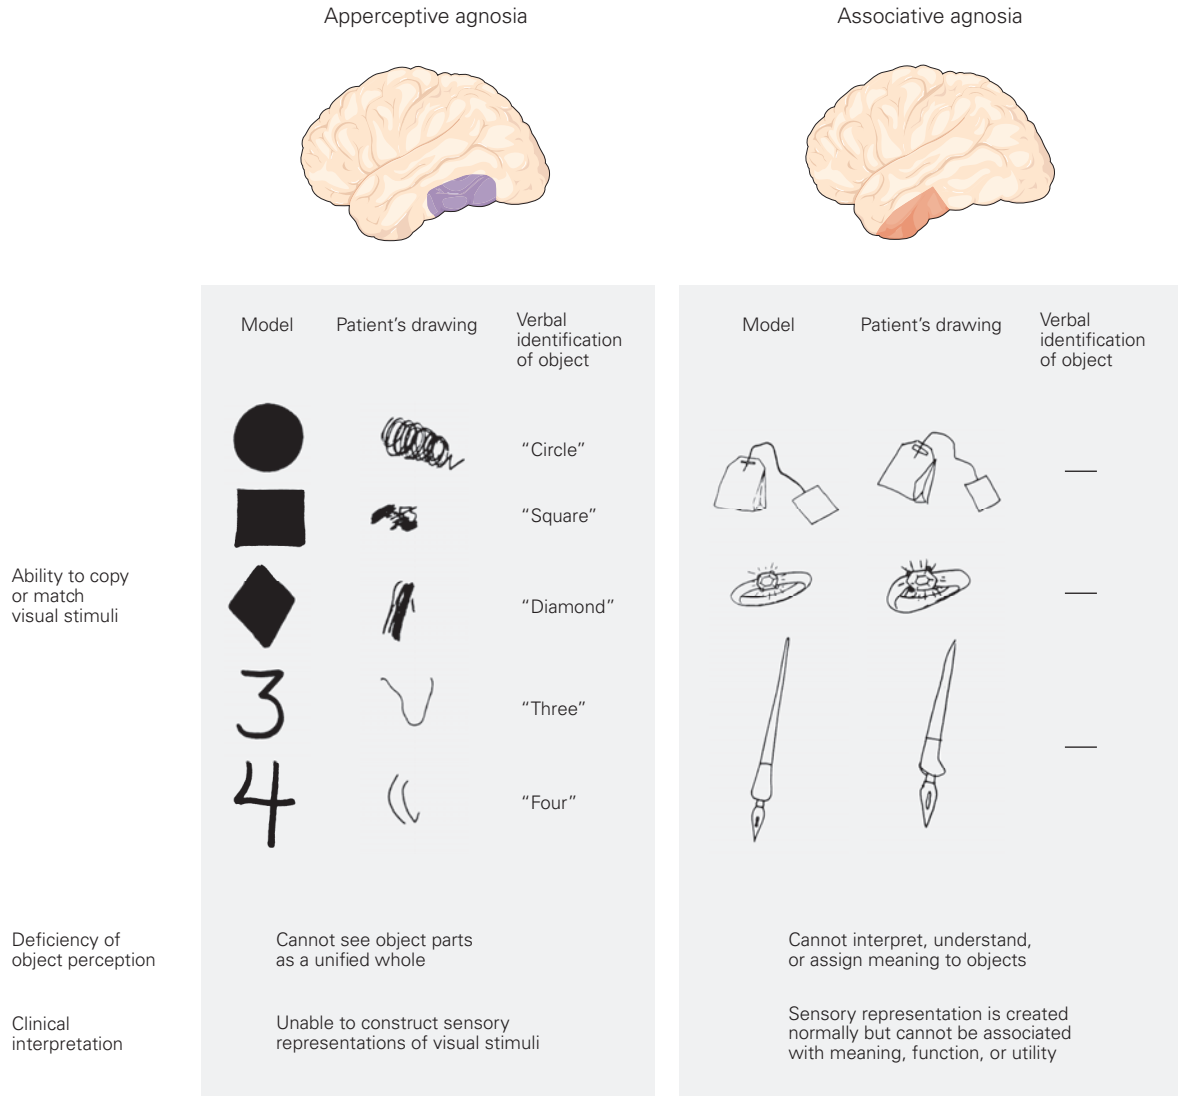

Figure 24–3 Neurons in the temporal lobe of humans are involved in object recognition. Damage to the inferior temporal cortex impairs the ability to recognize visual objects, a condition known as visual agnosia. There are two major categories of visual agnosia: Apperceptive agnosia results from damage to the posterior region, and associative agnosia results from damage of the anterior region. (Reproduced, with permission, from Farah 1990. © 1990 Massachusetts Institute of Technology.)

recognize faces, a form of associative agnosia known as *prosopagnosia.* Patients with prosopagnosia can identify a face as a face, recognize its parts, and even detect specific emotions expressed by the face, but they are unable to identify a particular face as belonging to a specific person.

Prosopagnosia is an example of a *category-specific agnosia*, in which patients with temporal lobe damage fail to recognize particular items belonging to a specific semantic category. Category-specific agnosias for living things, fruits, vegetables, tools, or animals have also been reported. Owing to the pronounced behavioral significance of faces and the normal ability of people to recognize an extraordinarily large number of faces, prosopagnosia may simply be the most commonly diagnosed variety of category-specific agnosia.

Neurons in the Inferior Temporal Cortex Encode Complex Visual Stimuli and Are Organized in Functionally Specialized Columns

The coding of visual information in the temporal lobe has been studied extensively using electrophysiological techniques, beginning with the work of Charles Gross and colleagues in the 1970s. Neurons in this region have distinctive response properties. They are relatively insensitive to simple stimulus features such as orientation and color. Instead, the vast majority possess large, centrally located receptive fields and encode complex stimulus features. These selectivities often appear somewhat arbitrary. An individual neuron might, for example, respond strongly to a crescent-shaped pattern of a particular color and texture. Cells with such unique selectivities likely provide inputs to higher-order neurons that respond to specific meaningful objects.

In fact, within the inferior temporal cortex, several small subpopulations of neurons are activated by highly meaningful objects, such as faces and hands (Figure 24–4), as Charles Gross discovered. For cells that respond to the sight of a hand, individual fingers are particularly critical. Among cells that respond to faces, the most effective stimulus for some cells is a frontal view of the face, whereas for others it is a side view. Although some neurons respond preferentially to faces in general, others respond only to specific

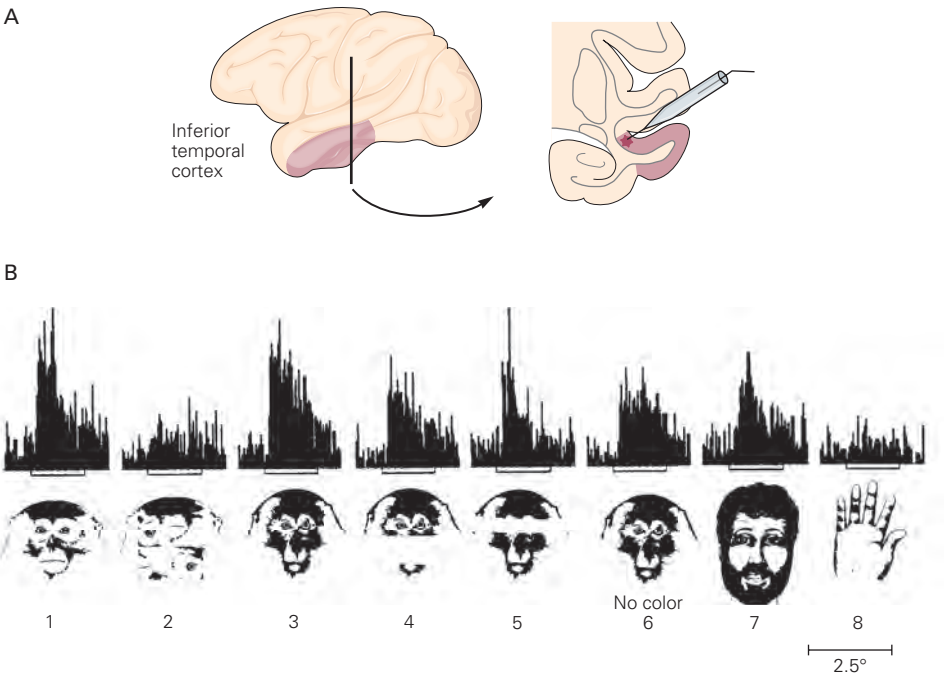

Figure 24–4 Neurons in the inferior temporal cortex of the monkey are involved in face recognition. (Reproduced, with permission, from Desimone et al. 1984. Copyright © 1984 Society for Neuroscience.)

A. The location of the inferior temporal cortex of the monkey is shown in a lateral view and coronal section. The colored area is the location of the recorded neurons.

B. Peristimulus time histograms illustrate the frequency of action potentials in a single neuron in response to different images (shown below the histograms). This neuron responded selectively to faces. Masking of critical features, such as the mouth or eyes (**4**, **5**), led to a substantial but not complete reduction in response. Scrambling the parts of the face (**2**) nearly eliminated the response.

facial expressions. It seems likely that such cells contribute directly to face recognition.

In initial relays in the cortical visual system, neurons that respond to the same stimulus features, such as orientation or direction of motion, but from different parts of the visual field are organized in columns. Cells within the inferior temporal cortex are similarly organized. Columns of neurons representing the same or similar stimulus properties commonly extend throughout the cortical thickness and over a range of approximately 400 μm. The columns are arranged such that different stimuli that possess some similar features are represented in partially overlapping columns (Figure 24–5). Thus, one stimulus can activate multiple columns. Horizontal connections can span many millimeters and may facilitate the formation of distributed networks for encoding objects.

The Primate Brain Contains Dedicated Systems for Face Processing

Prosopagnosia often occurs in the absence of any other form of agnosia. Such a highly specific perceptual deficit could be explained by focal lesions of face-selective neurons located in exclusive clusters. This idea was strengthened by the discovery of face-selective regions in the human brain by Nancy Kanwisher and colleagues using functional magnetic resonance imaging (fMRI) and by Gregory McCarthy and colleagues using direct electrophysiological recordings from the surface of the human brain. Kanwisher and colleagues found that during the presentation of pictures of faces and other objects one area in the human temporal lobe, the fusiform face area, responded significantly more during the presentation of faces compared to other objects.

Subsequently, several more face-selective areas were found, primarily in temporal but also in prefrontal cortex. Early studies of these areas provided circumstantial evidence for clustering of face-selective neurons. In later studies, Doris Tsao, Winrich Freiwald, and colleagues directly demonstrated such clustering and showed that face processing might be performed by a dedicated face-processing network spanning from the posterior part of inferior temporal cortex to prefrontal cortex. Using fMRI, they found six areas in temporal cortex and three in prefrontal cortex of the macaque monkey that responded more selectively to faces than to other objects. These areas, called face patches, are found at highly consistent locations across individuals and thus are named based on their location. Each face patch is a few millimeters in diameter and thus differs organizationally from the inferior temporal columns. Intracellular recordings from the face patches

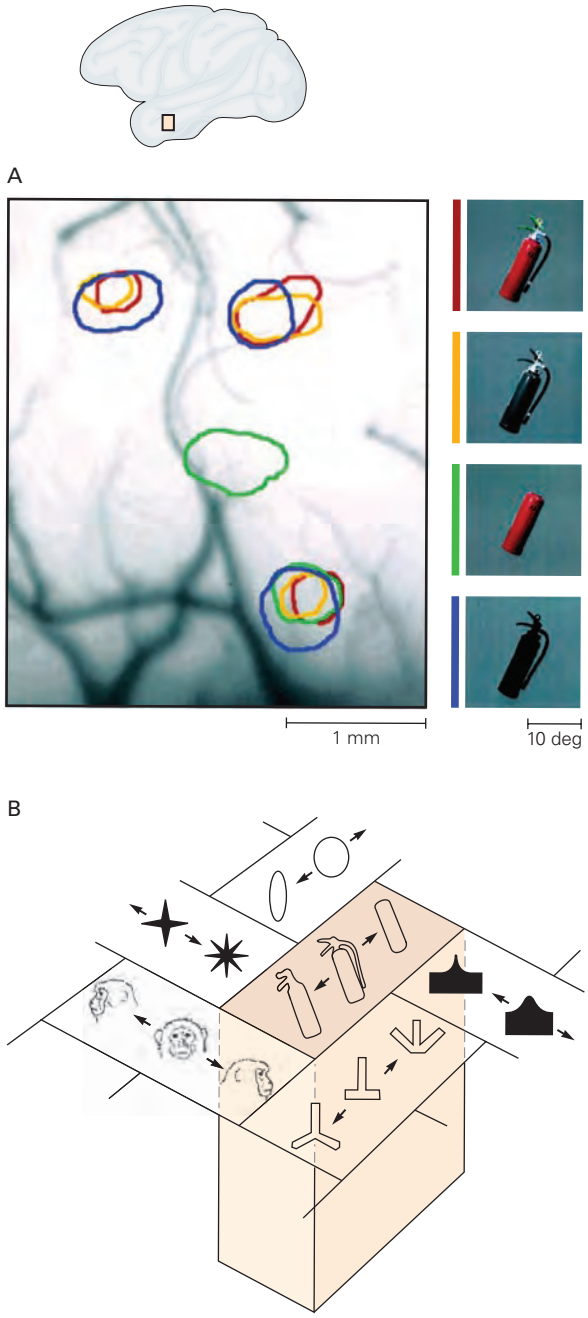

Figure 24–5 Neurons in the anterior portion of the inferior temporal cortex that respond to complex visual stimuli are organized into columns. (Reproduced, with permission, from Tanaka 2003. Copyright © 2003 Oxford University Press.)

A. Optical images of the surface of the anterior inferior temporal cortex illustrate regions selectively activated by the objects shown at the right.

B. Neurons of the inferior temporal cortex are organized in functionally specialized columns that extend from the surface of the cortex. According to this model, each column includes neurons that respond to a specific visually complex object. Columns of neurons that represent variations of an object, such as different faces or different fire extinguishers, constitute a hypercolumn.

revealed that the vast majority of cells respond selectively more to faces than to other objects. Thus, millions of face cells are clustered into a fixed number of small areas. These areas are directly connected to each other, thus forming a face-processing network. Within this network, each node appears to be functionally specialized. From posterior to anterior locations within the temporal lobe, the initial face patches respond to particular views of the face, and then face patches become gradually more selective to identity and less selective for angle of view. Furthermore, dorsal face areas within the temporal lobe exhibit a selectivity for natural facial motion, which ventral areas lack. Thus, a highly specialized network, located primarily in temporal cortex, processes the multiple dimensions of information conveyed by a face (Figure 24–6).

The Inferior Temporal Cortex Is Part of a Network of Cortical Areas Involved in Object Recognition

Object recognition is intimately intertwined with visual categorization, visual memory, and emotion, and the outputs of the inferior temporal cortex contribute to these functions (see Figure 24–2). Among the principal projections are those to the perirhinal and parahippocampal cortices, which lie medially adjacent to the ventral surface of the inferior temporal cortex (Figure 24–2C). These regions project, in turn, to the entorhinal cortex and the hippocampal formation, both of which are involved in long-term memory storage and retrieval. A second major projection from the inferior temporal cortex is to the prefrontal cortex, an important site for high-level visual processing. As we shall see, prefrontal neurons play important roles in object categorization, visual working memory, and memory recall.

The inferior temporal cortex also provides input—directly and indirectly via the perirhinal cortex—to the amygdala, which is believed to apply emotional valence to sensory stimuli and to engage the cognitive and visceral components of emotion (Chapter 42). Finally, the inferior temporal cortex is a major source of input to multimodal sensory areas of cortex such as the superior temporal polysensory area (Figure 24–2B), which lies dorsally adjacent to the inferior temporal cortex.

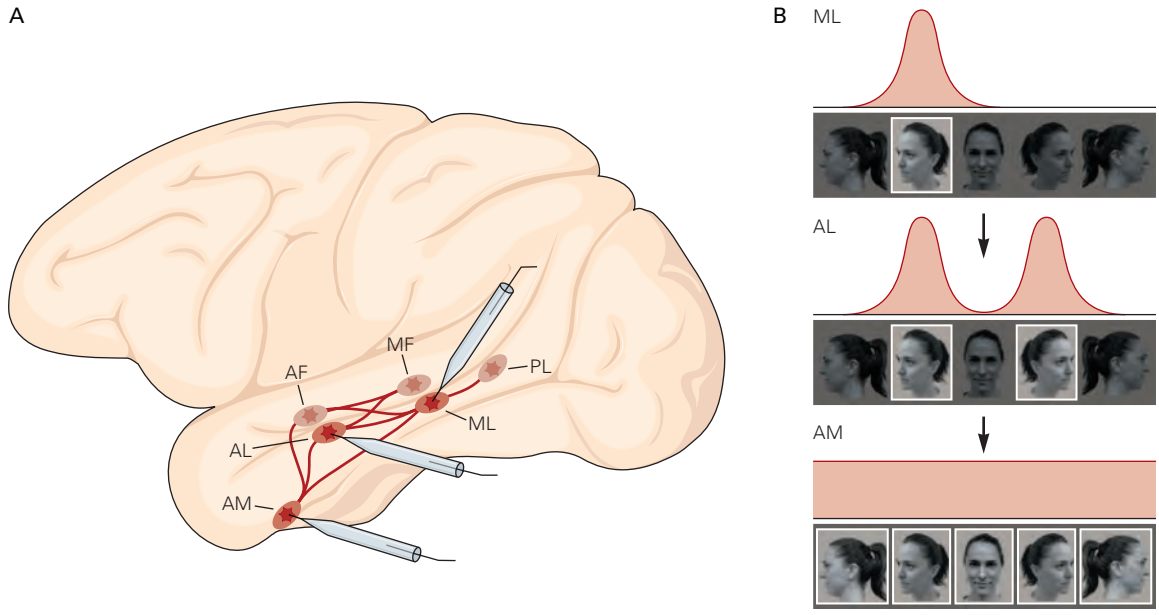

Figure 24–6 The temporal lobe contains a network of face-selective areas.

A. Functional magnetic resonance imaging of macaque monkeys watching pictures of faces and other objects identified six face-selective areas in the temporal lobe, inside and around the superior temporal sulcus. These areas occur at the same locations across subjects and have been given names based on their anatomical location (**PL**, posterior lateral; **ML**, medial lateral; **MF**, medial fundus of the superior temporal sulcus; **AL**, anterior lateral; **AF**, anterior fundus; **AM**, anterior medial). These areas are interconnected to form a face-processing network.

B. Single-neuron recordings from areas ML, AL, and AM show tuning to head orientation. ML cells are tuned to specific head orientations, many AL cells are tuned to multiple orientations that are mirror-symmetric versions of each other, and AM cells are broadly and more weakly tuned to head orientation. These three representations in interconnected areas can be thought of as transformations of each other (**arrows**).

Object Recognition Relies on Perceptual Constancy

The ability to recognize objects as the same under different viewing conditions, despite the sometimes markedly different retinal images, is one of the most functionally important requirements of visual experience. The invariant attributes of an object—for example, spatial and chromatic relationships between image features or characteristic features such as the stripes of a zebra—are cues to the identity and meaning of the objects.

For object recognition to take place, these invariant attributes must be represented independently of other image properties. The visual system does this with proficiency, and its behavioral manifestation is termed *perceptual constancy*. Perceptual constancy has many forms ranging from invariance across simple transformations of an object, such as changes of size or position, to more difficult ones, such as rotation in depth or changes in lighting, and even to the sameness of objects within a category: All zebras look alike.

One of the best examples is *size constancy.* An object placed at different distances from an observer is perceived as having the same size, even though the object produces images of different absolute size on the retina. Size constancy has been recognized for centuries, but only in the past several decades has it been possible to identify the neural mechanisms responsible. An early study found that lesions of the inferior temporal cortex lead to failures of size constancy in monkeys, suggesting that neurons in this area play a critical role in size constancy. Indeed, one of the most striking properties of individual inferior temporal neurons is the invariance of their shape selectivity even to very big changes in stimulus size (Figure 24–7A).

Another type of perceptual constancy is *position constancy*, in which objects are recognized as the same regardless of their location in the visual field. The pattern of selective response of many inferior temporal neurons does not vary when an object changes position within their large receptive fields (Figure 24–7B). *Form-cue invariance* refers to the constancy of a form when the cues that define the form change. The silhouette of Abraham Lincoln's head, for example, is readily recognizable whether it is black on white, white on black, or red on green. The responses of many inferior temporal neurons do not change with changes in contrast polarity (Figure 24–7C), color, or texture.

Viewpoint invariance refers to the perceptual constancy of three-dimensional objects observed from different angles. Because most objects we see are three-dimensional and opaque, when looked at from different viewpoints, some parts become invisible, while others are revealed, and all others change in appearance. Yet despite the limitless range of retinal images that might be cast by a familiar object, an observer can readily recognize an object independently of the angle at which it is viewed. There are notable exceptions to this rule, which generally occur when an object is viewed from an angle that yields an uncharacteristic retinal image, such as a bucket viewed from directly above.

Thus, object recognition mechanisms must infer the identity of objects from apparent complex shapes. Many neurons in inferior temporal cortex do not exhibit viewpoint invariance. In fact, many are systematically tuned to viewing angle. Yet at more anterior locations, neurons are not only more size and position invariant, but they also exhibit greater invariance to viewpoint. The face-processing system is a case in point. Neurons in posterior face patches are tuned to viewing angle, while neurons in anterior face patches exhibit great robustness to changes in viewpoint. Thus, population responses in posterior face areas contain more information about head orientation than those in anterior areas, while the anterior face patches provide more information about face identity across head orientations compared to posterior face areas. The degree of viewpoint invariance achieved in anterior inferior temporal cortex, by individual neurons and populations of neurons, might be sufficient to account for perceptual viewpoint invariance. But this has not been directly shown yet. Alternatively, viewpoint invariance may be achieved at a higher stage of cortical processing, such as the prefrontal cortex.

Studies of the conditions under which viewpoint invariance fails may lead to insights into the neural mechanisms of the behavior. One such condition is presentation of mirror images. Although mirror images are not identical, they are frequently perceived as such, a confusion reflecting a false-positive identification by the system for viewpoint invariance. Carl Olson and colleagues examined the responses of neurons in a particular region of the inferior temporal cortex to stimuli that were mirror images. Consistent with the perceptual confusion, many inferior temporal neurons responded similarly to both images. Similarly, in one face area between the posterior and anterior ones described earlier, profile-selective cells respond similarly to the left and right profile of a face. These results reinforce the conclusion that activity in the inferior temporal cortex reflects perceptual invariance, albeit incorrectly in this case, rather than the actual features of a stimulus.

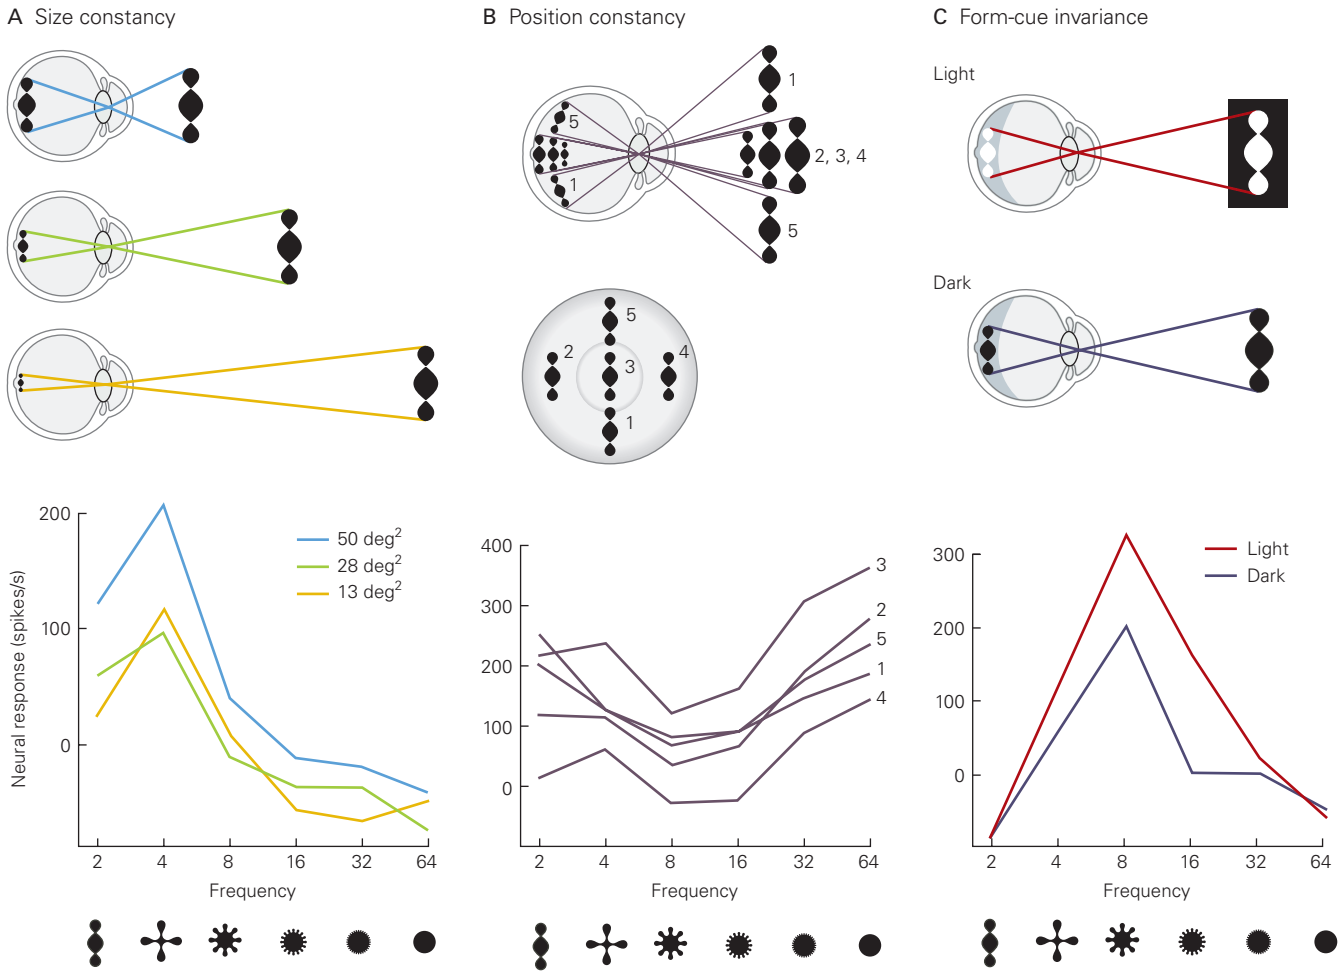

Figure 24–7 Perceptual constancy is reflected in the behavior of neurons in the inferior temporal cortex. The responses of many inferior temporal neurons are selective for stimuli with a particular frequency (number) of lobes but invariant to object size, position, and reflectance. (Reproduced, with permission, from Schwartz et al. 1983.)

A. *Size constancy.* An object is perceived to be the same even when the retinal image size decreases with the distance of the object in the visual field. The response of the vast majority of inferior temporal neurons to substantial changes in retinal image size is invariant, as illustrated here by the record of a single cell.

B. *Position constancy.* An object is perceived to be the same despite changes in position in the retinal image. Almost all inferior temporal neurons respond similarly to the same stimulus in different positions in the visual field, as illustrated here by the record of a single neuron.

C. *Form-cue invariance.* An object is perceived to be the same despite changes in reflectance. Most inferior temporal neurons respond similarly to the two images illustrated, as shown in the record of an individual neuron.

Categorical Perception of Objects Simplifies Behavior

All forms of perceptual constancy are the product of the visual system's attempts to generalize across different retinal images generated by a single object. A still more general type of constancy is the perception of individual objects as belonging to the same semantic category. The apples in a basket or the many appearances of the letter *A* in different fonts, for example, are physically distinct but are effortlessly perceived as *categorically* identical.

Categorical perception is classically defined as the ability to distinguish objects of different categories better than objects of the same category. For example, it is more difficult to discriminate between two red lights that differ in wavelength by 10 nm than to discriminate between red and orange lights with the same wavelength difference.

Categorical perception simplifies behavior. For example, it usually does not matter whether an apple

is completely spherical or slightly mottled on the left side or whether the seat we are offered is a Windsor or a Chippendale side chair. Similarly, reading ability requires that one be able to recognize the alphabet in a broad variety of type styles. Like the simpler forms of perceptual constancy, categorical perception relies on the brain's ability to extract invariant features of objects seen.

Is there a population of neurons that respond uniformly to objects within a category and differentially to objects of different categories? To test this, David Freedman and Earl Miller and colleagues created a set of images in which features of dogs and cats were merged; the proportions of dog and cat in the composite images varied continuously from one extreme to the other. Monkeys were trained to identify these stimuli reliably as either dog or cat. Miller and colleagues then recorded from visually responsive neurons in the dorsolateral prefrontal cortex, a region that receives direct input from the inferior temporal cortex. Not only did these neurons exhibit the predicted category-selective responses—responding well to cat but not dog, or vice versa—but the neuronal category boundary also corresponded to the behaviorally learned boundary (Figure 24–8). By contrast, neurons in inferior temporal cortex represented similarity of features, not categories.

The fact that category-specific agnosias sometimes follow damage to the temporal lobe suggests there are neurons in the inferior temporal cortex that are category-selective similar to those of neurons in the prefrontal cortex. Face-selective cells in the temporal cortex appear to meet this criterion, because their responses to a range of faces are often similar. Yet, these may constitute a special case, whereas for most stimulus conditions, category-selective responses may be characteristic of neurons in the prefrontal cortex, where visual responses are more commonly linked to the behavioral significance of the stimuli.

Visual Memory Is a Component of High-Level Visual Processing

Visual experience can be stored as memory, and visual memory influences the processing of incoming visual information. Object recognition in particular relies on the observer's previous experiences with objects. Thus, the contributions of the inferior temporal cortex to object recognition must be modifiable by experience.

Studies of the role of experience in visual perception have focused on two distinct types of experience-dependent plasticity. One stems from repeated exposure or practice, which leads to improvements in visual discrimination and object recognition ability. These experience-dependent changes constitute a form of implicit learning known as perceptual learning (Chapter 23). The other occurs in connection with the storage of explicit learning, the learning of facts or events that can be recalled consciously (Chapter 54).

Implicit Visual Learning Leads to Changes in the Selectivity of Neuronal Responses

The ability to discriminate complex visual stimuli is highly modifiable by experience. For example, individuals who attend to fine differences between automobile models improve their ability to recognize such differences.

In the inferior temporal cortex, neuronal selectivity for complex objects can undergo change that parallels change in the ability to distinguish objects. For example, in a study by Logothetis and colleagues, monkeys were trained to identify novel three-dimensional objects, such as randomly bent wire forms, from two-dimensional views of the objects. Extensive training led to pronounced improvements in the ability to recognize the objects from two-dimensional views. After training, a population of neurons was found that exhibited marked selectivity for the views seen earlier but not for other two-dimensional views of the same objects (Figure 24–9).

Other studies with monkeys have shown that familiarization with novel faces alters the tuning of face-selective neurons in the inferior temporal cortex. Similarly, when an animal has experience with novel objects formed from simple features, inferior temporal neurons become selective for those objects. Such neuronal changes have been found as a consequence of the animal engaging in active discrimination or simply passive viewing of visual stimuli, and they are often manifested as a sharpening of neural selectivity rather than changes in absolute firing rate. Sharpening is precisely the sort of neuronal change that could underlie improvements in perceptual discrimination of visual stimuli.

The Visual System Interacts With Working Memory and Long-Term Memory Systems

Object recognition and learning are intricately linked. In fact, learning can generate entire areas of functional specialization within inferior temporal cortex. For example, monkeys who learn at a young age to associate specific shapes (eg, a number symbol) with particular reward magnitudes develop specialized brain areas that process these specific shapes. These brain regions

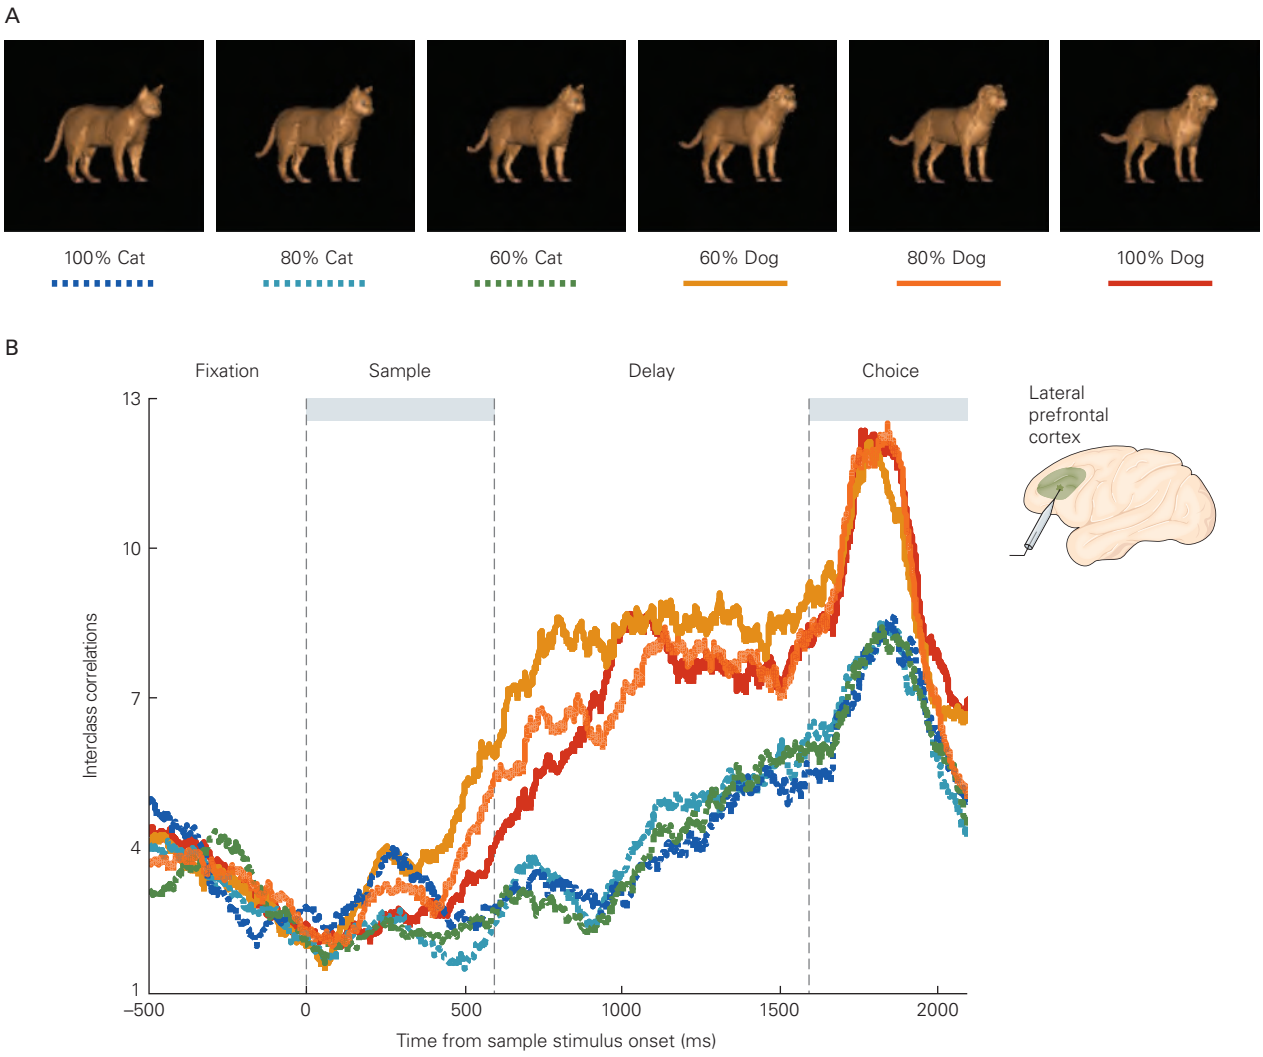

Figure 24–8 Neural coding for categorical perception. (Reproduced, with permission, from Freedman et al. 2002.)

A. The images combine cat and dog features in varying proportions. Monkeys were trained to categorize an image as cat or dog if it had 50% or more features of that animal.

B. Peristimulus time histograms illustrate the responses of a prefrontal cortex neuron to the images shown in part A. The neuron responded much more weakly to images of cats (100%, 80%, and 60%) than to images of dogs (60%, 80%, and 100%). Responses to images from the same category were very similar despite variations in retinal images that were as large as or even larger than the differences in retinal images between categories. Thus, the cell was category-specific. Such category-specific responses were common among visual neurons of the lateral prefrontal cortex.

develop close to the temporal lobe face patches discussed earlier.

Two issues concerning interaction between vision and memory have been investigated. First, how is visual information maintained in short-term working memory? Working memory has a limited capacity, acting like a buffer in a computer operating system, and consolidation into long-term memory is susceptible to interference (Chapter 54). Second, how are long-term visual memories and the associations between them stored and recalled?

In a visual delayed-response task requiring access to stimulus information beyond the duration of the stimulus (Box 24–1), many vision-related neurons in both the inferior temporal and prefrontal cortices continue firing during the delay. This delay-period activity is thought to maintain information in short-term working memory (Figure 24–11). Delay-period activity in the inferior temporal and prefrontal cortices differs in a number of ways. For one, activity in the inferior temporal cortex is associated with the short-term storage of visual patterns and color information, whereas

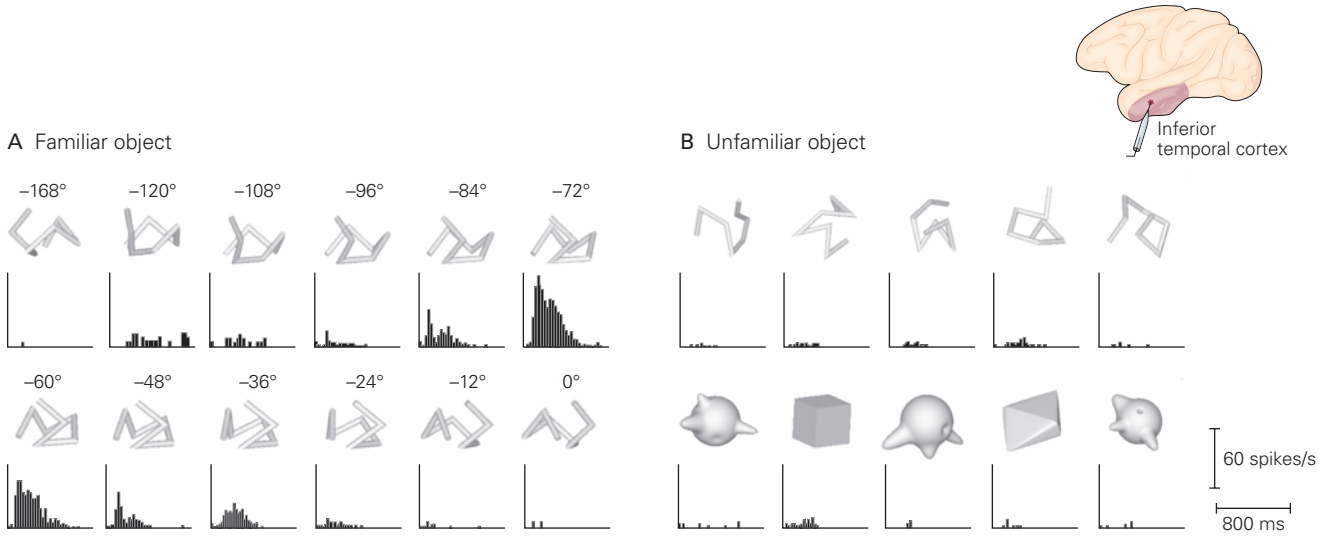

Figure 24–9 Familiarity with particular complex objects leads inferior temporal neurons to respond selectively for those objects. (Reproduced, with permission, from Logothetis and Pauls 1995. Copyright © 1995 Oxford University Press.)

A. Monkeys were trained to recognize a randomly bent wire from a set of two-dimensional views of the wire. The wire form was rotated 12° in successive views. Once recognition performance was stable at a high level, recordings were made from neurons in the inferior temporal cortex while each view was presented. Peristimulus time histograms show the responses of a typical neuron to each view. This neuron responded selectively to views that represented a small range of rotation of the object.

B. When the same neuron was tested with two sets of stimuli that were unfamiliar to the monkey, it failed to respond to any of these stimuli.

activity in the prefrontal cortex encodes visuospatial information as well as information received from other sensory modalities. Delay-period activity in the inferior temporal cortex also appears to be closely attuned to visual perception, for it encodes the sample image, but can be eliminated by the appearance of another image.

In the prefrontal cortex, by contrast, delay-period activity depends more on task requirements and is not terminated by intermittent sensory inputs, suggesting that it may play a role in the recall of long-term memories. Experiments by Earl Miller and colleagues support this view. In these experiments, monkeys were trained to associate multiple pairs of objects. They were then tested on whether they had learned these pairwise associations, using the following procedure. First, a single (sample) object was presented; then, after a brief delay, a second (test) object appeared. The monkey was instructed to indicate whether the test object was the object paired with the sample during previous training.

There are two possible ways to solve this task. During the delay, the animal could use a sensory code and keep a representation of the sample object online until the appearance of the test object, or it could remember the sample object's associate and keep information about the associate object online in a "prospective code" of what might appear as the test object. Remarkably, neuronal activity appears to transition from one to the other during the delay. Neurons in the prefrontal cortex initially encode the sensory properties of the sample object—the one just seen—but later begin to encode the expected (associated) object. As we shall see, such prospective coding in the prefrontal cortex may be the source of top-down signals to the inferior temporal cortex, activating neurons that represent the expected object and thus giving rise to conscious recall of that object.

The relation between long-term declarative memory storage and visual processing has been explored extensively in the context of remembered associations between visual stimuli. Over a century ago, William James, a founder of the American school of experimental psychology, suggested that learning visual associations might be mediated by enhanced connectivity between the neurons encoding individual stimuli. To test this hypothesis, Thomas Albright and colleagues trained monkeys to associate pairs of objects that had no prior physical or semantic relatedness. The monkeys were later tested while extracellular recordings of neurons in the inferior temporal cortex were made. Objects that had been paired often elicited similar neuronal

Box 24–1 Investigating Interactions Between Vision and Working Memory

The relationship between vision and memory can be studied by combining a neuropsychological approach with single-cell electrophysiological methods.

One behavioral paradigm used to study memory is the *delayed-response task*. A subject is required to make a specific response based on information remembered during a brief delay. In one form of this task, known as *delayed match-to-sample*, the subject must indicate whether a visual stimulus is the same or different from a previously viewed cue stimulus (sample) (Figure 24–10A).

When used in conjunction with single-cell recording, this task allows the experimenter to isolate three key components of a neuronal response: (1) the sensory component, the response elicited by the cue stimulus; (2) the short-term or working-memory component, the response that occurs during the delay between the cue and the match; and (3) the recognition-memory or familiarity component, the difference between the response elicited by the match stimulus and the earlier response to the cue stimulus.

A second behavioral paradigm, the *visual paired-association task*, has been used in conjunction with electrophysiology to explore the cellular mechanisms underlying the long-term storage and recall of associations. This task differs from the delayed match-to-sample task in that the match and cue are two different stimuli (Figure 24–10B).

The sample stimulus might consist of the letter *A* and the match stimulus the letter *B*. Through repeated temporal pairing and conditional reinforcement, subjects learn that *A* and *B* are predictive of one another: They are associated.

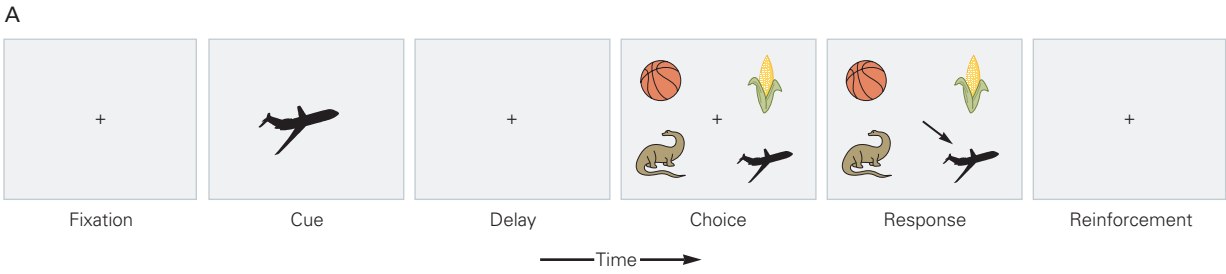

Figure 24–10A Delayed match-to-sample task. In this paradigm, a trial begins with the appearance of a fixation spot that directs the subject's attention and gaze to the center of the computer screen. A cue stimulus (the "sample") then appears briefly, typically for 500 ms, followed by a delay in which the display is blank. The delay can be varied to fit the experimental goals. Following the delay, the choice display appears, which contains several images, one of which is the cue (the "match"). The subject must respond by choosing the cue stimulus, typically either by pressing a button or by a saccade to the stimulus. In the task illustrated here, all of the test images appear at once (a simultaneous match-to-sample task). They can also be presented sequentially (a sequential match-to-sample task). Although the trial's duration may be longer for the sequential task, this paradigm can be advantageous for electrophysiological studies by limiting the visual stimuli present at any time.

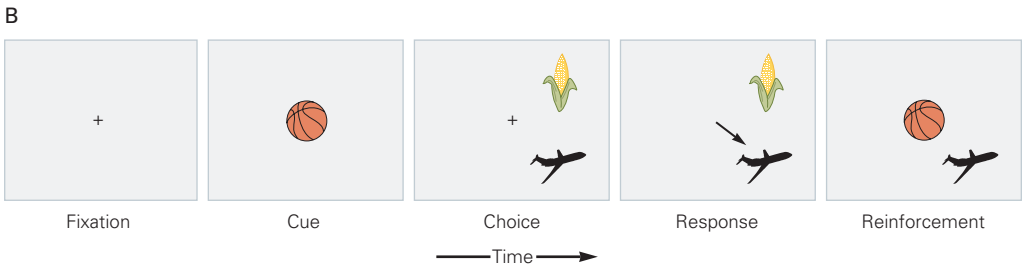

Figure 24–10B The paired-association task. This paradigm resembles the match-to-sample paradigm except that the cue and match are different stimuli. In the illustrated example, the basketball is the cue stimulus and the airplane is the experimenter-designated match stimulus. Because these stimuli have no inherent association, the subject must discover the designated association through trial-and-error learning. The task is thus to establish an association between nonidentical stimuli. The paired-association task can also incorporate a delay between presentation of the sample and test stimuli, and it can be used in both simultaneous (shown) and sequential forms.

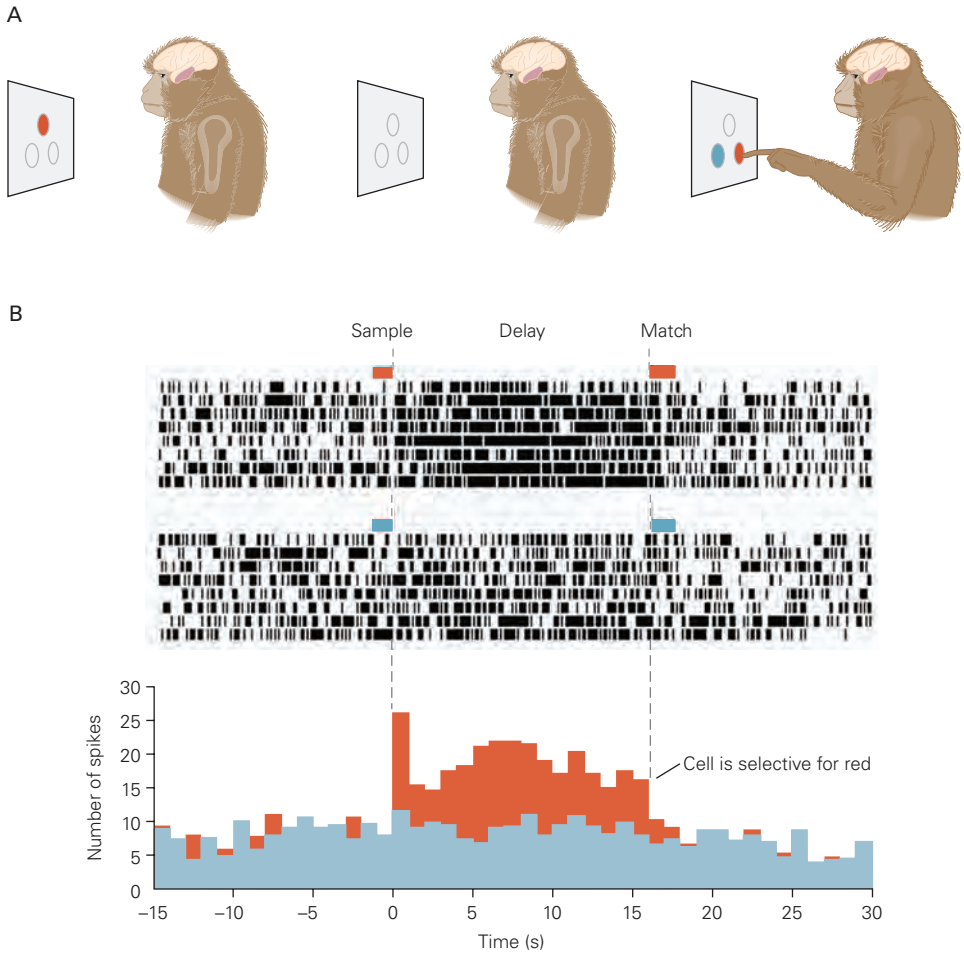

Figure 24–11 Neural activity representing an object is sustained while the object is held in working memory. (Reproduced, with permission, from Fuster and Jervey 1982. Copyright © 1982 Society for Neuroscience.)

A. Monkeys were trained to perform a color match-to-sample task. For example, a red stimulus was first presented and the animal later had to choose a red stimulus from among many colored stimuli. The task incorporated a brief delay (1–2 seconds) between display of the sample and the match, during which information about the correct target color had to be maintained in working memory. The **purple** area in the monkey's brain indicates the inferior temporal cortex.

B. Peristimulus time histograms and raster plots of action potentials illustrate responses of a single neuron in the inferior temporal cortex during the delayed match-to-sample task. The upper record is from trials in which the sample was red, and the lower record is from trials in which it was green (shown here as **blue**). The recordings show that the cell responds preferentially to red stimuli. In trials with a green sample, the activity of the neuron does not change, whereas in trials with a red sample, the cell exhibited a brief burst of activity following presentation of the sample and continued firing throughout the delay. Many visual neurons in the inferior temporal and prefrontal cortices exhibit this kind of behavior.

responses, as one would expect if functional connections had been enhanced, whereas responses elicited by unpaired objects were unrelated. Recordings from individual inferior temporal neurons while monkeys were learning new visual associations showed that a cell's responses to paired objects became more similar over the course of training (Figure 24–12). Most importantly, the changes in neuronal activity occurred on the same timescale as the changes in behavior, and the changes in neural activity depended on successful learning.

These learning-dependent changes in the stimulus selectivity of inferior temporal cortex neurons are long-lasting, suggesting that this cortical region is part of the neural circuitry for associative visual memories. The experimental results also support the view that learned associations are implemented rapidly by changes in the strength of synaptic connections between neurons representing the associated stimuli.

We know that the hippocampus and neocortical areas of the medial temporal lobe—the perirhinal, entorhinal, and parahippocampal cortices—are

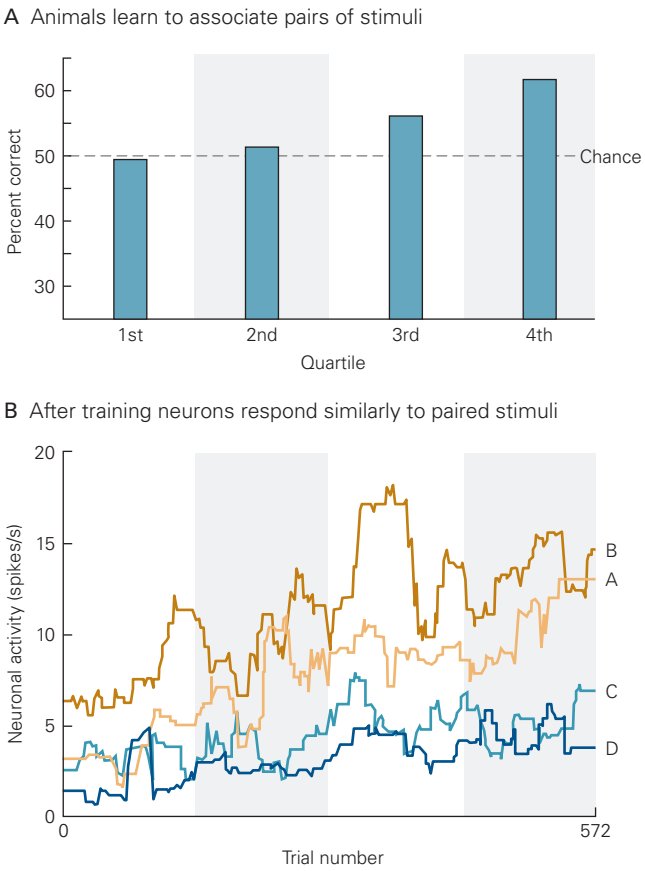

Figure 24–12 Object recognition is linked to associative memory. Monkeys learned associations between pairs of visual stimuli while activity was recorded from a neuron in the inferior temporal cortex. (Reproduced, with permission, from Messinger et al. 2001. © 2001 National Academy of Sciences.)

A. Behavioral performance on a paired-association task is plotted for each quartile of a single training session (572 trials). The animal was presented with four novel stimuli (A, B, C, D) and was required to learn two paired associations (A–B, C–D). As expected, performance began at chance (50% correct) and gradually climbed as the animal learned the associations.

B. Mean firing rates of an inferior temporal neuron recorded during the behavioral task described in part A. Each trace represents the firing rate during presentation of one of the four stimuli (A, B, C, or D). The responses to all stimuli were of similar magnitude at the outset. As the paired associations were learned, the neuronal responses to the paired stimuli A and B began to cluster at a different level from responses to the paired stimuli C and D. The neuron's activity thus corresponded to the learned associations between the two pairs.

essential both for the acquisition of associative visual memories and for the functional plasticity of the inferior temporal cortex. In fact, work by Yasushi Miyashita and colleagues showed that the aforementioned pair-association neurons are much more prevalent in perirhinal cortex than in anterior inferior temporal cortex. Thus, although learning changes the stimulus selectivity of neurons in both areas, the association between visually associated pairs grows stronger from inferior temporal to perirhinal cortex (Figure 24–2C). The hippocampus and medial temporal lobe may facilitate the reorganization of local neuronal circuitry in the inferior temporal cortex necessary to store associative visual memories. The reorganization itself may be a form of Hebbian plasticity (Chapter 49) initiated by the temporal coincidence of the associated visual stimuli.

Associative Recall of Visual Memories Depends on Top-Down Activation of the Cortical Neurons That Process Visual Stimuli

One of the most intriguing features of high-level visual processing is the fact that the detection of an image in one's visual field and the recall of the same image are subjectively similar. The former depends on the bottom-up flow of visual information and is what we traditionally regard as vision. The latter, by contrast, is a product of top-down information flow. This distinction is anatomically accurate but obscures the fact that under normal conditions afferent and descending signals collaborate to yield visual experience.

The study of associative visual memory has provided valuable insights into the cellular mechanisms underlying visual recall. As we have seen, visual associative memories are stored in the visual cortex through changes in the functional connectivity between neurons that independently represent the associated stimuli. The practical consequence of this change is that a neuron that responded only to stimulus *A* prior to learning will respond to both *A* and *B* after these stimuli have been associated (Figure 24–13). Activation of an *A*-responsive neuron by stimulus *B* can be viewed as the neuronal correlate of top-down recall of stimulus *A*.

Neurons in the inferior temporal cortex exhibit precisely this behavior. The activity correlated with cued recall is nearly identical to the bottom-up activation by the stimulus. These neurophysiological findings are supported by a number of brain imaging studies that have identified selective activity in the visual cortex during cued and spontaneous recall of objects.

Although learned associations between images are likely to be stored through circuit changes in the inferior temporal cortex, activation of these circuits for conscious recall depends on input from the prefrontal cortex. The afferent signal for one of a pair of images might be received by the inferior temporal cortex and relayed to prefrontal cortex, where the information

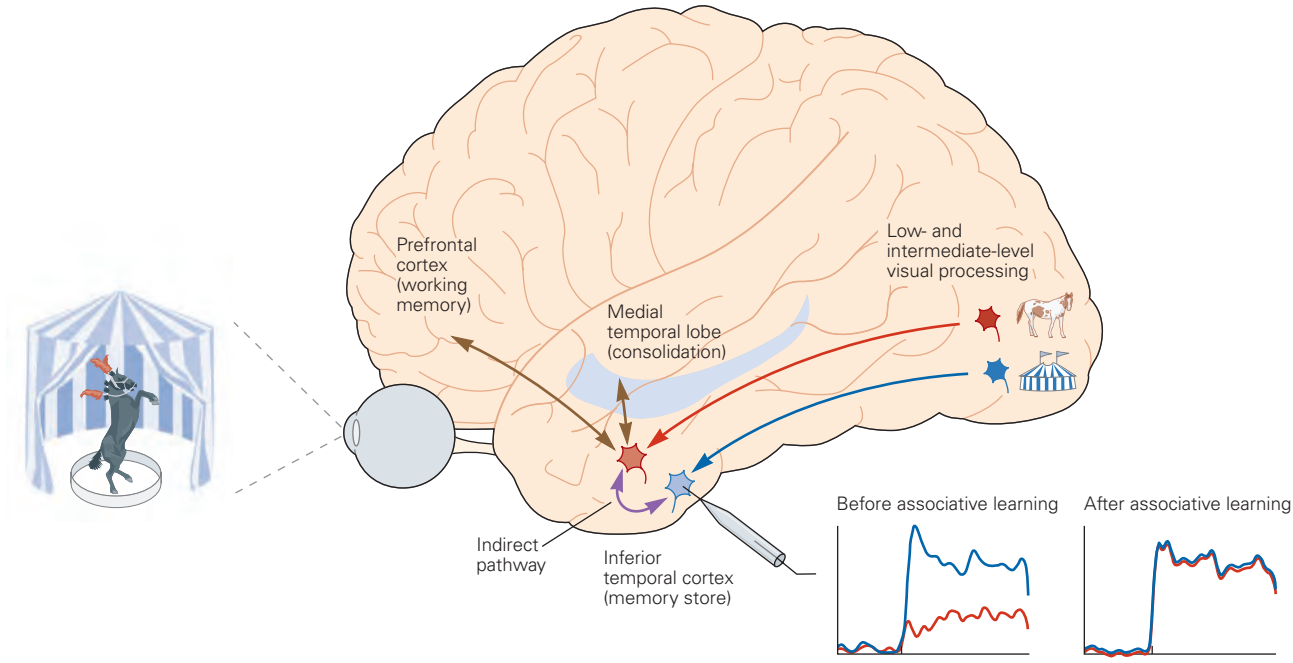

Figure 24–13 Circuits for visual association and recall. Bottom-up signals—afferent signals conveying information about objects in the observer's visual field—are combined into object representations in the inferior temporal cortex. Before associative learning, a neuron (**blue**) responds well to the circus tent but not to the horse. Learned associations between objects are mediated in the inferior temporal cortex by strengthening connections between neurons representing each of the paired objects (the indirect pathway in the figure). Thus, recall of the circus tent following presentation of the horse is achieved by activating the indirect pathway. Indirect activation can also be triggered by the contents of working memory (feedback from the prefrontal cortex). Under normal conditions, visual perception is the product of a combination of direct and indirect inputs to inferior temporal neurons.

would be maintained in working memory. As we have seen, the continued firing of many prefrontal neurons during the delay period of a delayed match-to-sample task initially represents information about the sample image but changes to the associated image that is expected to follow. Signals from prefrontal cortex to the inferior temporal cortex would selectively activate neurons representing the associated image, and that activation would constitute the neural correlate of visual recall.

Highlights

1. A key function of high-level vision is object recognition. Object recognition imbues visual perception with meaning. As the eminent neuropsychologist Hans-Lukas Teuber once wrote, failure of object recognition "would appear in its purest form as a normal percept that has somehow been stripped of its meaning."
2. Object recognition is difficult, primarily because of changes in appearance with changes in position, distance, orientation, or lighting conditions, possibly rendering different objects similar in appearance. Building computer models mimicking primate object recognition capabilities is a major challenge for current and future research.
3. Object recognition relies on a region of the temporal lobe called inferior temporal cortex. Visual information reaching inferior temporal cortex has already been processed through mechanisms of low- and mid-level vision.
4. Lesions to inferior temporal cortex cause visual agnosia, a loss in the ability to recognize objects. Apperceptive agnosia, the inability to match or copy complex objects, is distinguished from associative agnosia, the impairment of the ability to recognize an object's meaning or function. Predicting the exact nature of an agnosia from the pattern of lesioned or inactivated areas, and thus to go from understanding the *correlates* to the *causes* of neural object representations, is a major goal for the field of object recognition and neurology.

5. Individual cells in inferior temporal cortex can be highly shape-selective and respond selectively, eg, to a hand or a face. They can maintain selectivity across position, size, and even rotation—properties that might explain perceptual constancy.
6. Inferotemporal cortex comprises a yet-unknown number of areas with very different functional specializations. While the functional logic of the overall organization remains unknown, we do know that cells with similar selectivity group into cortical columns and that face cells are organized into larger units called face areas.
7. Face recognition is supported by multiple face areas, each with a unique functional specialization. Face areas are selectively coupled to form a face-processing network, which has emerged as a model system for high-level vision.
8. Inferotemporal cortex is interconnected with perirhinal and parahippocampal cortices for memory formation, with the amygdala for the assignment of emotional valence to objects, and with prefrontal cortex for object categorization and visual working memory. If associative memories are stored as patterns of connections between neurons, what then are the specific contributions of hippocampus and neocortical structures of the medial temporal lobe, and by what cellular mechanisms do they exert their influences? The confluence of molecular-genetic, cellular, neurophysiological, and behavioral approaches promises to solve these and other problems.
9. Objects are perceived as members of a category. This simplifies the selection of appropriate behaviors, which often do not depend on stimulus details. Neurons with categorical selectivity are found in dorsolateral prefrontal cortex, a main projection site of inferior temporal cortex.
10. Object recognition relies on past experience. Perceptual learning can improve the ability to discriminate between complex objects and refine neural selectivity in inferior temporal cortex.
11. Visual information can be held in short-term working memory to be available beyond the duration of a sensory stimulus. Neurons in temporal and prefrontal cortex can exhibit delay-period activity after the disappearance of a stimulus. How these networks establish the ability to keep information online is an open question.
12. High-level visual information processing changes with top-down modulation. The sensory experience of an image in view and the recall of the same stimulus from memory are subjectively similar. Neurons in inferior temporal cortex exhibit similar activity during bottom-up activation and cued recall.

Visual Processing for Attention and Action

The human brain has an amazing ability to direct action to objects in the visual world—a baby reaching for an object, a tennis player hitting a ball, an artist looking at a model. This ability requires that the visual system solve three problems: making a spatially accurate analysis of the visual world, choosing the object of interest from the welter of stimuli in the visual world, and transferring information on the location and details of the object to the motor system.

The Brain Compensates for Eye Movements to Create a Stable Representation of the Visual World

Although the visual system produces vivid representations of our visual world, as described in preceding chapters, a visual image is not like an instantaneous photographic record but is dynamically constructed from information conveyed in several discrete neural pathways from the eyes. When we look at a painting, for example, we explore it with a series of quick eye movements (saccades) that redirect the fovea to different objects of interest in the visual field. The brain must take into account these eye movements in the course of producing an interpretable visual image from the light stimuli in the retina.

As each saccade brings a new object onto the fovea, the image of the entire visual world shifts on the fovea. These shifts occur several times per second, such that after several minutes the record of movement is a jumble (Figure 25–1). With such constant movement, visual images should resemble an amateur video in which the image jerks around because the camera operator is not skilled at holding the camera steady. In fact, however, our vision is so stable that we are ordinarily unaware of the visual effects of saccades. This is so because the brain makes continual adjustments to the images falling on the retina after each saccade.

A simple laboratory experiment, shown in Figure 25–2, illustrates the biological challenge to the brain.

Motor Commands for Saccades Are Copied to the Visual System

The first insight into the brain mechanisms underlying visual stability came from an observation by Hermann von Helmholtz in the 19th century. He saw a patient who could not move his eye horizontally toward his ear because of a paralysis of the lateral rectus muscle. Whenever the patient attempted to look toward his ear, the entire visual world jumped in the opposite direction and then returned to the center of gaze.

Figure 25–1 Eye movements during vision. A subject viewed this painting (*An Unexpected Visitor* by Ilya Repin) for several minutes, making saccades to selected fixation points, primarily to faces. Lines indicate saccades, and spots indicate points of fixation. (Reproduced, with permission, from Yarbus 1967).

Helmholtz postulated that a copy of the motor command for each saccade was fed to the visual system so that the representation of the visual world could be adjusted to compensate for eye movement. This adjustment would lead to a stable image of the visual world. In the 19th century, Helmholtz called such a copy a "sense of effort," and in the 20th century, it was named an efference copy or corollary discharge.

The corollary discharge solves the problem of the double-step saccade. In order for a corollary discharge to affect visual perception across eye movements, motor information has to affect the activity of visual neurons. This is precisely what happens to neurons in the parietal cortex, frontal eye field, prestriate visual cortex, and superior colliculus when a monkey makes a saccade. Each saccade can be considered a vector with two dimensions—direction and amplitude. Although the retinal image is different after each saccade, the brain can use the vector of each saccade to reconstruct the whole visual scene from the sequence of retinal images.

The corollary discharge can be seen at the level of a single cell. Physiological studies in the Rhesus monkey, an animal whose oculomotor and visual systems resemble those of humans, have illuminated the

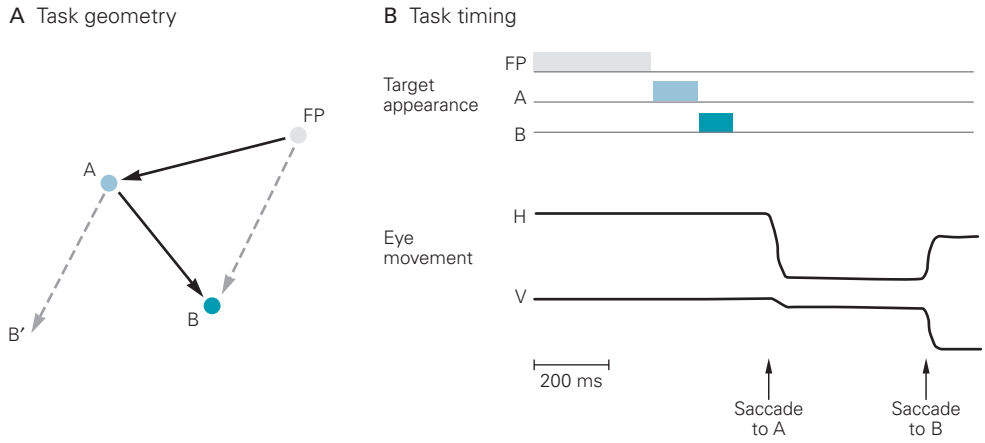

Figure 25–2 The double-step task illustrates how the brain stabilizes images during saccades.

A. A subject starts by looking at a fixation point (**FP**) that disappears, after which two saccade targets **A** and **B** appear and disappear sequentially before the subject can make the saccade. The first saccade (to target A) is simple. The retinal vector (FP→A) and the saccade vectors are the same. After the first saccade, the subject is looking at A. The retinal vector is A→B′, but the monkey must make a saccade whose vector is A→B. The brain must adjust the retinal vector to compensate for the first saccade.

B. Timing. The upper records show when the targets appear (**colored bars**). (Abbreviations: **H**, horizontal; **V**, vertical.)

problem. Every time a monkey makes a saccade, a stimulus currently not in the receptive field of a neuron in the lateral intraparietal area, and therefore incapable of exciting the neuron, will excite the neuron if the impending saccade will bring the stimulus into the receptive field, even before the saccade occurs (Figure 25–3). Thus, a corollary discharge of the impending saccade affects the visual responsiveness of the parietal neuron.

This transient remapping of the receptive field explains how subjects can perform the double-step task. Consider the diagram in Figure 25–2A. The task begins with the monkey directing gaze to the fixation point (FP). After the monkey makes the first saccade, the retinal vector A→B′ is no longer useful for making the A→B saccade. However, the FP→A saccade remaps the activity of the cell describing the vector A→B, so it responds to the target at the retinal location of B, which was not in its receptive field when the monkey was looking at FP. Remapping is found in a number of cortical and subcortical areas, including lateral intraparietal area, frontal eye field, medial intraparietal area, intermediate layers of the superior colliculus, and prestriate areas V4, V3a, and V2. As we shall see, remapping facilitates both visual perception around the time of a saccade and the accuracy of visually guided movement.

The first question this raises is: How does the brain obtain the vector of the saccade that it feeds back to the visual system? We know from decades of research that the motor command for the vector is represented in the superior colliculus on the roof of the midbrain (Chapter 35). Each neuron in the superior colliculus is tuned to saccades of a given vector, such that the neurons collectively provide a map of the vectors of all possible saccades. Inactivation of the superior colliculus affects the monkey's ability to make saccades. Electrical stimulation of the superior colliculus evokes saccades of the vector described by the neurons at the stimulation site. But this provides the vectors that actually drive the eye, not the vectors that inform perception about the vector of the saccade. How does the vector information used to move the eye become available to brain processes that do not move the eye but do require information about how it moved?

Since the vectors for moving the eye have been identified in the superior colliculus, it is reasonable to expect that this also might be the source of a corollary discharge. Indeed, it is. The superior colliculus has both descending pathways for generating the saccades and ascending pathways to the cerebral cortex that could carry the corollary discharge of the impending movement (Figure 25–4). The pathways to the cortex pass through the thalamus, as does all internal and almost all external information reaching the cerebral cortex.

The motor signal in the thalamus is not necessarily a corollary discharge; it could also be a movement command that simply passes through the cerebral cortex. That is not the case, however, because inactivation of this pathway in the thalamus does not alter the amplitude and direction of saccades. It is not driving saccades. It is more likely to be a corollary discharge. After inactivation of the thalamic pathway, monkeys cannot accurately perform the second saccade of the double-step task. In addition, inactivation disrupts the

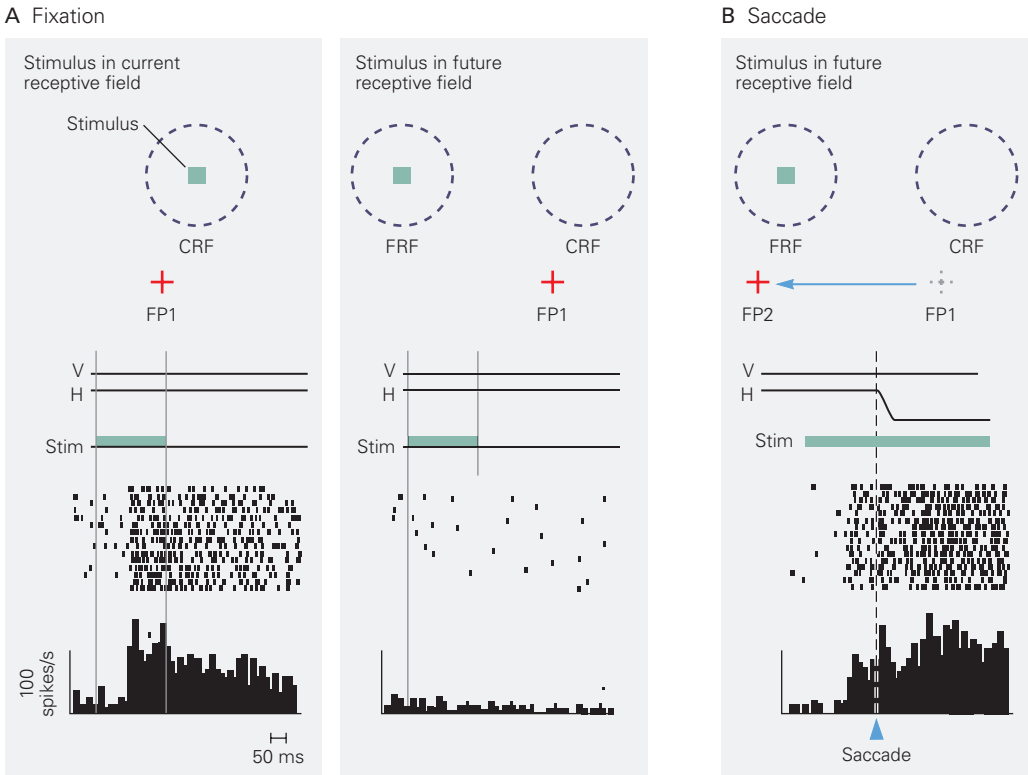

Figure 25–3 Remapping of the receptive field of a visual neuron in the parietal cortex of a monkey in conjunction with saccadic eye movements. (**A** [*left*] and **B** adapted, with permission, from Duhamel, Colby, and Goldberg 1992. **A** [*right*] reproduced with permission, from M.E. Goldberg.)

A. *Left:* The monkey looks at fixation point 1 (**FP1**), and the cell responds to the abrupt onset of a task-irrelevant stimulus in the current receptive field (**CRF**). Successive trials are synchronized on the appearance of the stimulus. (Abbreviations: **H**, horizontal eye position; **V**, vertical eye position.) *Right:* The monkey looks at FP1, and the cell does not respond to a stimulus flashed in the future receptive field (**FRF**).

B. The monkey makes a saccade from FP1 to FP2, which will bring the cell's receptive field onto the stimulus in the FRF. Now the cell fires even before the saccade begins, which means that a corollary discharge of the saccade plan remapped the area of the retina to which the cell responds.

receptive field remapping described earlier (Figure 25–3B). Because disrupting the corollary discharge disrupts both receptive field remapping and the behavioral compensation for eye movements, it is likely that the corollary discharge is essential for solving the problem of spatial accuracy for action.

To determine whether the corollary discharge also provides the information that allows the visual system to perceive the location of objects that appeared before a saccade, the monkey is trained to indicate where it thinks its eyes are directed at the end of the saccade. We can measure where the motor system moved the eye, but what we want to know is the monkey's perception of the change in its eye direction with each saccade. This can be determined using a task developed for humans by Heiner Deubel and his colleagues and adapted for monkeys. In this task, the monkey looks at a fixation point and then makes a saccade to a target (Figure 25–5A). During the saccade, the target temporarily disappears; when it reappears, it has been displaced to a location left or right of the original target. After the trial, the monkey moves a bar to the right or left to indicate the direction of the displacement (Figure 25–5A).

Over a series of trials, the monkey's responses are plotted to generate a psychometric curve (Figure 25–5B). This curve show the actual intrasaccadic target displacement (horizontal axis) in the same (forward) or opposite (backward) direction as the initial saccade, and how frequently the monkey reports that it was moved forward (vertical axis). The monkey responded that the target had moved forward 100% of the time when the target was 3° to the right. When the target moved 3° to the left, the monkey responded that it had never moved forward. The point on the psychometric curve where the monkey reported forward and backward displacements with equal frequency (the 50% horizontal line) was taken as the perceptual null point.

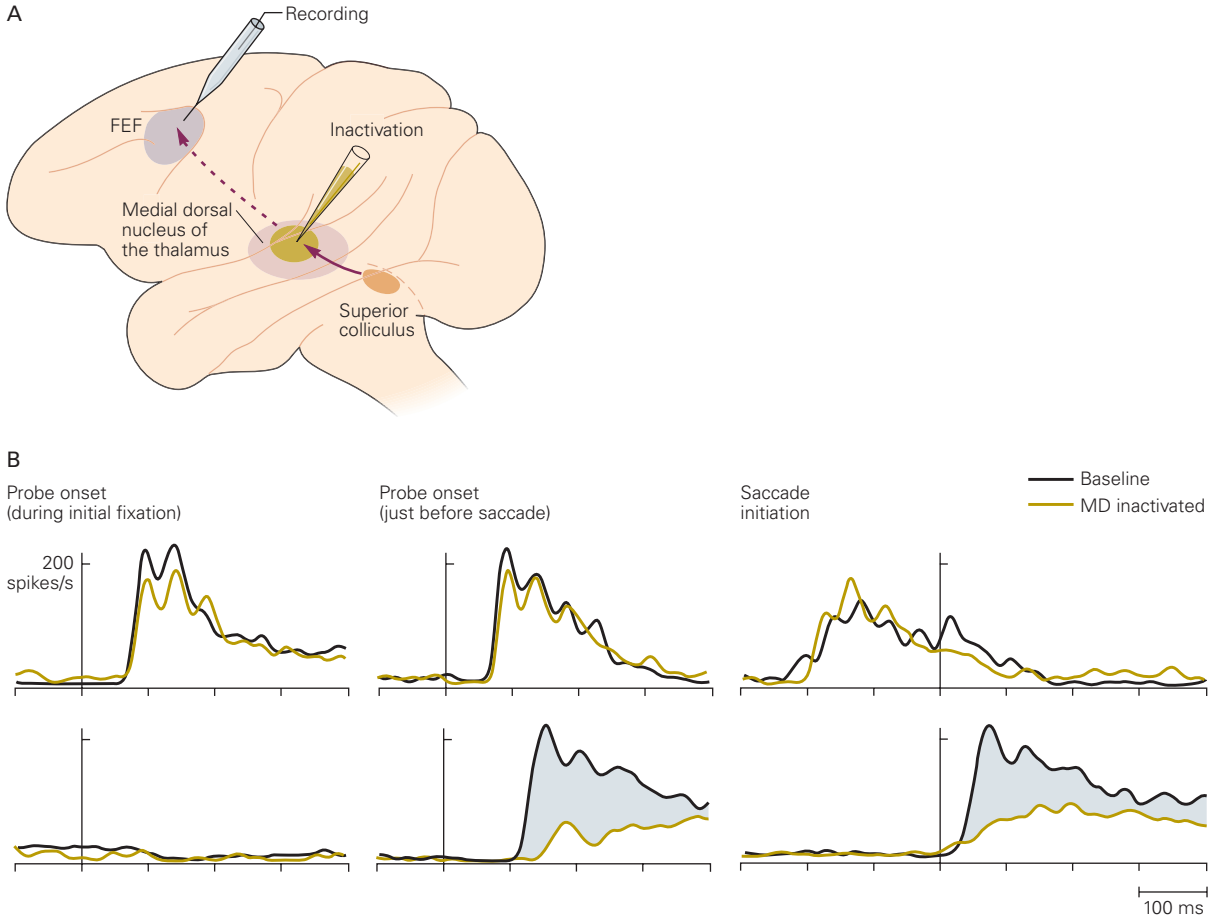

Figure 25–4 A corollary discharge from the motor program for saccades directs a shift in location of the receptive field of frontal eye field neurons prior to the saccade. (Adapted, with permission, from Sommer and Wurtz 2008. Copyright © 2008 by Annual Reviews.)

A. One possible pathway for the corollary discharge originates in saccade-generating neurons in the superior colliculus, passes through the medial dorsal nucleus of the thalamus, and terminates in the frontal eye field (**FEF**) in the frontal cortex.

B. When the medial dorsal nucleus (**MD**) is inactivated, the response of a frontal eye field neuron to a stimulus probe in the cell's current receptive field is unaffected (**upper records**), whereas the response to a stimulus in a future (post-saccade) receptive field is severely impaired (**lower records**). This result demonstrates that a corollary discharge from the saccade motor program directs the shift in the neuron's receptive field properties.

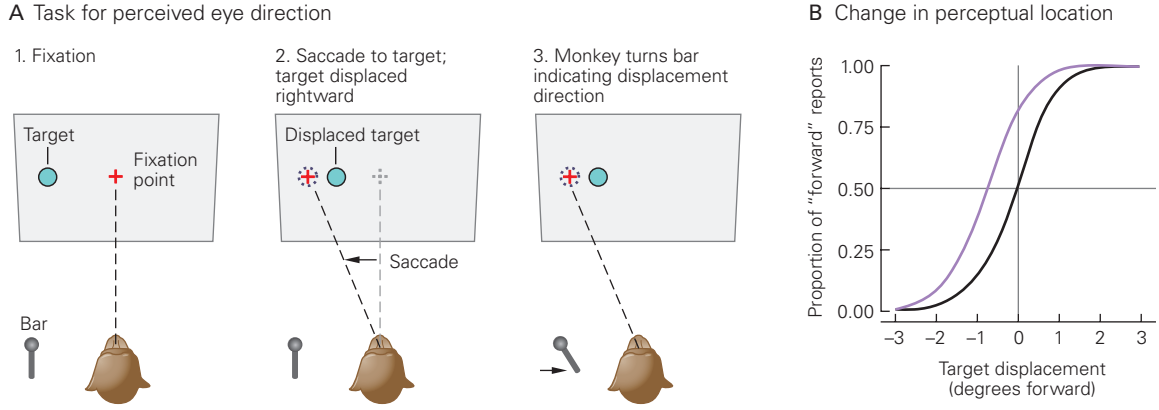

Figure 25–5 Perceived saccade direction changes with disruption of corollary discharge.

A. At the start of each trial, the monkey fixates a target on a screen (**1**). When the fixation point is turned off, the monkey makes a saccade to the target; during the saccade, the target is displaced randomly (up to 3°) either to the left or to the right (**2**). After the saccade to the original target, the monkey receives a reward for manually moving a bar in the direction of the target displacement (**3**).

B. Psychometric curves before (**black**) and after (**purple**) inactivation of the medial dorsal nucleus of the thalamus, which contains the relay neurons for the corollary discharge in its pathway between the superior colliculus and the frontal cortex. The curve shows the proportion of forward (in the direction of the saccade) judgments (y-axis) for each target displacement (x-axis). The post-saccadic target location at which the monkey perceived no displacement is defined as the perceptual null location. (Adapted, with permission, from Cavanaugh et al. 2016.)

We take this point to be the monkey's perception of the original target location. If the target were not perceived to move, it must be in the same location as before the saccade; in a normal monkey, that point is close to zero (Figure 25–5B).

We now have a corollary discharge that can provide the vector for each saccade and a task for a monkey that allows us to determine where it perceives the target to be at the end of the saccade. If the corollary discharge contributes to the monkey's perception, then inactivating the corollary discharge should change the animal's perception of target location. It does. The purple curve in Figure 25–5B represents the perceived location after corollary discharge inactivation; the curve shifts to the left after inactivation of the medial dorsal nucleus of the thalamus. The conclusion is that the corollary discharge does provide the vector of the saccade, which is necessary for the monkey to perceive that the target had moved. With each saccade, corollary discharge information provides perceptual information for determining the amplitude and direction of the current saccade, and it does so with machine-like precision several times per second.

The corollary discharge provides the vector information available before the saccade is made, but it is not the only source of information. Two other types of information must be evaluated after the saccade has taken place: visual cues and eye muscle proprioception. Visual cues are unlikely to be a factor in the perceptual experiment described (Figure 25–5) because the experiment was done in total darkness except for light scattered from the very dim fixation point and saccade target. In the light, however, could visual cues be a factor? In fact, repeating the experiment in the light did not improve the monkey's judgment and frequently made it worse.

Oculomotor proprioception is unlikely to provide the vector information at the end of the saccade because, on average, the metrics of the saccades before and during inactivation do not change, so there is little reason to expect that the muscle proprioception will have changed. In addition, while the corollary discharge begins at least 100 ms before the saccade, neuronal activity from oculomotor proprioception reaches the lateral intraparietal area about 150 ms after the saccade. As we will see in the next section, the role of proprioception in perception might be to provide information long after the saccade ends.

Finally, there is a second potential disruption of vision produced by saccades: a blur as the saccade sweeps the visual scene across the retina. The blur is not seen, however, because neuronal activity in a number of visual areas is suppressed around the time of every saccade. This so-called saccadic suppression was first seen in the superior colliculus and has subsequently been seen in the thalamus and areas of visual cortex beyond primary visual cortex.

A corollary discharge contributes to this neuronal activity suppression because the suppression occurs even in total darkness (no vision) and even if eye movement is blocked (no proprioception). Suppression can also be produced by visual masking, which occurs when one stimulus reduces the perception of a following or preceding stimulus. If a saccade starts in total darkness, and an object is then flashed and extinguished before the saccade ends, a blur can be seen during the saccade. If a mask is flashed after the saccade, the blur is suppressed. A correlate of such a masking effect is clearly seen in neurons in primary visual cortex. The suppression resulting from a corollary discharge is relatively weak but is present with all saccades; that from visual masking is much stronger but is present only in the light.

Oculomotor Proprioception Can Contribute to Spatially Accurate Perception and Behavior

Charles Sherrington suggested that the way the brain compensates for a moving eye is to measure directly where the eyes are in the orbit and adjust the visual signal for changes in position. Richard Andersen and Vernon Mountcastle discovered that the responses of parietal visual neurons with retinotopic receptive fields are modulated by the position of the eye in the orbit in a linear fashion called the *gain field* (Figure 25–6). From this relationship, the position of an object in head-centered (craniotopic) coordinates can easily be calculated.

Where does the eye position signal that creates the gain fields come from? It could come from a corollary discharge of eye position, or it could come from a proprioceptive mechanism. Human eye muscles have two structures that could contribute to oculomotor proprioception: muscle spindles and myotendinous cylinders, or palisade endings, an eye-specific structure. Area 3a, the region of somatosensory cortex to which skeletal muscle spindles project, has a representation of the position of the eye, which arises from proprioceptors in the contralateral orbit (Figure 25–7).

However, the proprioceptive measurement of eye position lags changes in eye position by 60 ms, and for 150 ms after a saccade, the gain fields modulate the visual response as if the monkey were still looking at the presaccadic target, long after the corollary discharge has remapped the visual response. Therefore, the eye position signal creating the gain fields probably arises from a proprioceptive mechanism. The possibility

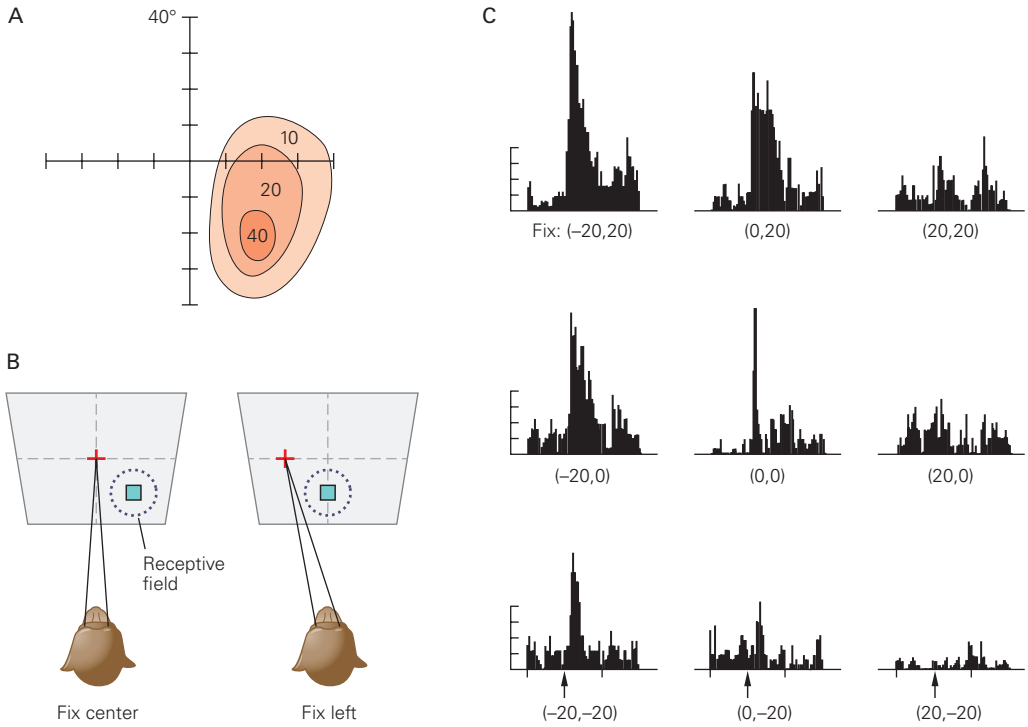

Figure 25–6 The position of the eye in the orbit affects the responses of parietal visual neurons with retinotopic receptive fields.

A. Receptive field relative to the fovea. Contour plot indicates spike rates for different spatial locations. Numbers are spikes per second for each contour at the maximum position.

B. The receptive field moves in space with the eye. On the left the monkey is fixating the center of the screen. On the right the same monkey is fixating 20° to the left of center. For the recordings in C, the stimulus (**blue square**) is always presented in the center of the receptive field.

C. Responses to a stimulus at the optimum location in the receptive field change as a function of the position of the eye in the orbit, from a maximum when the monkey fixates a point at –20°,20° to a minimum when the monkey fixates a point at 20°,–20°. **Arrows** indicate onset of stimulus flash. Trial duration, 1.5 sec; ordinate, 25 spikes/division. (Adapted, with permission, from Andersen, Essick, and Siegel 1985. Copyright © 1985 AAAS.)

exists that the brain calculates the spatial location of an object that appeared before an eye movement using two mechanisms: a corollary discharge that is rapid and a proprioceptive signal that is slow but can be more accurate than the corollary discharge. The proprioceptive signal can also be used to calibrate the corollary discharge.

Visual Scrutiny Is Driven by Attention and Arousal Circuits

In the 19th century, William James described attention as "the taking possession by the mind in clear and vivid form, of one out of what seem several simultaneously possible objects or trains of thought. It implies withdrawal from some things in order to deal effectively with others." James went on to describe two different kinds of attention: "It is either passive, reflex, non-voluntary, effortless or active and voluntary. In passive immediate sensorial attention the stimulus is a sense-impression, either very intense, voluminous, or sudden … big things, bright things, moving things … blood."

Your attention to this page as you read it is an example of voluntary attention. If a bright light suddenly flashed, your attention would probably be pulled away involuntarily from the page. Large changes in the visual scene that occur outside the focus of attention are often missed until the subject directs attention to them, a phenomenon referred to as change blindness (Figure 25–8).

Voluntary attention is closely linked to saccadic eye movements because the fovea has a much denser array of cones than the peripheral retina (Chapter 17) and moving the fovea to an attended object permits a finer-grain analysis than is possible with peripheral vision. Attention that selects a point in space, whether or not it is accompanied by a saccade, is called spatial attention. Searching for a specific kind of object, for

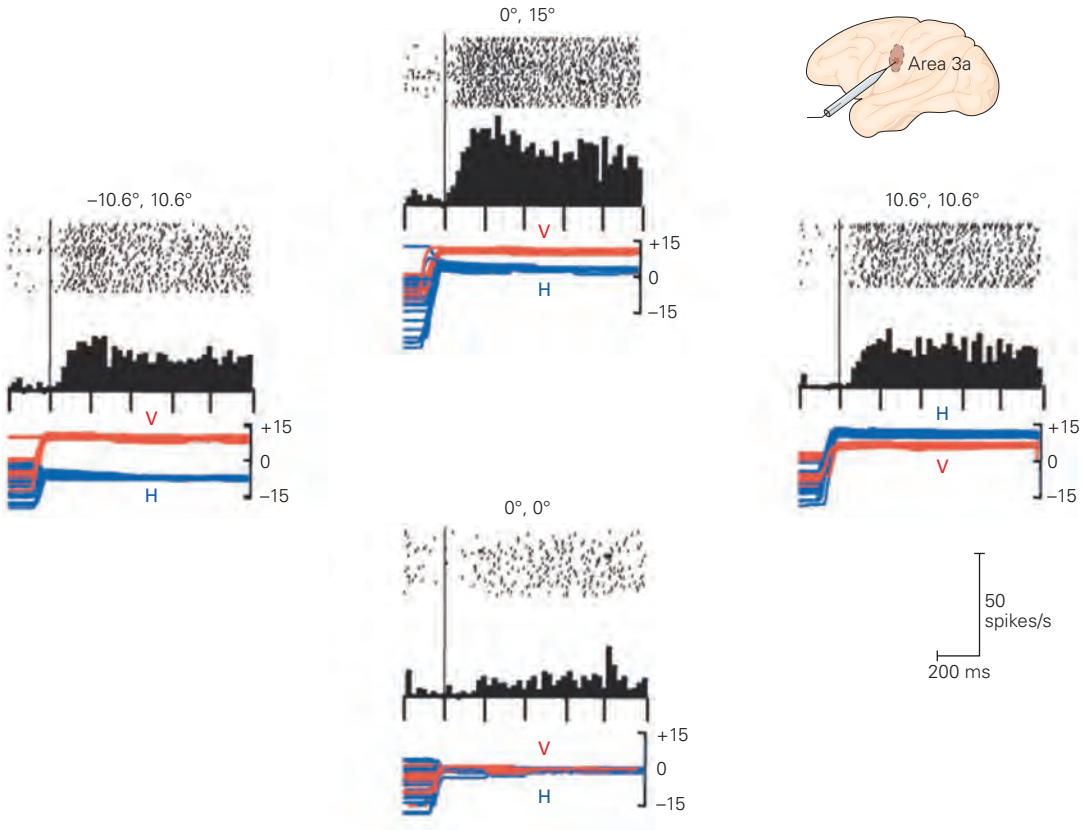

Figure 25–7 Eye position neuron in somatosensory cortex area 3a. Each panel shows horizontal (**H**) and vertical (**V**) eye position and the activity of the neuron after the monkey made a saccade to the eye position indicated above each raster. The neuron responds much more briskly when the eye is at 0°,15° than when it is at 0°,0°. (Reproduced, with permission, from Wang et al. 2007.)

example a red O among red and green Qs, involves a second kind of attention, feature attention: In your search, you ignore the green letters and attend only to the red ones.

Attention, both voluntary and involuntary, shortens reaction time and makes visual perception more sensitive. This increased sensitivity includes the abilities to detect objects at a lower contrast and ignore distracters close to an attended object. The abrupt appearance of a behaviorally irrelevant cue, such as a light flash, reduces the reaction time to a test stimulus presented 300 ms later in the same place. Conversely, when the cue appears away from the test stimulus, the reaction time is increased. The light flash draws involuntary attention to its location, thus accelerating the visual response to the test stimulus. Similarly, when a subject plans a saccade to a particular part of the visual field, the contrast threshold at which any object there can be detected is improved 50% by a cue.

Clinical studies have long implicated the parietal lobe in visual attention. Patients with lesions of the right parietal lobe have normal visual fields. When their visual perception is studied with a single stimulus in an uncomplicated visual environment, their responses are normal. However, when presented with a more complicated visual environment, with objects in the left and right visual hemifields, these patients tend to report less of what lies in the left hemifield (contralateral to their lesion) than in the right hemifield (ipsilateral to their lesion). This deficit, known as *neglect* (Chapter 59), arises because attention is focused on the visual hemifield ipsilateral to the lesion. Even when patients are presented with only two stimuli, one in each hemifield, they report seeing only the stimulus in the ipsilateral hemifield. When attention is focused on one stimulus in the affected hemifield and a second stimulus is presented in the unaffected hemifield, patients do not have the ability to shift attention to the new stimulus, even though the sensory pathway from the eye to the striate and prestriate cortex is intact.

This neglect of the contralateral visual hemifield extends to the neglect of the contralateral half of

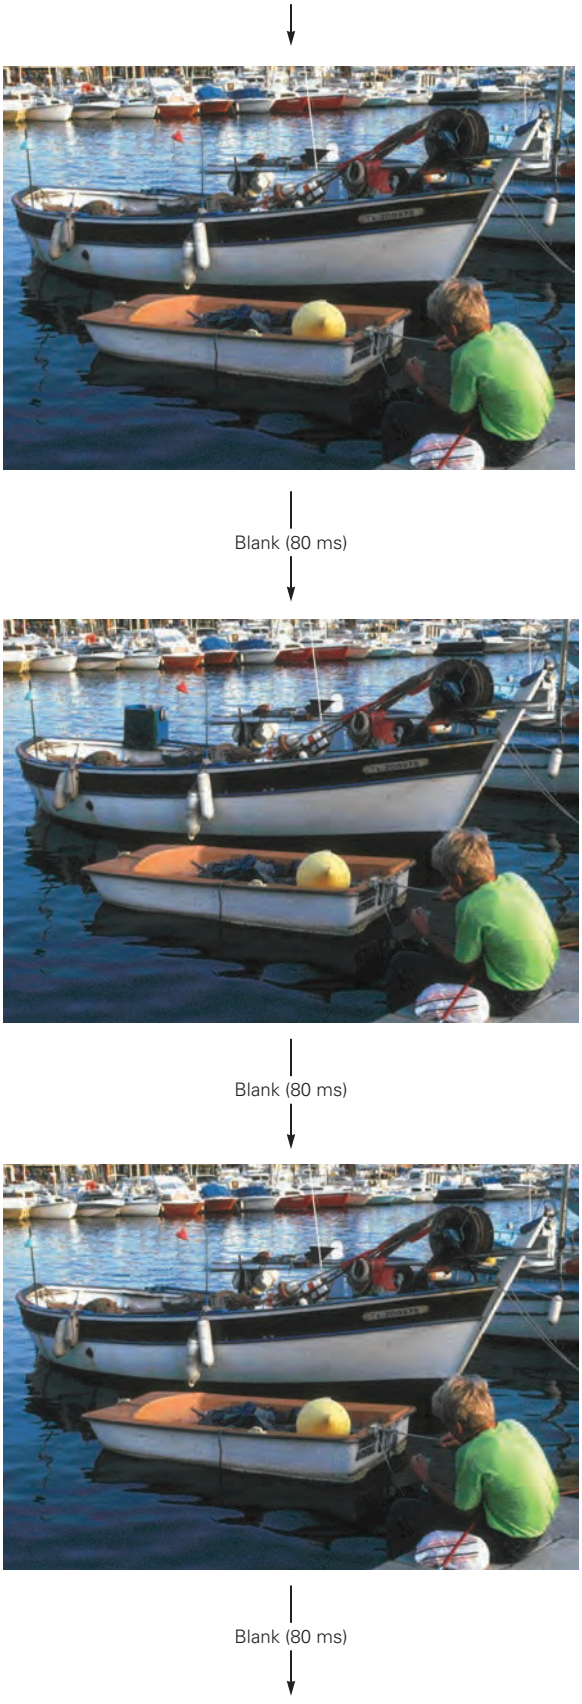

Figure 25–8 Change blindness. In a test for change blindness, one picture is presented followed by a blank screen for 80 ms, followed by the second picture, another blank screen, and a repeat of the cycle (*left*). The subject is asked to report what changed in the scene. Although there is a substantial difference between the two pictures, it takes multiple repetitions for most observers to detect the difference. (Reproduced, with permission, from Ronald Rensink.)

individual objects (Figure 25–9). Patients with right parietal lobe deficits often have difficulty reproducing drawings. When asked to draw a clock, for example, they may force all of the numbers into the right side of the clock's face, or when asked to bisect a line, they may place the midline well to the right of the line's actual center.

The process of attentional selection is evident at the level of single parietal neurons in the monkey. The responses of neurons in the lateral intraparietal area to a visual stimulus depend not only on the physical properties of the stimulus but also on its importance

Figure 25–9 Drawing of a candlestick by a patient with a lesion of the right parietal lobe. The patient neglects the left side of the candlestick, drawing only its right half. (Reproduced, with permission, from Halligan and Marshall 2001. Copyright © 2001 Academic Press.)

to the monkey. Thus, the responses to a behaviorally irrelevant stimulus are much smaller than for any event that evokes attention, such as the abrupt onset of a visual stimulus in the receptive field or the planning of a saccade to the receptive field of the neuron.

Although neurons in the lateral intraparietal area collectively represent the entire visual hemifield, the neurons active at any one moment represent only the important objects in the hemifield, a priority map of the visual field. The lateral intraparietal area acts as a summing junction for a number of different signals: saccade planning, abrupt stimulus onset, and the cognitive aspects of a searched-for feature.

The absolute value of the neuronal response evoked by an object does not by itself determine whether that animal is attending to that object. When a monkey plans a saccade to a stimulus in the visual field, attention is on the goal of the saccade, and the activity evoked by the saccade plan lies at the peak of the priority map. However, if a bright light appears elsewhere in the visual field, attention is involuntarily drawn to the bright light, which evokes more neuronal activity than does the saccade plan. Thus, the locus of attention can be identified only by examining the entire priority map and choosing its peak; it cannot be identified by monitoring activity at any one point alone (Box 25–1).

Box 25–1 The Priority Map in Parietal Cortex

Neurons in the lateral intraparietal area of the monkey represent only those objects of potential importance to the monkey, a priority map of the visual field. This selectivity for objects of behavioral importance can be demonstrated by recording from neurons in a monkey while the animal makes eye movements across a stable array of objects.

Stable objects in the visual world are rarely the objects of attention. In the lateral intraparietal area, as in most other visual centers of the brain, neuronal receptive fields are retinotopic; that is, they are defined relative to the center of gaze. As a monkey scans the visual field, fixed objects enter and leave the receptive fields of neurons with every eye movement without disrupting the monkey's attention (Figure 25–10).

The abrupt appearance of a visual stimulus involuntarily evokes attention. When a task-irrelevant light flashes in the receptive field of a lateral intraparietal

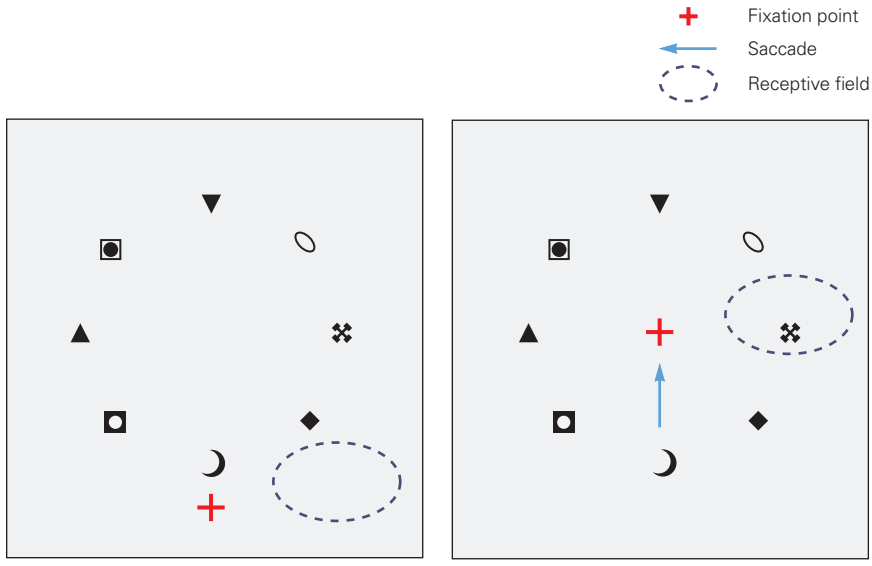

Figure 25–10 Exploring a stable array of objects. The monkey views a screen with a number of objects that remain in place throughout the experiment. The monkey's gaze can be positioned so that none of the objects are included in the receptive field of a neuron (*left*), or the monkey can make a saccade that brings one of the objects into the receptive field (*right*). (*continued*)

The Parietal Cortex Provides Visual Information to the Motor System

Vision interacts with the supplementary and premotor cortices to prepare the motor system for action. For example, when you pick up a pencil, your fingers are separated from your thumb by the width of the pencil; when you pick up a drink, your fingers are separated from your thumb by the width of the glass. The visual system helps to adjust the grip width before your hand arrives at the object. Similarly, when you insert a letter into a mail slot, your hand is aligned to place the letter in the slot. If the slot is tilted, your hand tilts to match.

Patients with lesions of the parietal cortex cannot adjust their grip width or wrist angle using visual information alone, even though they can verbally describe the size of the object or the orientation of the slot. Conversely, patients with intact parietal lobes and deficits in the ventral stream cannot describe the size of an object or its orientation but can adjust their grip width and orient their hands as well as normal subjects can. Neurons in parietal cortex are a critical source of information needed to manipulate or move objects.

Box 25–1 The Priority Map in Parietal Cortex (continued)

neuron, that cell responds briskly (Figure 25–11A). In contrast, a stable, task-irrelevant stimulus evokes little response when eye movement brings it into the neuron's receptive field (Figure 25–11B).

It is possible that the saccade that brings the stable object into the receptive field suppresses the visual response. This is not the case. A second experiment uses a similar array, except there is no stimulus at the location to which the saccade had brought the receptive field in the stable array experiment. The monkey fixates so that no member of the array is in the receptive field, and then the task-irrelevant stimulus suddenly appears at the post-saccade location of the receptive field. Now the monkey makes a saccade to the center of the array, bringing the recently appeared stimulus into the receptive field, and the cell fires intensely (Figure 25–11C). When the monkey makes the saccade, the two arrays are identical. However, the stable stimulus is presumably unattended,

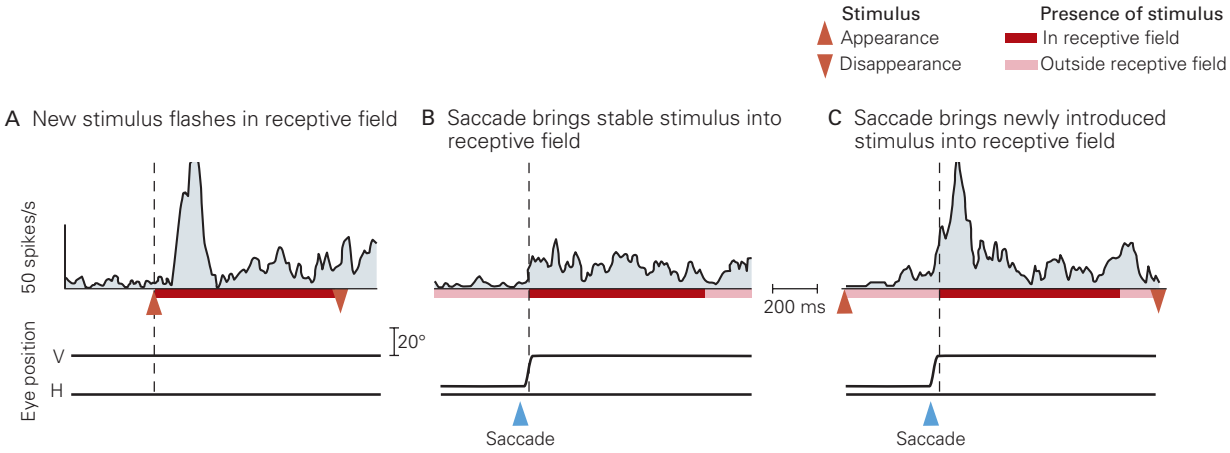

Figure 25–11 A neuron in the lateral intraparietal area fires only in response to salient stimuli. In each panel, neuronal activity and eye positions are plotted across time.

A. A stimulus flashes in the receptive field while the monkey fixates.

B. The monkey makes a saccade that brings a stable, task-irrelevant stimulus into the receptive field.

C. The monkey makes a saccade that brings the location of the recent light flash into the receptive field.

The neural operations behind visually guided movements involve identifying targets, specifying their qualities, and ultimately generating a motor program to accomplish the movement. Neurons in the parietal cortex provide the visual information necessary for independent movement of the fingers.

The representation of space in the parietal cortex is not organized into a single map like the retinotopic map in primary visual cortex. Instead, it is divided into at least four areas (LIP, MIP, VIP, AIP) that analyze the visual world in ways appropriate for individual motor systems. These four areas project visual information to the areas of premotor and frontal cortex that control individual voluntary movements (Figure 25–13).

Neurons in the medial intraparietal area describe the targets for reaching movements and project to the premotor area that controls reaching movements. The anterior intraparietal cortex has neurons that signal the size, depth, and orientation of objects that can be grasped. Neurons in this area respond to stimuli that could be the targets for a grasping movement, and these neurons are also active when the animal makes the movement (Figure 25–14). Neurons in the lateral

whereas the recently flashed stimulus evokes attention and a much larger response. Stable objects can evoke enhanced responses when they become relevant to the animal's current behavior.

A stable object can also be made behaviorally important. In that case, the neurons increase their firing rate when the monkey has to attend to the stable object brought into the receptive field by the saccade (Figure 25–12).

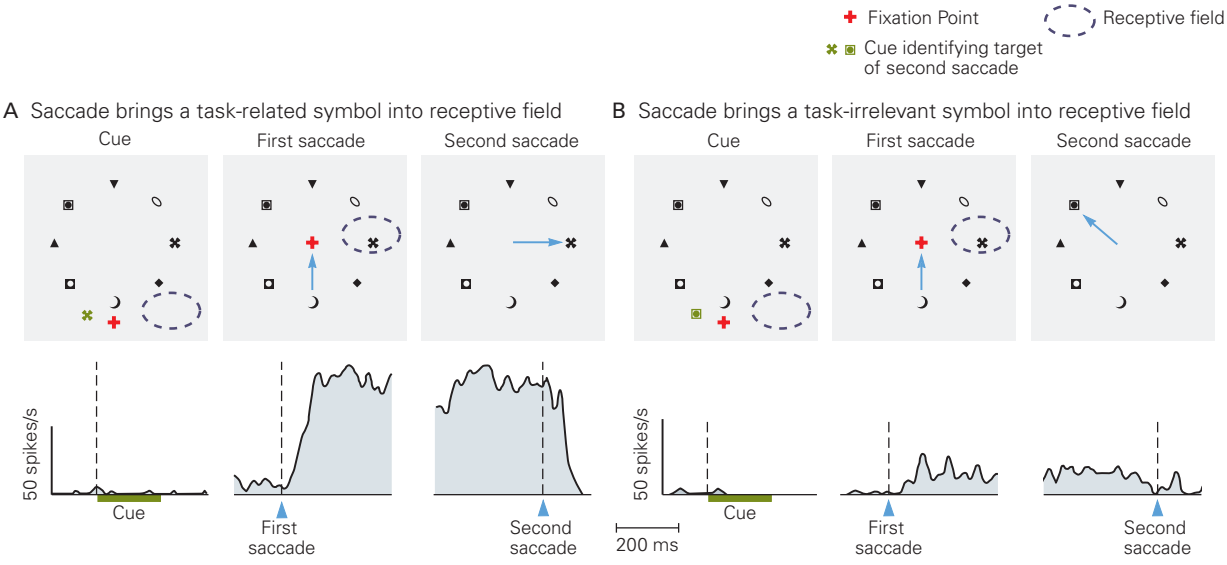

Figure 25–12 A neuron in the lateral intraparietal area fires before a saccade to a significant stable object. On each trial, one object in a stable array becomes significant to the monkey because the monkey must make a saccade to it. The monkey fixates a point outside the array, and a cue that matches an object in the array appears outside the neuron's receptive field. The monkey must then make a saccade to the center of the array and a second saccade to the object that matches the cue. Two experiments are shown (in parts A and B). The *left* panel shows the neuron's response to the appearance of the cue outside the receptive field, the *center* panel shows the response after the first saccade brings the cued object into the receptive field, and the *right* panel shows the response just before the second saccade to the cued object. The cues are shown here in **green** for clarity but were black in the experiment. The visual scene at the time of the saccade is identical in both experiments.

A. The monkey is trained to make the second saccade to the cued object; the cell fires intensely when the first saccade brings the object into the receptive field.

B. The monkey is trained to make the second saccade to an object outside the receptive field; the cell fires much less when the saccade brings the task-irrelevant stimulus into the receptive field.

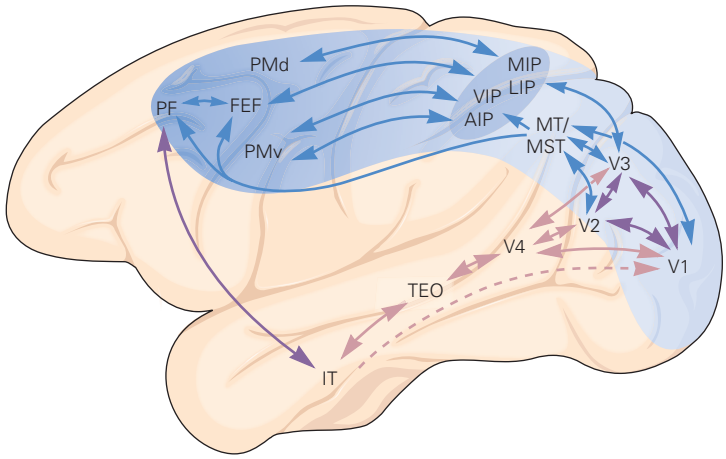

Figure 25–13 **Pathways involved in visual processing for action.** The dorsal visual pathway (**blue**) extends to the posterior parietal cortex and then to the frontal cortex. The ventral visual pathway (**pink**) is considered in Chapter 24. There are bidirectional projections from the inferior temporal cortex to the prefrontal cortex. (Abbreviations: **AIP**, anterior intraparietal cortex; **FEF**, frontal eye field; **IT**, inferior temporal cortex; **LIP**, lateral intraparietal cortex; **MIP**, medial intraparietal cortex; **MST**, medial superior temporal cortex; **MT**, middle temporal cortex; **PF**, prefrontal cortex; **PMd**, **PMv**, dorsal and ventral premotor cortices; **TEO**, occipitotemporal cortex; **VIP**, ventral intraparietal cortex; **V1–V4**, areas of visual cortex.)

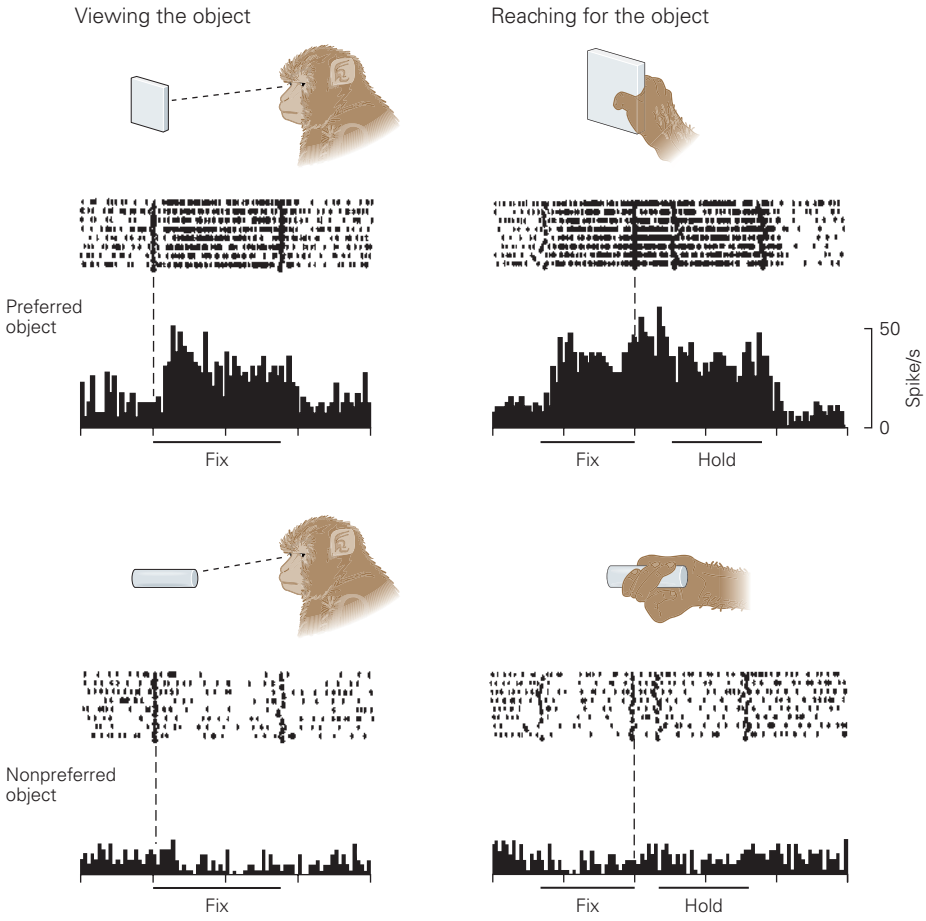

Figure 25–14 **Neurons in the anterior intraparietal cortex respond selectively to specific shapes.** The neuron shown here is selective for a rectangle, whether viewing the object or reaching for it. The neuron is not responsive to the cylinder in either case. (Reproduced, with permission, from Murata et al. 2000.)

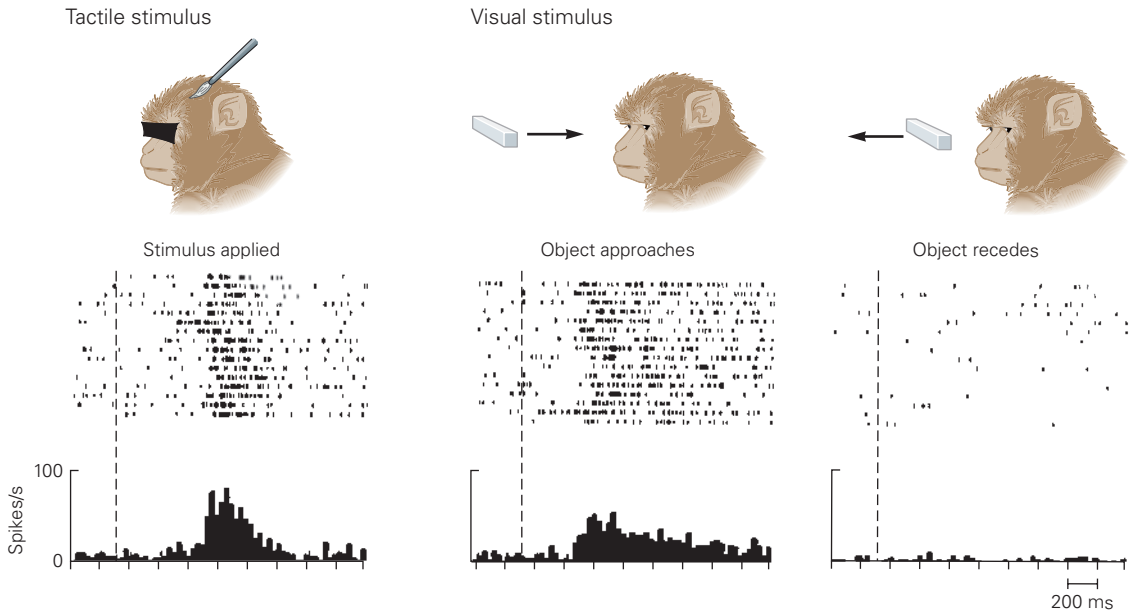

Figure 25–15 Bimodal neurons in the ventral intraparietal cortex of a monkey respond to both visual and tactile stimuli. The neuron shown here responds to tactile stimulation of the monkey's head or to a visual stimulus coming toward the head, but not to the same stimulus moving away from the head. (Reproduced, with permission, from Duhamel, Colby, and Goldberg 1998.)

intraparietal area specify the targets for saccades, and project to the frontal eye field.

Because a monkey cannot see its mouth, the ventral intraparietal area has bimodal neurons that respond to tactile stimuli on the face (Figure 25–15) and to objects in the visual world that are approaching the tactile receptive field, allowing the brain to estimate that an object is near the mouth. The ventral intraparietal area projects to the face area of premotor cortex.

Highlights

1. The image of the world enters the brain via the eye, which is constantly moving in the head. The visual system must compensate for changes in eye position to calculate spatial locations from retinal locations. Helmholtz postulated that the brain solves this problem by feeding back the motor signal that drives the eye to the visual system, to compensate for the effect of the eye movement. This motor feedback to the visual system is called corollary discharge.
2. Neurons in the lateral intraparietal area, which provides visual information to the oculomotor system, show evidence of this corollary discharge. Neurons that ordinarily do not respond to a particular stimulus in space will respond to it if an impending saccade will bring that stimulus into its receptive field.
3. This receptive field remapping depends on a pathway that goes from the intermediate layers of the superior colliculus to the medial dorsal nucleus of the thalamus to the frontal eye field. Medial dorsal nucleus inactivation impairs monkeys' ability to identify where their eyes land after a saccade, suggesting the corollary discharge has a perceptual as well as a motor role.
4. Sherrington postulated that the brain uses eye position to calculate the spatial location of objects from the position of their images on the retina. There is a representation of eye position in somatosensory cortex. Eye position modulates the visual responses of parietal neurons, and target position in space is simple to calculate from this modulation.
5. An unanswered question is how the brain chooses between the eye position and corollary discharge mechanisms to determine spatial position. Because corollary discharge precedes the change in eye position and proprioception follows it, could the brain use both positions at different times?
6. Attention is the ability of the brain to select objects in the world for further analysis. Without attention, spatial perception is severely limited. For

example, humans have great difficulty noticing a change in the visual world unless their attention is drawn to the spatial location of a change.

7. The activity of neurons in the parietal cortex predicts a monkey's locus of spatial attention as measured by their perceptual thresholds. The parietal cortex sums a number of different signals—motor, visual, cognitive—to create a priority map of the visual field. The motor system uses this map to choose targets for movement. The visual system uses the same map to find the locus of visual attention.
8. Lesions in the parietal cortex cause a neglect of the contralateral visual world.
9. Visual information provided by the parietal cortex enables the motor system to adjust hand grip to match the size of the object to which it reaches before the hand actually lands on the target. By contrast, patients with perceptual deficits caused by lesions in inferior temporal cortex adjust their grip perfectly well even though they cannot describe the nature or size of the object to which they reach perfectly.
10. There are at least four different visual maps in the intraparietal sulcus, each of which corresponds to a particular motor workspace.
11. Neurons in the anterior intraparietal area respond to targets for grasping, respond even when monkeys make grasping movements in total darkness, and project to the grasp region of premotor cortex.
12. Neurons in the ventral intraparietal area respond to objects coming toward the mouth, have tactile receptive fields on the face, and project to the mouth area of premotor cortex.
13. Neurons in the medial intraparietal area have a representation of arm position and respond to targets for reaching.
14. Neurons in the lateral intraparietal area respond to targets for eye movements and objects of visual attention, discharge before eye movements, and have a representation of eye position. Activity of these neurons is modulated by the position of the eyes in the orbit.
15. Neurons in the face region of area 3a in the somatosensory cortex have a representation of the position of the eye in the orbit that arises from the contralateral eye.

Auditory Processing by the Cochlea

Human experience is enriched by the ability to distinguish a remarkable range of sounds—from the intimacy of a whisper to the warmth of a conversation, from the complexity of a symphony to the roar of a stadium. Hearing begins when the sensory cells of the cochlea, the receptor organ of the inner ear, transduce sound energy into electrical signals and forward them to the brain. Our ability to recognize small differences in sounds stems from the cochlea's capacity to distinguish among frequency components, their amplitudes, and their relative timing.

Hearing depends on the remarkable properties of hair cells, the cellular microphones of the inner ear. Hair cells transduce mechanical vibrations elicited by sounds into electrical signals, which are then relayed to the brain for interpretation. The hair cells can measure motions of atomic dimensions and transduce stimuli ranging from static inputs to those at frequencies of tens of kilohertz. Remarkably, hair cells can also serve as mechanical amplifiers that augment auditory sensitivity. Each of the paired cochleae contains approximately 16,000 of these cells. Deterioration of hair cells and their innervation accounts for most of the hearing loss that afflicts about 10% of the population in industrialized countries.

The Ear Has Three Functional Parts

Sound consists of alternating compressions and rarefactions propagated by an elastic medium, the air, at a speed of approximately 340 m/s. This wave of pressure changes carries mechanical energy that stems from the work produced on air by our vocal apparatus or some other sound source. The mechanical energy is captured and transmitted to the receptor organ, where it is transduced into electrical signals suitable for neural analysis. These three tasks are associated with the external ear, the middle ear, and the cochlea of the inner ear, respectively (Figure 26–1).

The most obvious component of the human external ear is the auricle, a prominent fold of cartilage-supported skin. The auricle acts as a reflector to capture sound efficiently and focus it into the external auditory meatus, or ear canal. The ear canal ends at the tympanum, or eardrum, a diaphragm approximately 9 mm in diameter and 50 µm in thickness.

The external ear is not uniformly effective at capturing sound from all directions; the auricle's corrugated surface collects sounds best when they originate at different, but specific, positions with respect to the head. Our capacity to localize sounds in space, especially along the vertical axis, depends critically on these sound-gathering properties. Each auricle has a unique topography; its effect on sound reflections at different frequencies is learned by the brain early in life.

The middle ear is an air-filled pouch connected to the pharynx by the Eustachian tube. Airborne sound traverses the middle ear as vibrations of the auditory ossicles, three tiny bones that are linked together: the malleus (hammer), incus (anvil), and stapes (stirrup; Figure 26–1). A long extension of the malleus is attached to the tympanic membrane; its other extreme makes a ligamentous connection to the incus, which is similarly connected to the stapes. The flattened base of the stapes, the footplate, is seated in an opening—the oval window—in the bony covering of the cochlea. The auditory ossicles are relics of evolution. The stapes was originally a component of the gill support of ancient fish; the malleus and incus were components of the primary jaw joint in reptilian ancestors.

The inner ear includes the auditory sensory organ, the cochlea (Greek *cochlos,* snail), a coiled structure of progressively diminishing diameter wound around a conical bony core (Figure 26–1). In humans, the cochlea is approximately 9 mm across, the size of a chickpea, and is embedded within the temporal bone. The interior of the cochlea consists of three parallel liquid-filled compartments termed *scalae*. In a cross section of the cochlea at any position along its spiral course, the top compartment is the *scala vestibuli* (Figure 26–2). At the broad, basal end of this chamber is the oval window, the opening that is sealed by the footplate of the stapes. The bottom compartment is the *scala tympani;* it too has a basal aperture, the round window, which is closed by

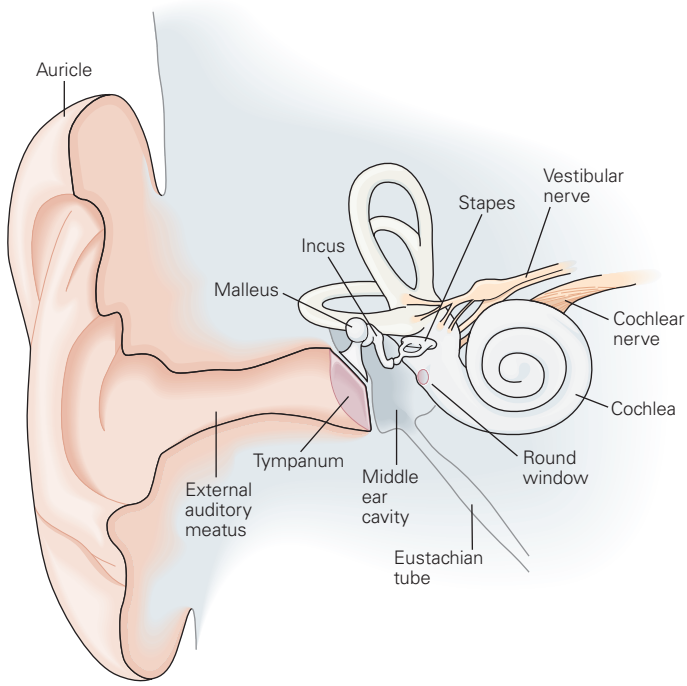

Figure 26–1 The structure of the human ear. The external ear, especially the prominent auricle, focuses sound into the external auditory meatus. Alternating increases and decreases in air pressure vibrate the tympanum. These vibrations are conveyed across the air-filled middle ear by three tiny, linked bones: the malleus, the incus, and the stapes. Vibration of the stapes stimulates the cochlea, the hearing organ of the inner ear.

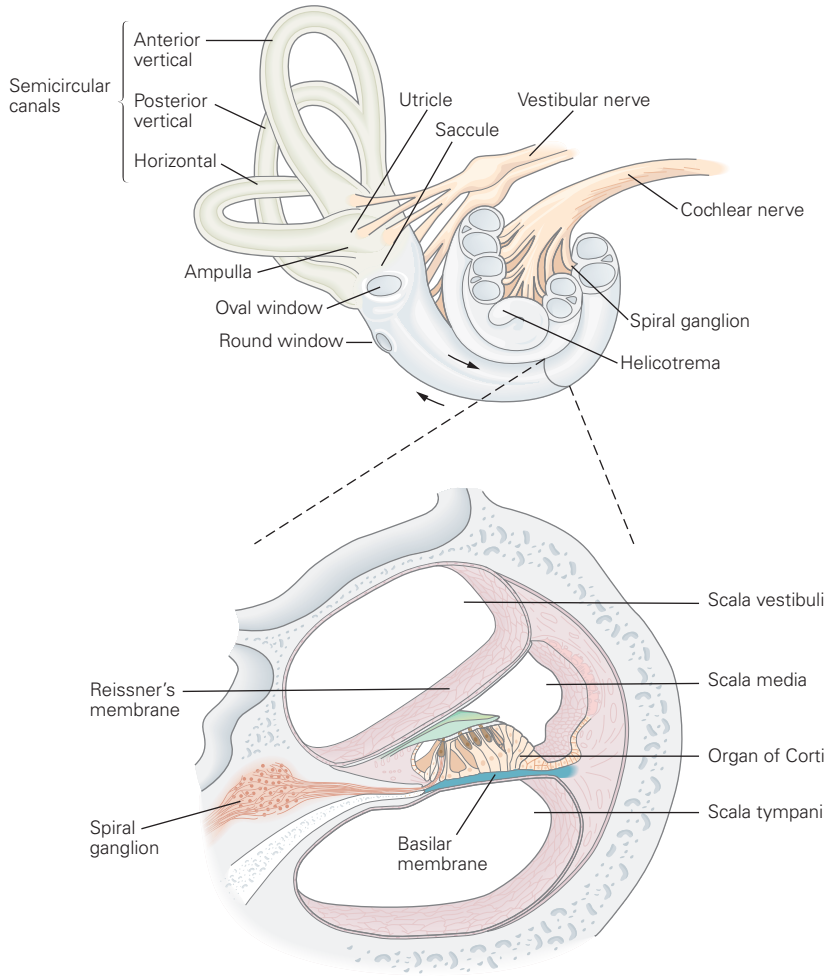

Figure 26–2 The structure of the cochlea. A cross section of the cochlea shows the arrangement of the three liquid-filled ducts or scalae, each of which is approximately 33 mm long. The scala vestibuli and scala tympani communicate through the helicotrema at the apex of the cochlea. At the base, each duct is closed by a sealed aperture. The scala vestibuli is closed by the oval window, against which the stapes pushes in response to sound; the scala tympani is closed by the round window, a thin, flexible membrane. Between these two compartments lies the scala media, an endolymph-filled tube whose epithelial lining includes the 16,000 hair cells in the organ of Corti surmounting the basilar membrane (**blue**). The hair cells are covered by the tectorial membrane (**green**). The cross section in the lower diagram has been rotated so that the cochlear apex is oriented toward the top.

a thin, elastic diaphragm beyond which lies the air of the middle-ear cavity. The two chambers are separated along most of their length by the cochlear partition but communicate with one another at the very tip of the cochlea, through the helicotrema.

The cochlear partition contains the third liquid-filled cavity, the *scala media,* and is delimited by two membranes. The thin Reissner's, or vestibular, membrane divides the scala media from the scala vestibuli. The basilar membrane separates the cochlear partition from the scala tympani and supports the complex sensory structure involved in auditory transduction, the organ of Corti (Figure 26–2).

Hearing Commences With the Capture of Sound Energy by the Ear

Psychophysical experiments have established that we perceive an approximately equal increment in loudness for each 10-fold increase in the magnitude of a sound stimulus. This type of relation is characteristic

of many of our senses and is the basis of the Weber-Fechner law (Chapter 17). A logarithmic scale is therefore useful in relating the magnitude of sound pressure to perceived loudness. Sound pressure corresponds to the sound-evoked modulation of the air pressure with respect to the mean atmospheric pressure; the louder the sound, the larger is the modulation. The sound-pressure level, L, of any sound may be expressed in decibels (dB) as

$$L = 20 \cdot \log_{10}(P / P_{REF}),$$

in which P, the magnitude of the stimulus, is the root-mean-square sound pressure (in units of pascals, abbreviated Pa, or newtons per square meter). For a sinusoidal stimulus, the amplitude exceeds the root-mean-square value by a factor of $\sqrt{2}$. The arbitrary reference level on this scale, 0 dB sound-pressure level (SPL), corresponds to a root-mean-square sound pressure, P_{REF}, of 20 μPa. This level represents the approximate threshold of human hearing at 1 to 4 kHz, the frequency range in which our ears are most sensitive.

Sound consists of very small alternating changes in the local air pressure. The loudest sound tolerable to humans, approximately 120 dB SPL, transiently alters the local atmospheric pressure by only ±0.01%. In contrast, a sound at the threshold level causes a change in the local pressure of much less than one part in a billion. From the faintest sounds that can be detected to sounds so intense that they hurt, the sound pressure increases by one millionfold, which correspond to a trillionfold range in stimulus power. The dynamic range of hearing is enormous.

Despite their small magnitude, sound-induced increases and decreases in air pressure move the tympanum inward and outward (Figure 26–3A,B). Near threshold, the amplitude of vibration is in the picometer range, which is comparable to the tympanum's own thermal fluctuations. Even loud sounds elicit vibrations of the tympanum that do not exceed 1 μm in amplitude. The resulting motions of the ossicles are essentially like those of two interconnected levers (the malleus and incus) and a piston (the stapes). The vibration of the incus alternately drives the stapes deeper into the oval window and retracts it, like a piston that pushes and pulls cyclically upon the liquid in the scala vestibuli. In humans, the area of the eardrum is about 20-fold larger than that of the stapes footplate. As a result, pressure changes applied on the liquid of scala vestibuli by the stapes footplate are larger than those pushing and pulling the tympanum. Pressures are further magnified by the lever operating between the malleus and the incus, the incus in humans being only about 70% of the length of the malleus.

The action of the stapes produces pressure changes that propagate through the liquid of the scala vestibuli at the speed of sound in water. Because liquids are virtually incompressible, however, the primary effect of the stapes's motion is to displace the liquid in the scala vestibuli in the one direction that is not restricted by a rigid boundary: toward the elastic cochlear partition (Figure 26–3B). The deflection of the cochlear partition downward increases the pressure in the scala tympani, displacing a liquid mass that causes outward bowing of the round window. Each cycle of a sound stimulus thus evokes a cycle of up-and-down movement of a minuscule volume of liquid in each of the cochlea's three chambers, thus displacing the sensory organ.

By increasing the magnitude of pressure changes by up to 30-fold, the overall effect of the middle ear is to match the low impedance of the air outside the ear to the higher impedance of the cochlear partition, thus ensuring the efficient transfer of sound energy from the first medium to the second. The pressure gain afforded by the middle ear depends on sound frequency, which determines the U-shape tuning curve of auditory threshold.

Changes of the middle ear's normal structure that reduce its displacement amplitudes can lead to *conductive hearing loss*, of which two forms are especially common. First, scar tissue caused by middle-ear infection (*otitis media*) can immobilize the tympanum or ossicles. Second, a proliferation of bone in the ligamentous attachments of the ossicles can reduce their normal freedom of motion. This chronic condition of unknown origin, termed *otosclerosis*, can lead to severe deafness.

A clinician may test for conductive hearing loss by the simple Rinné test. A patient is asked to assess the loudness of a vibrating tuning fork under two conditions: when the tuning fork is held in the air or when it is pressed against the head just behind the ear. For the second stimulus, sound is conducted through bone to the cochlea. If the second stimulus is perceived to be louder, the patient's conductive pathway through the middle ear may be damaged, but the inner ear is likely to be intact. In contrast, if bone conduction is not more efficient than airborne stimulation, the patient may have inner-ear damage, that is, sensorineural hearing loss. The diagnosis of conductive hearing loss is important, because surgical intervention can be highly effective: Removal of scar tissue or reconstitution of the conductive pathway with a prosthesis may restore excellent hearing.

The Hydrodynamic and Mechanical Apparatus of the Cochlea Delivers Mechanical Stimuli to the Receptor Cells

The Basilar Membrane Is a Mechanical Analyzer of Sound Frequency

The continuous variation of the mechanical properties of the basilar membrane along the cochlea's length, approximately 33 mm, is key to the cochlea's operation. The basilar membrane at the base of the human cochlea is less than one-fifth as broad as at the apex. Thus, although the cochlear chambers become progressively smaller from the organ's base toward its apex, the basilar membrane *increases* in width (Figure 26–3C). Moreover, the basilar membrane is relatively thick toward the base of the cochlea but thinner at the apex. Both morphological gradients contribute to a base-to-apex decrease in basilar-membrane stiffness. Radial collagen fibers within the membrane determine most of its elasticity. The basilar membrane may schematically be regarded as a set of weakly coupled radial segments of increasing length along the longitudinal axis of the cochlea, with the shortest segment at the base and the longest segment at the apex, analogous to the multiple strings of a piano.

Stimulation with a pure tone evokes a complex and elegant movement of the basilar membrane. Over one complete cycle of a tone, each affected segment along the basilar membrane undergoes a single cycle of vibration (Figure 26–3D,E). The various segments of the membrane do not, however, oscillate in phase with one another. As first demonstrated by Georg von Békésy using stroboscopic illumination, each segment reaches its maximal amplitude of motion slightly later than its basal neighbor. The normalized sinusoidal movement of the basilar membrane reproduces that of the stapes, but with a time delay that increases with the distance from the cochlear base.

The overall pattern of motion of the membrane is that of a traveling wave that traverses the cochlea from the stiff base toward the floppier apex. As each wave advances toward the apex, the amplitude of vibration grows to a maximum and then declines rapidly. The position at which the traveling wave reaches its maximal amplitude depends on sound frequency. The basilar membrane at the base of the cochlea responds best to the highest audible frequencies—in humans approximately 20 kHz. At the cochlear apex, the membrane responds to frequencies as low as 20 Hz. The intervening frequencies are represented along the basilar

Figure 26–3 (Opposite) Motion of the basilar membrane.

A. An uncoiled cochlea, with its base displaced to show its relation to the scalae, indicates the flow of stimulus energy. Sound vibrates the tympanum, which sets the three ossicles of the middle ear in motion. The piston-like action of the stapes, a bone inserted partially into the elastic oval window, produces oscillatory pressure differences that rapidly propagate along the scala vestibuli and scala tympani. Low-frequency pressure differences are shunted through the helicotrema, where the two ducts communicate.

B. The functional properties of the cochlea are conceptually simplified if the cochlea is viewed as a linear structure with only two liquid-filled compartments separated by the elastic basilar membrane.

C. The basilar membrane, here represented in a surface view, increases in width from approximately 50 μm near the base to 500 μm near the apex of the cochlea. Radial collagen fibers run from the neural to the abneural edge of the membrane. As the result of its morphological gradients, the basilar membrane's mechanical properties vary continuously along its length.

D. The oscillatory stimulation of a sound causes a traveling wave on the basilar membrane, shown here within the envelope of maximal displacement over an entire cycle. The magnitude of movement is grossly exaggerated in the vertical direction; the loudest tolerable sounds move the basilar membrane by only ±150 nm, a scaled distance less than one-hundredth the width of the lines representing the basilar membrane in these figures.

E. An enlargement of the active region in D demonstrates the motion of the basilar membrane in response to stimulation with sound of a single frequency. The continuous curve depicts a traveling wave at one instant; the vertical scale of basilar-membrane deflection is exaggerated about one-millionfold. The **dashed** and **dotted curves** portray the traveling wave at successively later times as it progresses from the cochlear base (*left*) toward the apex (*right*). As the wave approaches the characteristic place for the stimulus frequency, it slows and grows in amplitude. The stimulus energy is then transferred to hair cells at positions within the wave's peak.

F. Each frequency of stimulation excites maximal motion at a particular position along the basilar membrane. Low-frequency sounds produce basilar-membrane motion near the apex, where the membrane is relatively broad and soft. Mid-frequency sounds excite the membrane in its middle. The highest frequencies that we can hear excite the basilar membrane at its narrow, stiff base. The mapping of sound frequency onto the basilar membrane is approximately logarithmic.

G. The basilar membrane performs spectral analysis of complex sounds. In this example, a sound with three prominent frequencies, such as the three formants of a vowel sound, excites basilar-membrane motion in three regions, each of which represents a particular frequency. Hair cells in the corresponding positions transduce the basilar-membrane oscillations into receptor potentials, which in turn excite the nerve fibers that innervate these particular regions.

membrane in a continuous array (Figure 26–3F). In the 19th century, the German physiologist Hermann von Helmholtz was the first to appreciate that the basilar membrane's operation is essentially the inverse of a piano's. The piano synthesizes a complex sound by combining the pure tones produced by numerous vibrating strings; the cochlea, by contrast, deconstructs a complex sound by isolating the component tones at the appropriate segments of the basilar membrane.

For any frequency within the auditory range, there is a characteristic place along the basilar membrane at which the magnitude of vibration is maximal. Although the morphological gradients of the basilar membrane are key to the process, the actual dispersion of a sound's frequency components along the cochlea's longitudinal axis depends on the mechanical properties of the cochlear partition as a whole. In particular, as we shall detail later, the hair cells within the organ of Corti provide active mechanical feedback that sharpens mechanical tuning of the basilar membrane and enhances its sensitivity to sound. The arrangement of vibration frequencies along the basilar membrane is an example of a *tonotopic map.* The relationship between frequency and position along the basilar membrane varies monotonically, but is not linear; the logarithm of the frequency decreases roughly in proportion to the distance from the cochlea's base. The frequencies from 20 kHz to 2 kHz, those between 2 kHz and 200 Hz, and those spanning 200 Hz to 20 Hz are each represented by approximately one-third of the basilar membrane's extent.

Analysis of the response to a complex sound illustrates how the basilar membrane operates in daily life. A vowel sound in human speech, for example, ordinarily comprises three dominant frequency components termed formants. Each frequency component of the stimulus establishes a traveling wave that, to a first approximation, is independent of the waves evoked by the others (Figure 26–3G) and reaches its peak excursion at a point on the basilar membrane appropriate for that frequency component. The basilar membrane thus acts as a mechanical frequency analyzer by distributing the energies associated with the different frequency components of the stimulus to hair cells arrayed along its length. In doing so, the basilar membrane begins the encoding of the frequencies in a sound.

The Organ of Corti Is the Site of Mechanoelectrical Transduction in the Cochlea

The organ of Corti, a ridge of epithelium extending along the basilar membrane, is the receptor organ of the inner ear. Each organ of Corti contains approximately 16,000 hair cells that are innervated by approximately 30,000 *afferent* nerve fibers; these are fibers that carry information into the brain along the eighth cranial nerve. Like the basilar membrane itself, each hair cell is most sensitive to a particular frequency, and these frequencies are logarithmically mapped in descending order from the cochlea's base to its apex. Thus, the information transmitted by these sensory cells to their innervating nerve fibers is also tonotopically organized.

The organ of Corti includes a variety of cells, some of unknown function, but four types have obvious importance. First, there are two types of hair cells. The *inner hair cells* form a single row of approximately 3,500 cells, whereas approximately 12,000 *outer hair cells* lie in three rows farther from the central axis of the cochlear spiral (Figure 26–4). The space between the inner and outer hair cells is delimited and mechanically supported by pillar cells. The outer hair cells are supported at their bases by Deiters's (phalangeal) cells.

A second epithelial ridge adjacent to the organ of Corti, but nearer the cochlea's central axis, gives rise to the tectorial membrane, a gelatinous shelf that covers the organ of Corti (Figure 26–4). The tectorial membrane is anchored at its base, and its tapered distal edge forms a fragile connection with the organ of Corti.

Hair cells are not neurons; they lack both dendrites and axons (Figure 26–5A). A special saline solution, the endolymph that fills scala media, bathes the cell's apical aspect. Tight junctions between hair cells and supporting cells separate this liquid from the standard extracellular fluid, or perilymph, that contacts the basolateral surface of the cell. Immediately below the tight junctions, a desmosomal junction provides a strong mechanical attachment for the hair cell to its neighbors.

The hair bundle, which serves as a receptive antenna for mechanical stimuli, projects from the flattened apical surface of the hair cell. Each bundle comprises a few tens to a few hundred cylindrical processes, the *stereocilia*, arranged in 2 to 10 parallel rows and extending several micrometers from the cell surface. Successive stereocilia across a cell's surface vary monotonically in height; a hair bundle is beveled like the tip of a hypodermic needle (Figure 26–5B). The inner hair-cell bundles of the mammalian cochlea, when viewed from above, have a roughly linear form. Outer hair-cell bundles, in contrast, have a V or W shape (Figure 26–6).

Each stereocilium is a rigid cylinder whose core consists of a fascicle of actin filaments that are heavily cross-linked by the proteins plastin (fimbrin), fascin, and epsin. Cross-linking renders a stereocilium

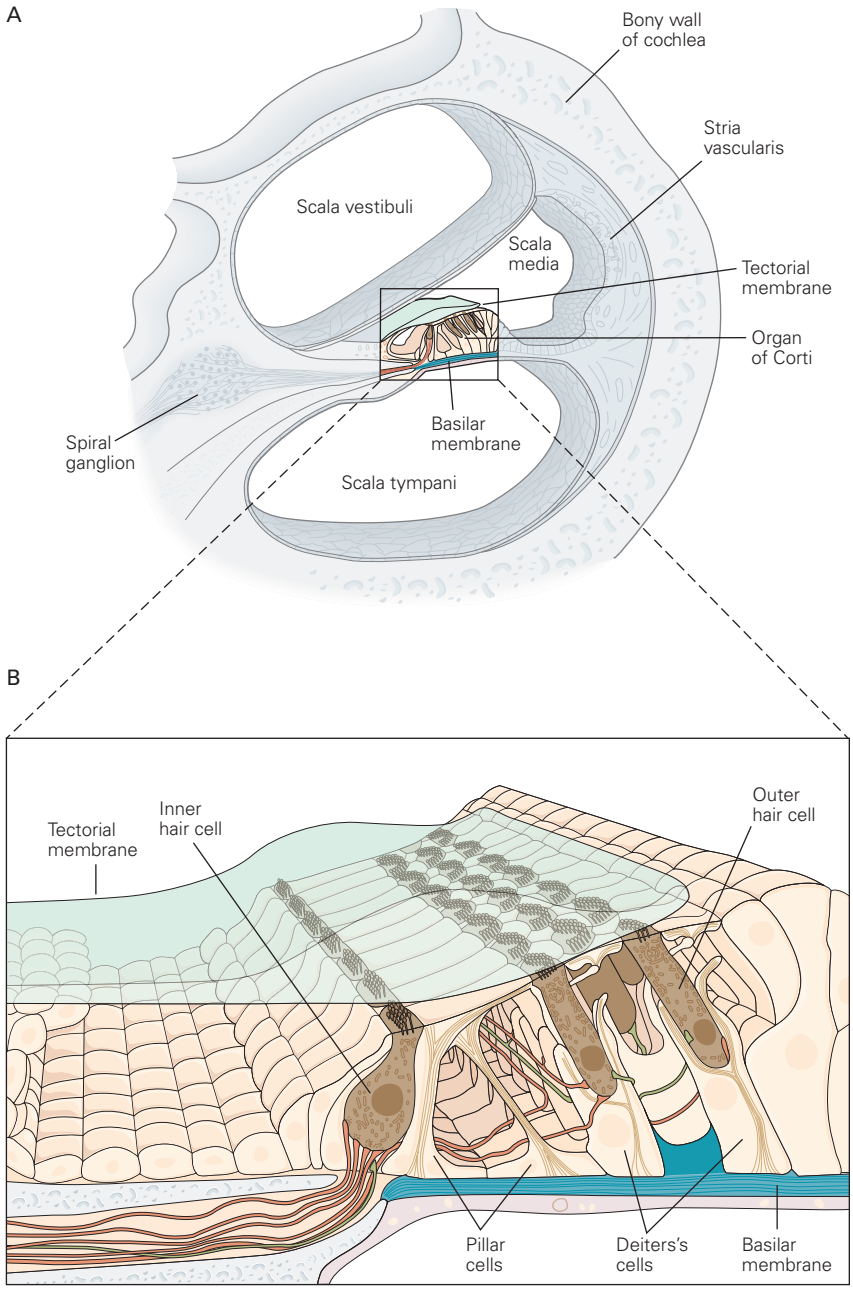

Figure 26–4 Cellular architecture of the human organ of Corti. Although there are differences among species, the basic plan is similar for all mammals.

A. The organ of Corti, the inner ear's receptor organ, is an epithelial strip that surmounts the elastic basilar membrane. The organ contains some 16,000 hair cells arrayed in four rows: a single row of inner hair cells and three rows of outer hair cells. The mechanically sensitive hair bundles of these receptor cells protrude into endolymph, the liquid within the scala media. Reissner's membrane, which provides the upper boundary of the scala media, separates the endolymph from the perilymph in the scala vestibuli. The hair bundles of outer hair cells are attached at their tops to the lower surface of the tectorial membrane, a gelatinous shelf that extends the full length of the basilar membrane.

B. The hair cells are separated and supported by pillar cells and Deiters's cells. One hair cell has been removed from the middle row of outer hair cells to reveal the three-dimensional relationship between supporting cells and hair cells. Afferent and efferent nerve endings are colored in **red** and **green**, respectively.

much more rigid than would be expected for a bundle of unconnected actin filaments. The actin core of the stereocilium is covered by a tubular sheath of plasma membrane. Although a stereocilium is of constant diameter along most of its length, it tapers just above its basal insertion (see Figure 25–5B). Correspondingly, the number of actin filaments diminishes from several hundred to only a few dozen. This thin cluster of microfilaments anchors the stereocilium in the cuticular plate, a thick mesh of interlinked actin filaments beneath the apical cell membrane. Because of this tapered structure, a mechanical force applied at the tip causes the stereocilium to pivot around its basal insertion. Horizontal top connectors interconnect adjacent stereocilia near their tips. These extracellular filaments restrict the bundle to move as a unit during stimulation at low frequencies. At high frequencies, the viscosity of the liquid between the stereocilia also opposes their separation and thus ensures the unitary motion of the hair bundle.

During its early development, every hair bundle includes at its tall edge a single true cilium, the *kinocilium* (Figure 26–5). Like other cilia, this structure possesses at its core an axoneme, or array of nine paired microtubules, and often an additional central pair of microtubules. The kinocilium is not essential for mechanoelectrical transduction, for in mammalian cochlear hair cells, it degenerates around the time of birth.

Hair Cells Transform Mechanical Energy Into Neural Signals

Deflection of the Hair Bundle Initiates Mechanoelectrical Transduction

Just as in vestibular organs (Chapter 27), mechanical deflection of the hair bundle is the stimulus that excites hair cells of the cochlea. Stimuli elicit an electrical response, the receptor potential, by opening or closing—a process termed "gating"—mechanically sensitive ion channels. The hair cell's response depends on the direction and magnitude of the stimulus.

In an unstimulated cell, 10% to 50% of the channels involved in stimulus transduction are open. As a result, the cell's resting potential, which lies within a range of approximately –70 to –30 mV, is determined in part by the influx of cations through these channels. A stimulus that displaces the bundle toward its tall edge opens additional channels, thereby depolarizing the cell (Figure 26–7). In contrast, a stimulus that displaces the bundle toward its short edge shuts transduction channels that are open at rest, thus hyperpolarizing

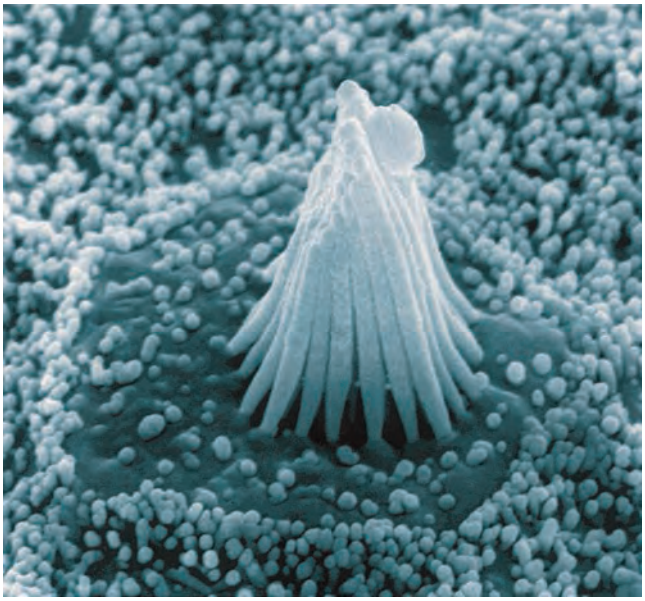

Figure 26–5 (Left) Structure of a vertebrate hair cell.

A. The epithelial character of the hair cell is evident in this drawing of the sensory epithelium from a frog's internal ear. The cylindrical hair cell is joined to adjacent supporting cells by a junctional complex around its apex. The hair bundle, a mechanically sensitive organelle, extends from the cell's apical surface. The bundle comprises some 60 stereocilia arranged in stepped rows of varying length. At the bundle's tall edge stands the single kinocilium, an axonemal structure with a bulbous swelling at its tip; in the mammalian cochlea, this organelle degenerates around the time of birth. Deflection of the hair bundle's top to the right depolarizes the hair cell; movement in the opposite direction elicits hyperpolarization. The hair cell is surrounded by supporting cells, whose apical surfaces bear a stubble of microvilli. Afferent and efferent synapses contact the basolateral surface of the plasma membrane.

B. This scanning electron micrograph of a hair cell's apical surface reveals the hair bundle protruding approximately 8 μm into the endolymph. (Image reproduced, with permission, from A.J. Hudspeth.)

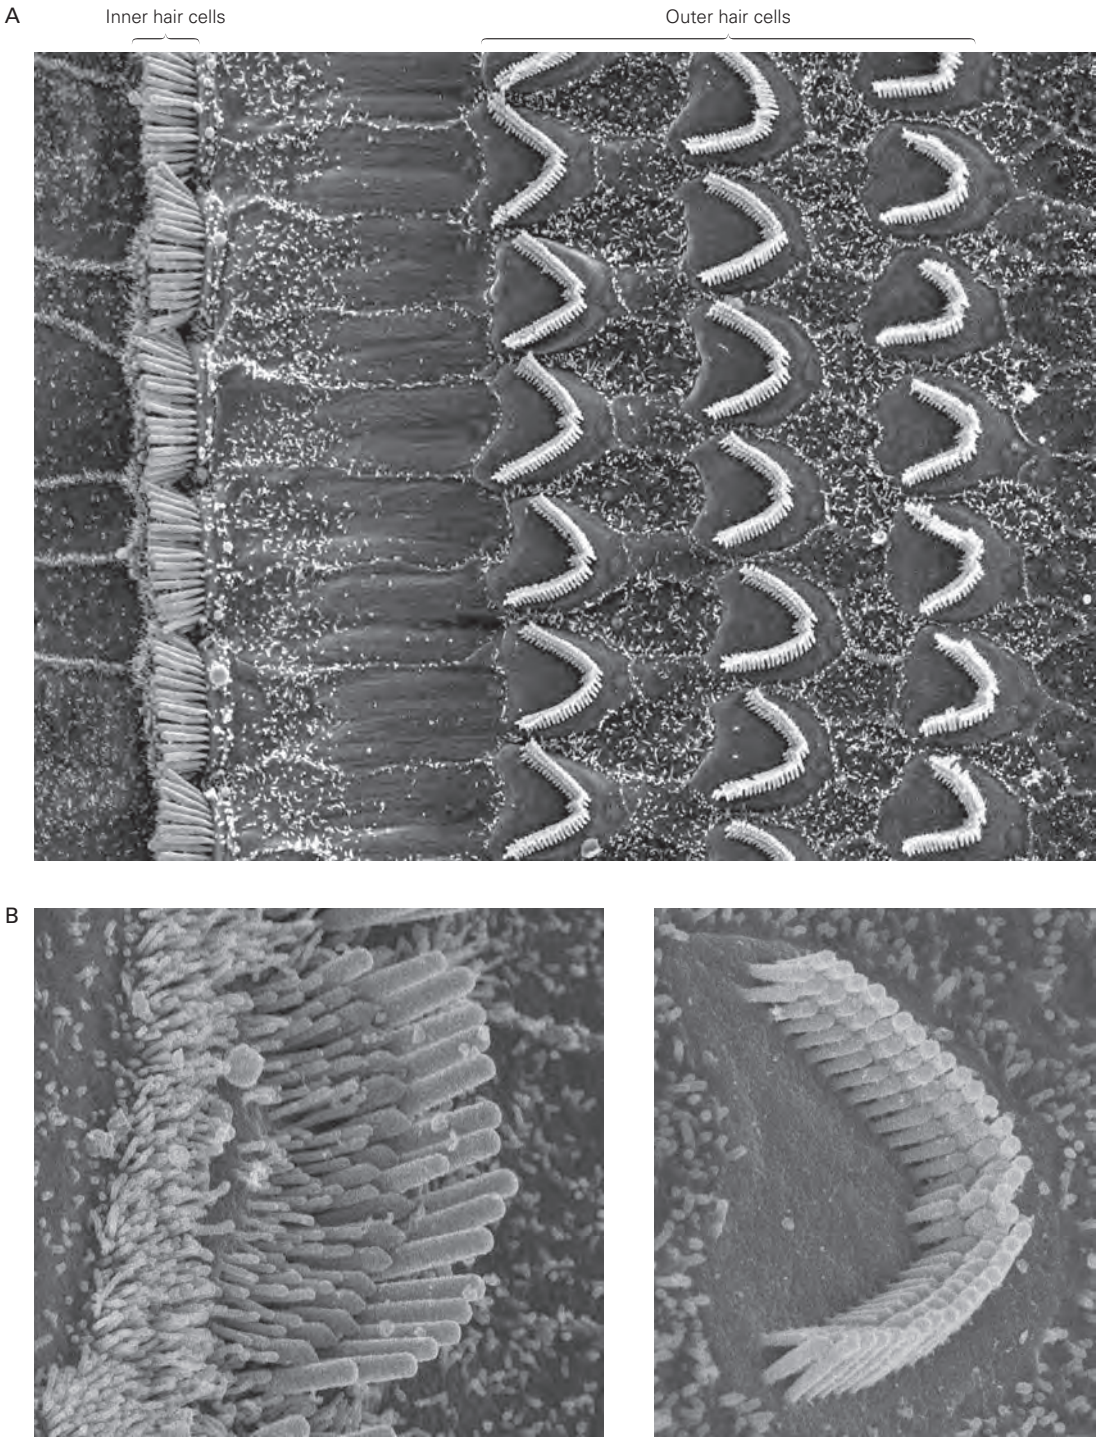

Figure 26–6 Arrangement of the hair cells in the organ of Corti. (Images reproduced, with permission, from D. Furness, Keele University, United Kingdom.)

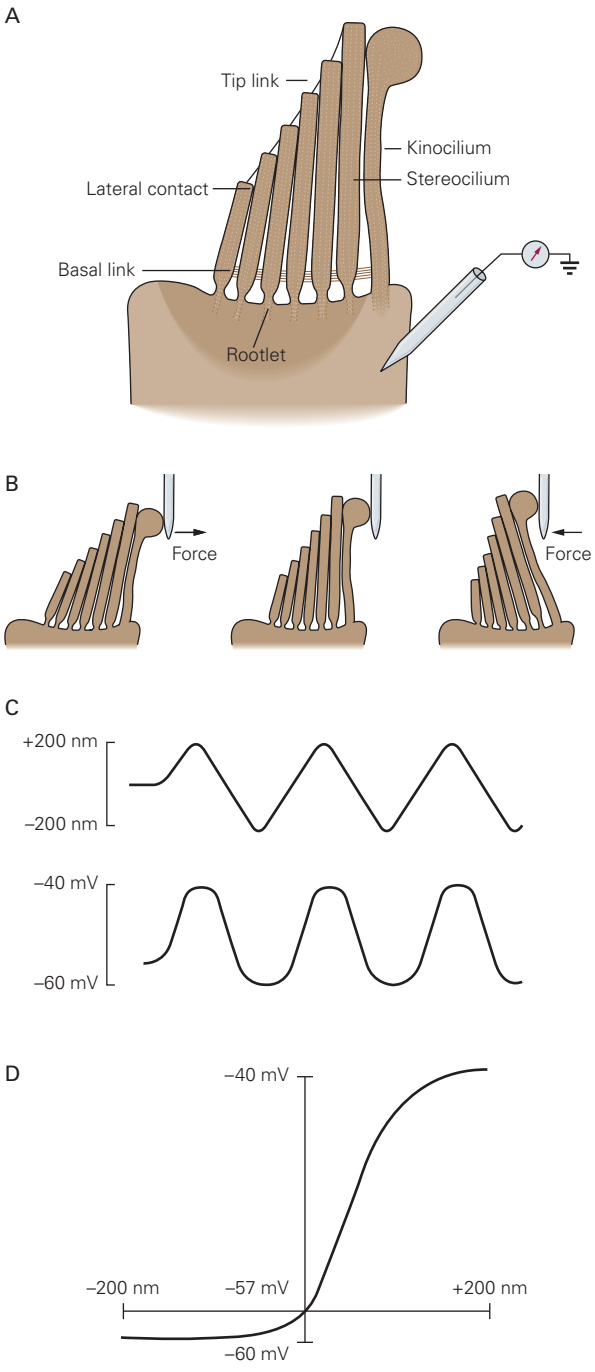
A. Inner hair cells form a single row, and the stereocilia of each cell are arranged linearly. In contrast, outer hair cells are distributed in three rows, and the stereocilia of each cell are arranged in a V configuration. The apical surfaces of several other cells are visible: from left to right, inner spiral sulcus cells, pillar cells, Deiters's cells, and Hensen's cells (see Figure 26–4).

B. Higher magnification shows the linear configuration of the hair bundle atop an inner hair cell (*left*) and the V configuration of an outer hair-cell bundle (*right*), as well as the arrangement of the stereocilia in rows of increasing heights.

the cell. Hair cells respond most to stimuli parallel to the hair bundle's axis of morphological mirror symmetry: Stimuli at right angles to the axis produce little change from the resting potential. An oblique stimulus elicits a response proportional to its vectorial projection along the axis of sensitivity.



A hair cell's receptor potential is graded. As the stimulus amplitude increases, the receptor potential grows progressively larger up to the point of saturation. The receptor potential of an inner hair cell can be as great as 25 mV in peak-to-peak magnitude. The relation between a bundle's deflection and the resulting electrical response is sigmoidal (Figure 26–7D). A displacement of only ±100 nm represents approximately 90% of the response range. During normal stimulation, a hair bundle moves through an angle of ±1° or so, that is, by much less than the diameter of one stereocilium.

When observed in vitro, a hair bundle exhibits Brownian motion of approximately ±3 nm, whereas the threshold of hearing corresponds to basilar-membrane movements of as little as ±0.3 nm. There are at least three mechanisms that explain how the hair bundle may respond to motion smaller than its own noise. First, because the cochlear partition does not move as a rigid body, the movement of the hair bundle is larger than that of the basilar membrane. Second, frequency-selective amplification of low stimuli actively pulls the signal out of the noise. Finally, mechanical coupling to a group of neighbors results in synchronization that effectively reduces noise. At hearing threshold, a stimulus evokes a receptor potential near 100 μV in amplitude.

The ion channels in hair cells that mediate mechanoelectrical transduction are relatively nonselective, cation-passing pores with a conductance near 100 pS. From the known size of small organic cations and fluorescent molecules that can traverse the channel, the transduction channel's pore must be about 1.3 nm in diameter. Most of the transduction current is carried by K^+, the cation with the highest concentration in the endolymph bathing the hair bundle. Although

Figure 26–7 (Left) Mechanical sensitivity of a hair cell.

A. A recording electrode is inserted into a frog hair cell.

B. A probe attached to the bulbous tip of the stereocilium is moved by a piezoelectric stimulator, deflecting the elastic hair bundle from its resting position. The actual deflections are generally only one-tenth as large as those portrayed.

C. When the top of a hair bundle is displaced back and forth (**upper trace**), the opening and closing of mechanically sensitive ion channels produce an oscillatory receptor potential (**lower trace**) that—as here—may saturate in both the depolarizing and the hyperpolarizing directions.

D. The relation between hair-bundle deflection (abscissa) and receptor potential (ordinate) is sigmoidal. The entire operating range is only approximately 100 nm, less than the diameter of an individual stereocilium. At rest, the hair bundle operates within the steep region of the sigmoid, which ensures significant receptor potentials in response to weak stimuli.

endolymph is relatively poor in Ca^{2+}, a small fraction of the transduction current is carried by this ion. Fluorescent indicators indicate that Ca^{2+} entry, and thus mechanoelectrical transduction, occurs precisely at the stereociliary tips of a deflected hair bundle. Single-channel recordings, together with the observation that the magnitude of the transduction current is roughly proportional to the number of functional stereocilia remaining in a microdissected bundle, indicate that there are probably only two active transduction channels per stereocilium.

The large diameter and poor selectivity of the pore permit transduction channels to be blocked by aminoglycoside antibiotics such as streptomycin, gentamicin, and tobramycin. When used in large doses to counter bacterial infections, these drugs have a toxic effect on hair cells; the antibiotics damage hair bundles and eventually kill hair cells. These drugs pass through transduction channels at a low rate and thus cause long-term toxic effects by interfering with protein synthesis on the mitochondrial ribosomes, which resemble bacterial ribosomes. Consistent with this hypothesis, human sensitivity to aminoglycosides is maternally inherited, as are the mitochondria, and in many instances reflects a single base change in the 12S ribosomal RNA gene of the mitochondrion.

Mechanical Force Directly Opens Transduction Channels

The mechanism for gating of transduction channels in hair cells differs fundamentally from the mechanisms used for electrical signals in neurons such as the action potential or postsynaptic potential. Many ion channels respond to changes in membrane potential or to specific ligands (Chapters 8, 10, and 12–14). In contrast, two lines of evidence suggest that the mechanoelectrical transduction channels in the hair cell are activated by mechanical strain.

First, a bundle is stiffer along its axis of mechanical sensitivity than at a right angle. This observation suggests that a portion of the work done in deflecting a bundle goes into elastic elements, termed *gating springs,* which pull on the molecular gates of the transduction channels. Because the gating springs contribute over half of a hair bundle's stiffness, the transduction channels efficiently capture the energy supplied when a bundle is deflected. In addition, the mechanical properties of a hair bundle vary during channel gating: When channels open or close, stiffness decreases and friction increases. Both phenomena are expected if the channels are gated directly through a mechanical linkage to the hair bundle.

A second indication that transduction channels are directly controlled by gating springs is the rapidity with which hair cells respond. The response latency is so brief, only a few microseconds, that gating is more likely to be direct than to involve a second messenger (Chapter 14). Moreover, the electrical responses of hair cells to a series of step stimuli of increasing magnitude become both larger and faster. This behavior favors a kinetic scheme in which mechanical force controls the rate constant for channel gating.

The *tip link* is a probable component of the gating spring. A tip link is a fine molecular braid joining the distal end of one stereocilium to the side of the longest adjacent process (Figure 26–8A). Deflection of a hair bundle toward its tall edge tenses the tip link and promotes channel opening; movement in the opposite direction slackens the link and allows the associated channels to close (Figure 26–8B).

Three experimental results suggest that the tip links are components of the gating springs. First, tip links are universal features of hair bundles and are situated at the site of transduction. The transduction channels are indeed located at the stereociliary tips, thus near the lower insertion point of the tip link. Second, the orientation of the links is consistent with the vectorial sensitivity of transduction. The links invariably interconnect stereocilia in a direction parallel with the hair bundle's axis of mechanosensitivity. Finally, when tip links are disrupted by exposing hair cells to Ca^{2+} chelators, transduction vanishes. As the tip links regenerate over the course of approximately 12 hours, a hair cell regains mechanosensitivity. It remains unclear whether the elasticity of gating springs resides primarily in the tip links or in the structures at their two insertions.

In the mammalian cochlea, hair bundles are deflected through their linkage to the tectorial membrane. When the basilar membrane oscillates up and down in response to a sound, the organ of Corti and the overlying tectorial membrane move with it. Because the basilar and tectorial membranes pivot about different lines of insertion, however, their up-and-down motion is accompanied by a back-and-forth shearing motion between the upper surface of the organ of Corti and the lower surface of the tectorial membrane. This is the motion that is detected by hair cells (Figure 26–9).

The hair bundles of outer hair cells, whose tips are firmly attached to the tectorial membrane, are directly deflected by this movement. The hair bundles of inner hair cells, which do not contact the tectorial membrane, are deflected by movement of the liquid beneath the membrane. This mode of stimulation affords some mechanical magnification of the signals reaching hair

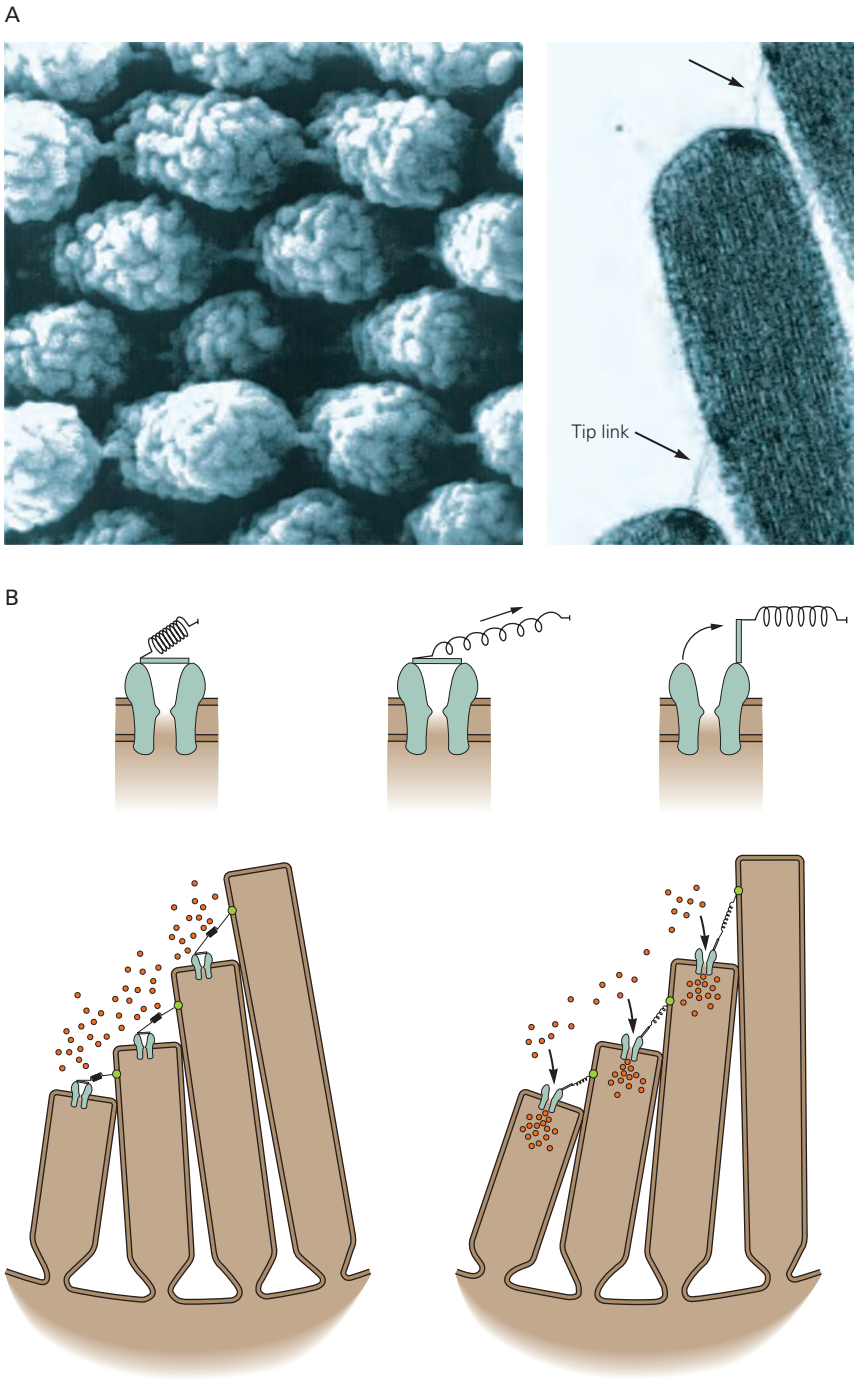


Figure 26–8 Mechanoelectrical transduction by hair cells.

A. A tip link connects each stereocilium to the side of the longest adjacent stereocilium, as seen in a scanning electron micrograph (*left*) and a transmission electron micrograph (*right*) of a hair bundle's top surface. Each tip link is only 3 nm in diameter and 150 to 200 nm in length. The links appear stouter in the illustration on the left because of metallic coating during specimen preparation. (Reproduced, with permission, from Assad, Shepherd, and Corey 1991; reproduced, with permission, from Hudspeth and Gillespie 1994.)

B. Top: Ion flux through the channel that underlies mechanoelectrical transduction in hair cells is regulated by a molecular gate. The opening and closing of the gate are controlled by the tension in an elastic element, the gating spring, which senses hair-bundle displacement. (Adapted, with permission, from Howard and Hudspeth 1988.)

Bottom: When the hair bundle is at rest, each transduction channel fluctuates between closed and open states, spending most of its time shut. Displacement of the bundle in the positive direction increases the tension in the gating spring, here assumed to be in part a tip link, attached to each channel's molecular gate. The enhanced tension promotes channel opening and the influx of cations, thereby producing a depolarizing receptor potential. (Adapted, with permission, from Hudspeth 1989.)

bundles. At least for high-frequency stimuli, the movements of hair bundles are thought to be severalfold greater than that of the basilar membrane.

Direct Mechanoelectrical Transduction Is Rapid

Hair cells operate much more quickly than do other sensory receptor cells of the vertebrate nervous system and, indeed, more quickly than neurons themselves. To deal with the frequencies of biologically relevant sounds, transduction by hair cells must be rapid. Given the behavior of sound in air and the dimensions of sound-emitting and sound-absorbing organs such as vocal cords and eardrums, optimal auditory communication occurs in the frequency range of 10 Hz to 100 kHz. Much higher frequencies propagate

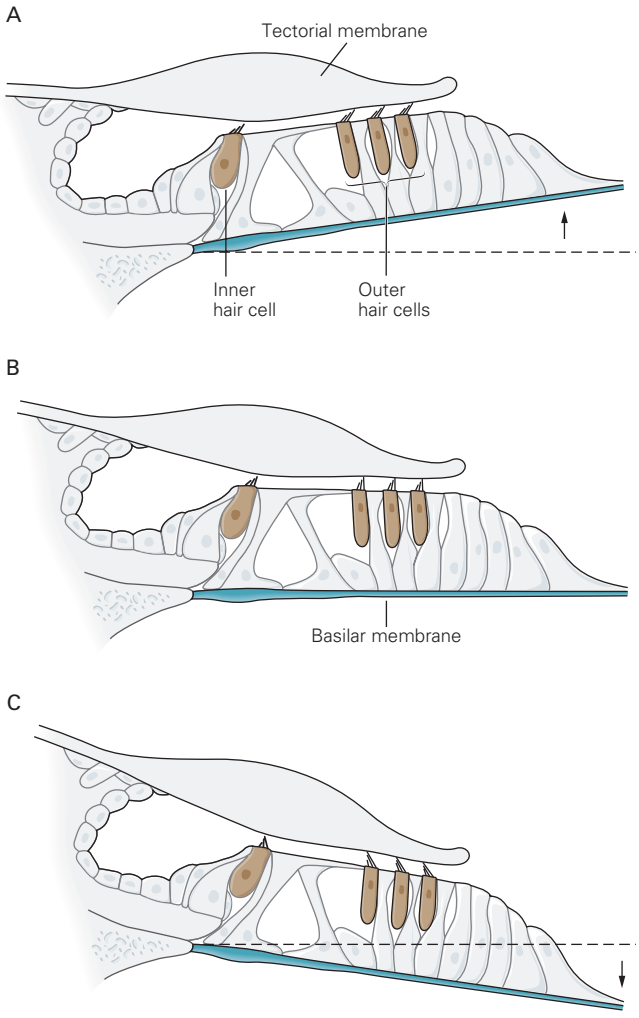

Figure 26–9 Forces acting on cochlear hair cells. Hair cells in the cochlea are stimulated when the basilar membrane is driven up and down by differences in the pressure between the scala vestibuli and scala tympani. This motion is accompanied by shearing movements between the tectorial membrane and organ of Corti. These motions deflect the hair bundles of outer hair cells, which are attached to the lower surface of the tectorial membrane. The hair bundles of inner hair cells, which are not attached to the tectorial membrane, are deflected by the movement of liquid in the space beneath that structure. In both instances, the deflection initiates mechanoelectrical transduction of the stimulus.

A. When the basilar membrane is driven upward, shear between the hair cells and the tectorial membrane deflects hair bundles in the excitatory direction, toward their tall edge.

B. At the midpoint of an oscillation, the hair bundles resume their resting position.

C. When the basilar membrane moves downward, the hair bundles are driven in the inhibitory direction.

poorly through air; much lower frequencies are inefficiently produced and poorly captured by animals of moderate size. Even in animals sensitive to relatively low frequencies, such as frogs, the in vitro transduction current in response to a step stimulus of moderate intensity rises with a time constant of only 80 µs at room temperature. For mammals to be able to respond to frequencies greater than 100 kHz, the hair cells evidently display gating times that are an order of magnitude smaller. Locating sound sources, one of the most important functions of hearing, sets even more stringent limits on the speed of transduction (Chapter 28). A sound from a source directly to one side of a person reaches the nearer ear somewhat sooner than the farther, by at most 700 µs in humans. An observer can locate sound sources on the basis of much smaller delays, about 10 µs. For this to occur, hair cells must be capable of transducing acoustic waveforms with microsecond-level resolution.

Deafness Genes Provide Components of the Mechanotransduction Machinery

Genetic studies of deafness in both humans and mouse models have provided entry points into the molecular composition of the mechanotransduction machinery of the hair cell. In particular, the upper two-thirds of the tip link consist of two parallel molecules of cadherin-23, whereas the lower third comprises two parallel molecules of protocadherin-15 (Figure 26–10). The two components are joined at their tips in a Ca^{2+}-sensitive manner; lowering the extracellular Ca^{2+} concentration below approximately 1 µM disrupts their association. In humans, mutations in the genes coding for cadherin 23 (*USH1D*) and protocadherin 15 (*USH1F*) lead to the most severe form of the Usher syndrome, an autosomal recessive disorder that associates severe-to-profound congenital deafness, constant vestibular dysfunction, and retinitis pigmentosa with a prepubertal onset. The study of other genes involved in this type of Usher syndrome has revealed that the upper end of the tip link is anchored to the actin core of a stereocilium by a protein complex that includes the scaffolding proteins sans (*USH1G*) and harmonin (*USH1C*), as well as the molecular motor myosin 7a (*USH1B*).

The small number of channels in a hair cell, along with the lack of high-affinity ligands with which to label them, explains why the biochemical identity of the transduction channels has long remained uncertain. However, recent genetic, biochemical, and biophysical experiments indicate that four integral transmembrane proteins are intimately related to the transduction channel: transmembrane channel-like proteins 1 and

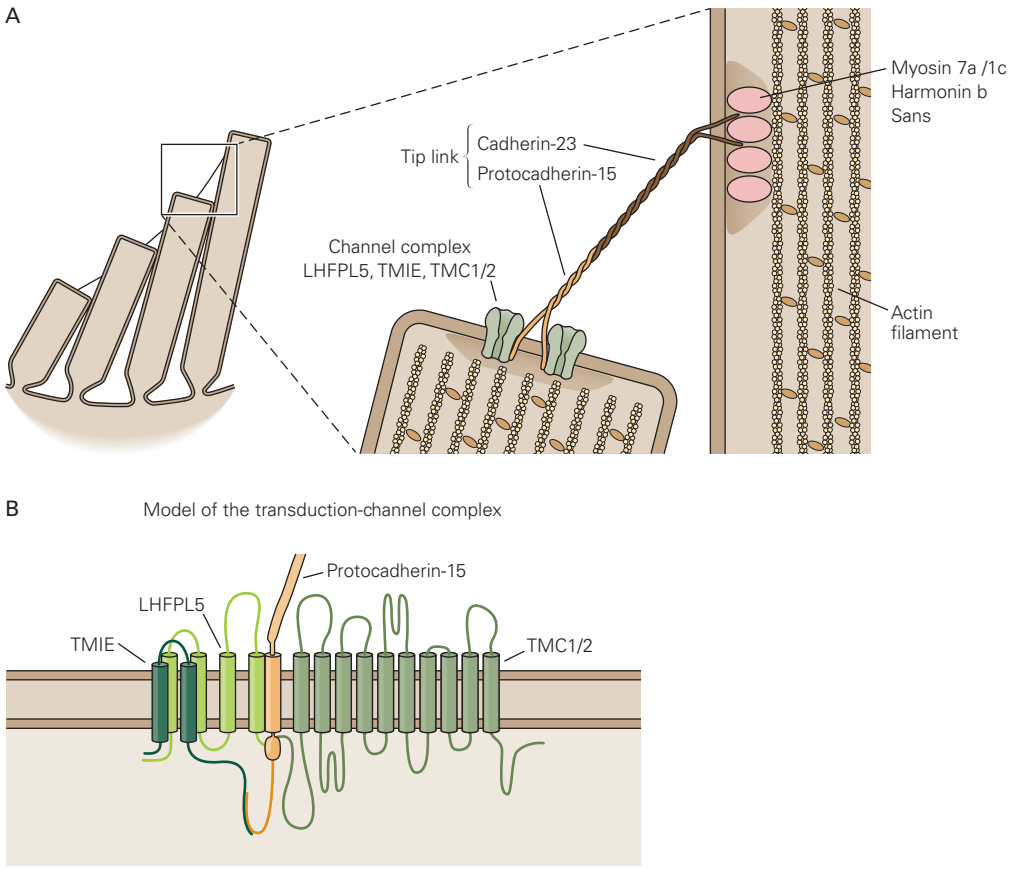

Figure 26–10 Molecular composition of the transduction machinery.

A. The tip link is composed of the heterophilic association of protocadherin 15 and cadherin 23. Two transduction channels are localized near the lower insertion point of the tip link at the tip of the shorter stereocilium. Each channel is part of a molecular complex that includes the proteins TMC1/2, LHFPL5, and TMIE. At the upper insertion point on the flank of the longer stereocilium, cadherin 23 interacts with harmonin b and the molecular motor myosin 7a, which both bind to actin and thus anchor the tip link. The protein sans serves as a scaffolding protein. In vestibular hair cells, myosin 1c may set the tip link under tension, but the presence of this motor protein is uncertain in cochlear hair cells.

B. Model of the transduction-channel complex. TMC1/2, LHFPL5, and TMIE interact with protocadherin 15 and, thus, with the lower end of the tip link. TMIE also interacts with LHFPL5. The detailed arrangement of these proteins within the transduction apparatus is still unknown. Unlike what the figure suggests, TMC1 has been proposed to assemble as a dimer, with each TMC1 molecule contributing a permeation pathway for cations. (Adapted, with permission, from Wu and Müller 2016 and Pan et al. 2018.)

2 (TMC1 and TMC2), tetraspan membrane protein in hair-cell stereocilia (TMHS; official nomenclature LHFPL5), and transmembrane inner-ear-expressed gene (TMIE; Figure 26–10). Mechanotransduction is abolished in mouse hair cells lacking TMIE, even though all other known components of the transduction machinery appear to be properly in place. However, because TMIE contains only two predicted transmembrane domains, it seems highly unlikely that this protein alone constitutes an ion channel. In the absence of LHFPL5, the conductance of the transduction channel is reduced, but significant transduction currents can still be measured, suggesting that this protein is not an essential part of the channel pore.

Multiple lines of evidence advocate for TMC1 and TMC2 as components of the transduction channel. Both proteins are localized near the lower insertion point of the tip link, where the transduction current enters the hair cell, interact with the tip-link constituent protocadherin 15, and their onset of expression coincides with that of mechanoelectrical transduction. In addition, transduction channels in a mouse carrying a single point mutation in the *Tmc1* gene show lower conductance and Ca^{2+} permeability, indicating that TMC1 is very close to the channel's pore. Individual

cysteine substitutions made at sites that are predicted to be in or near the channel pore confirm that TMC1 belongs to the main conductive pathway. Indeed, covalent modification of the cysteine residues with a positively charged reagent leads to a reduction of the single-channel conductance in several TMC1 mutants. The cysteine-modifying reagent has no effect when the reagent is applied after the hair bundle has been deflected towards its short edge (to close the transduction channels) or when access to the channel pore is prevented by a channel blocker. TMC1 is thus unlikely to constitute an accessory channel subunit that forms a vestibule to the pore-forming protein(s). Instead, the evidence is strong that TMC1 forms at least part of the pore of the transduction channel. In cochlear hair cells, TMC1 and TMC2 are coexpressed during neonatal development, but only TMC1 expression is maintained through adulthood.

Dynamic Feedback Mechanisms Determine the Sensitivity of the Hair Cells

Hair cells must cope with acoustic stimuli that have a very low energy content. If the stimulus consists of a periodic signal, such as the sinusoidal pressure of a pure tone, a detection system can increase the signal-to-noise ratio by enhancing selectively the response to a relevant frequency. Hair cells respond best at a characteristic frequency of acoustic stimulation. The frequency selectivity of a given hair cell results in part from passive extrinsic filtering of its mechanical input, in particular as a result of the tonotopic arrangement of the mammalian basilar membrane. In addition, when it is appropriate that low-frequency inputs be disregarded, hair cells possess a unique mechanism of adaptation that acts as a high-pass filter. Hair cells also employ mechanical amplification that enhances and further tunes their mechanosensitivity.

Hair Cells Are Tuned to Specific Stimulus Frequencies

Every cochlear hair cell is most sensitive to stimulation at a specific frequency, termed its characteristic, natural, or best frequency. On average, the characteristic frequencies of adjacent inner hair cells differ by approximately 0.2%; adjacent piano strings, in comparison, are tuned to frequencies some 6% apart. Because the traveling wave evoked even by a pure sinusoidal stimulus spreads somewhat along the basilar membrane, the sensitivity of a cochlear hair cell extends within a limited range above and below its characteristic frequency, the more so with a greater level of stimulation. At low levels, a pure tone recruits approximately 100 hair cells. The frequency sensitivity of a hair cell may be displayed as a tuning curve. To construct a tuning curve, an experimenter stimulates the ear with pure tones at numerous frequencies below, at, and above the cell's characteristic frequency. The level of stimulation is adjusted for each frequency until the cell's response reaches a predefined criterion magnitude. The tuning curve is then a graph of sound level, presented logarithmically in decibels SPL, as a function of stimulus frequency.

The tuning curve for an inner hair cell is typically V-shaped (Figure 26–11). The curve's tip represents the cell's characteristic frequency, the frequency that produces the criterion response for the lowest level of the stimulus. Sounds of greater or lesser frequencies require higher levels to excite the cell to the criterion response. As a consequence of the traveling wave's shape, the slope of a tuning curve is far steeper on its high-frequency flank than on its low-frequency flank.

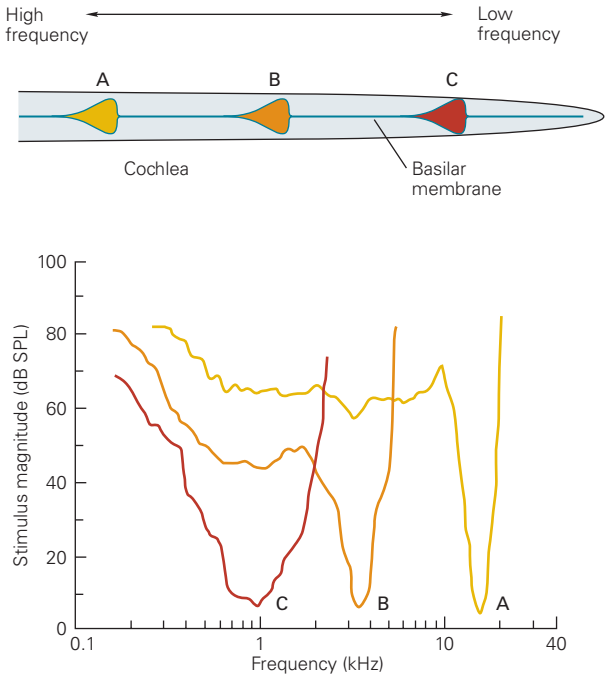

Figure 26–11 Tuning curves for cochlear hair cells. To construct a curve, the experimenter presents sound at several frequencies. At each frequency, the stimulus intensity is adjusted until the cell produces a criterion response, here 1 mV. The curve thus reflects the threshold of the cell for stimulation over a range of frequencies. Each cell is most sensitive to a specific frequency, its characteristic frequency. The threshold rises briskly—the sensitivity falls rapidly—as the stimulus frequency is raised or lowered. The characteristic frequency depends on the position of the hair cell along the longitudinal axis of the cochlea. (Reproduced, with permission, from Kiang 1980. Copyright © 1980 Acoustical Society of America.)

In the same way as a tuning fork's resonant frequency depends on the size of its tines, the heights of the hair bundles vary systematically along the tonotopic axis. Hair cells that respond to low-frequency stimuli have the tallest bundles, whereas those that respond to the highest-frequency signals possess the shortest bundles. In the human cochlea, for example, an inner hair cell with a characteristic frequency of 20 kHz bears a 4-μm hair bundle. At the opposite extreme, a cell sensitive to a 20-Hz stimulus has a bundle more than 7 μm high. A similar morphological gradient is observed with outer hair cells, supplementing the extrinsic tuning accomplished by the basilar membrane.

Hair Cells Adapt to Sustained Stimulation

Despite the precision with which a hair bundle grows, it cannot develop in such a way that the sensitive transduction apparatus is always perfectly poised at its position of greatest mechanosensitivity. Some mechanism must compensate for developmental irregularities, as well as for environmental changes, by adjusting the gating springs so that transduction channels are responsive to weak stimuli at the bundle's resting position. To ensure this, an adaptation process continuously resets the hair bundle's range of mechanical sensitivity. As a result of adaptation, a hair cell can maintain a high sensitivity to transient stimuli while rejecting static inputs a million times as large.

Adaptation manifests itself as a progressive decrease in the receptor potential during protracted deflection of the hair bundle (Figure 26–12). The process is not one of desensitization, for the responsiveness of the receptor persists. Instead, during a prolonged step stimulus, the sigmoidal relationship between the initial receptor potential and the bundle's position shifts in the direction of the applied stimulus. As a result, the membrane potential of the hair cell progressively returns to near its resting value. Adaptation is incomplete, however; the relation between the membrane potential and the bundle position shifts by approximately 80% of the deflected position.

How does adaptation occur? Because the mechanical force exerted by a hair bundle changes as adaptation proceeds, the process evidently involves an adjustment in the tension borne by the gating springs. It appears likely that the structure anchoring the upper end of each tip link, the *insertional plaque,* is repositioned during adaptation by an active molecular motor (Figure 26–12). The transduction channels are inherently more stable in a closed state, for they close when the tip links are disrupted. A motor is thus also required to maintain a significant fraction (10%–50%) of the transduction channels open at rest by continuously pulling on the gating springs. Several dozen myosin molecules associated with the upper end of each tip link are thought to maintain tension by ascending the actin core of the stereocilium and pulling the link's insertion with them.

When a stimulus step increases the tension in a gating spring, the associated transduction channel opens, permitting an influx of cations. As Ca^{2+} ions accumulate in the stereociliary cytoplasm, they reduce the upward force of the myosin molecules, thereby shortening the gating spring. When the spring reaches its resting tension, closure of the channel reduces the Ca^{2+} influx to its original level, restoring a balance between the upward force of myosin and the downward tension in the spring.

Hair bundles contain at least five isoforms of myosin, the motor molecule associated with motility along actin filaments (Chapter 31). In vestibular hair cells, immunohistochemical studies and site-directed mutagenesis implicate myosin 1c in adaptation. In cochlear hair cells, the role of myosin 1c in adaptation has remained elusive. Another motor protein, myosin 7a, is present near the upper insertion point of the tip link and mutations in the corresponding gene (*USH1B*) are associated with deafness. Hair-cell bundles defective for myosin 7a are disorganized, suggesting that this motor is involved at least in hair-bundle development.

If it were only to set the operating point of the transduction apparatus, adaptation could afford to operate on much slower timescales than the period of acoustic stimuli. This is the case in response to large deflections of the hair bundle, for which the time constant of adaptation is approximately 20 ms or more when endolymph bathes the hair bundle. This slow adaptation is compatible with the activity of a myosin-based motor driven by the cyclical hydrolysis of adenosine triphosphate (ATP). Yet, after being pulled open by an excitatory step stimulus of small magnitude, transduction channels reclose with typical timescales of less than 1 ms and thus short enough to be compatible with auditory frequencies. Current models posit that Ca^{2+} ions entering a hair cell through a transduction channel bind to or near the channel's pore, thereby energetically favoring channel closure. The kinetics of this fast adaptation varies systematically along the tonotopic axis of auditory organs, indicating that adaptation may help in setting the hair cell's characteristic frequency of maximal responsiveness. In addition, the reciprocal relationship between channel gating and tip-link tension means that adaptive channel rearrangements evoke internal forces that drive active hair-bundle movements. The mechanical correlate of adaptation

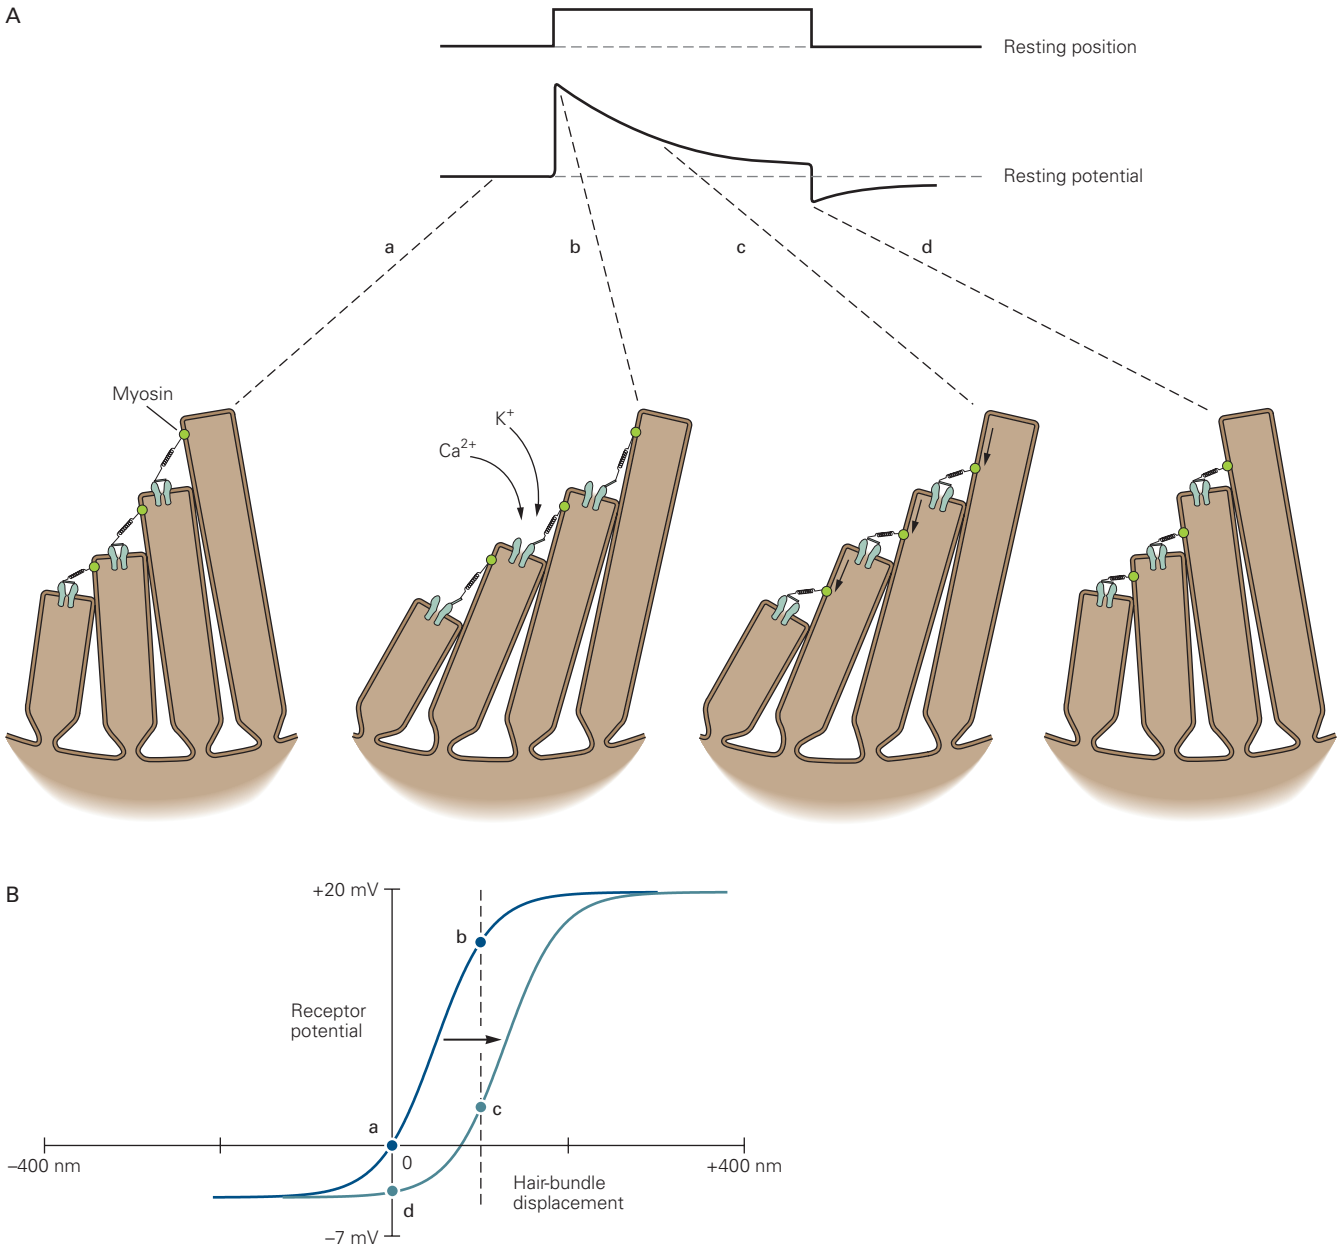

Figure 26–12 Adaptation of mechanoelectrical transduction in hair cells. **A.** Prolonged deflection of the hair bundle in the positive direction (**upper trace**) elicits an initial depolarization followed by a decline to a plateau and an undershoot at the cessation of the stimulus (**lower trace**). The four schematic hair-cell bundles illustrate the states of the transduction channels before (**a**) and during the illustrated phases of the adaptation (**b–d**). Initially, the stimulation increases tension in the tip link (second bundle), thus opening transduction channels. As stimulation continues, however, a tip link's upper attachment is thought to slide down the stereocilium, allowing each channel to close during adaptation (third bundle). Prolonged deflection of the hair bundle in the negative direction elicits a complementary response. The cell is slightly hyperpolarized at first but shows a rebound depolarization at the end of stimulation; tension is restored to the initially slack tip link as myosin molecules actively pull up the link's upper insertion. **B.** As adaptation proceeds, the sigmoidal relation between hair bundle displacement and the receptor potential of the hair cell shifts to the right along the abscissa, in the direction of the new hair-bundle position (**dashed line**), without substantial changes in the curve's shape or amplitude. The shift explains why the receptor potential decreases over time as shown in **A** between states **b** and **c**, restoring the membrane potential of the hair cell to near its value when there is no stimulus. This result implies that adaptation restores mechanical sensitivity to small rapid deflections of the hair bundle in the presence of a protracted stimulus that would otherwise saturate mechanoelectrical transduction. The four states of the transduction channels shown in **A** are marked (**a–d**). (Adapted, with permission, from Hudspeth and Gillespie 1994.)

thus provides feedback that can enhance the stimulus to the hair cell.

Sound Energy Is Mechanically Amplified in the Cochlea

The inner ear faces an important obstacle to efficient operation: A large portion of the energy in an acoustic stimulus goes into overcoming the damping effects of cochlear liquids on hair-cell and basilar-membrane motion rather than into excitation of hair cells. The sensitivity of the cochlea is too great, and auditory frequency selectivity too sharp, to result solely from the inner ear's passive mechanical properties. The cochlea must therefore possess some means of actively amplifying sound energy.

One indication that amplification occurs in the cochlea comes from measurements of the basilar membrane's movements with sensitive laser interferometers. In a preparation stimulated with low-level sound, the basilar-membrane motion is highly dependent on frequency. The movement is maximal at the appropriate frequency for the position at which the measurement is made—the characteristic frequency—but drops abruptly at higher or lower frequencies. As the sound level is increased, however, the frequency selectivity of the vibration becomes less sharp; the peak in the relationship between amplitude and frequency broadens. In addition, the membrane's sensitivity to sound, defined as the vibration amplitude per unit of sound pressure, declines precipitously. When stimulated at the characteristic frequency, the sensitivity of basilar-membrane motion to stimulation at 80 dB SPL is less than 1% of that for 10 dB SPL excitation. The basilar membrane displays a compressive nonlinearity that accommodates the millionfold variation of sound pressure that characterizes audible sounds (0–120 dB SPL) into only two to three orders of magnitude of vibration amplitude (±0.3–300 nm). The sensitivity and frequency selectivity predicted in modeling studies of a passive cochlea correspond to those observed with high-level stimuli. This result implies that the motion of the basilar membrane is augmented more than 100-fold during low-level stimulation at the characteristic frequency, but that amplification diminishes progressively as the stimulus grows in strength. Consequently, amplification lowers the threshold of hearing by more than 40 to 50 dB SPL.

In addition to this circumstantial evidence, experimental observations support the idea that the cochlea contains a mechanical amplifier. When a normal human ear is stimulated with a click, that ear emits one to several measurable pulses of sound within

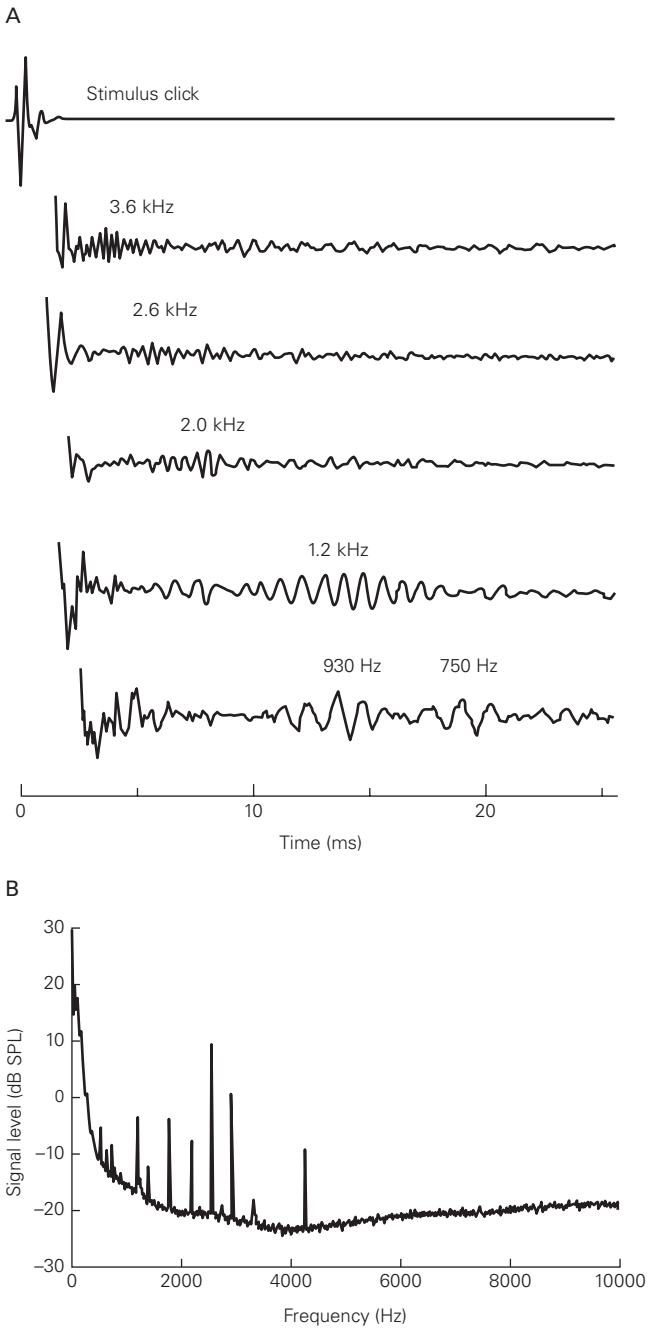

Figure 26–13 The cochlea actively emits sounds.

A. The records display evoked otoacoustic emissions from the ears of five human subjects. A brief click (**top trace**) was played into each ear through a miniature speaker. A few milliseconds later, a tiny microphone in the external auditory meatus detected one or more bursts of sound emission from the ear. (Adapted, with permission, from Wilson 1980. Copyright © 1980 Elsevier B.V.)

B. Under suitably quiet recording conditions, spontaneous otoacoustic emissions occur in most normal human ears. This spectrum displays the acoustic power of six prominent emissions and several smaller ones from one ear. (Reproduced, with permission, from Murphy et al. 1995. Copyright © 1995, Acoustical Society of America.)

milliseconds (Figure 26–13A). Because they can carry more energy than the stimulus, these so-called *evoked otoacoustic emissions* cannot simply be echoes; they represent the emission of mechanical energy by the cochlea, triggered by acoustic stimulation. In accordance with the compressive nonlinearity associated with cochlear amplification, the relative level of the emissions decreases with the stimulus level.

A still more compelling manifestation of the cochlea's active amplification is *spontaneous otoacoustic emission.* When a suitably sensitive microphone is used to measure sound pressure in the ear canals of subjects in a quiet environment, at least 70% of normal human ears continuously emit one or more pure tones (Figure 26–13B). Although these sounds are generally too faint to be directly audible by others, physicians have reported actually hearing sounds emanating from the ears of newborns!

What is the source of evoked and spontaneous otoacoustic emissions, and thus presumably of cochlear amplification as well? Several lines of evidence implicate outer hair cells as the elements that enhance cochlear sensitivity and frequency selectivity and hence act as the motors for amplification. The afferent nerve fibers that extensively innervate the inner hair cells make only minimal contacts with the outer hair cells (Figure 26–4). Instead, the outer hair cells receive an extensive efferent innervation that, when activated, decreases cochlear sensitivity and frequency discrimination. In addition, when stimulated electrically, an isolated outer hair cell displays the unique phenomenon of electromotility: The cell body shortens by up to several micrometers when depolarized and elongates when hyperpolarized (Figure 26–14). This response can occur at frequencies exceeding 80 kHz, an attractive feature for a process postulated to assist high-frequency hearing.

The energy for these movements is drawn from the experimentally imposed electrical field rather than from hydrolysis of an energy-rich substrate such as ATP. Movement occurs when changes in the electric field across the membrane reorient molecules of the protein prestin. The concerted movement of several million of these molecules, which are packed in the lateral cell membranes of outer hair cells, changes the membrane's area and thus the cell's length. When an outer hair cell transduces mechanical stimulation of its hair bundle into receptor potentials, cochlear amplification might then occur when voltage-induced movement of the cell body augments basilar-membrane motion. Consistent with this hypothesis, mutation of certain amino acid residues required for the voltage sensitivity of prestin abolishes the active process in mice.

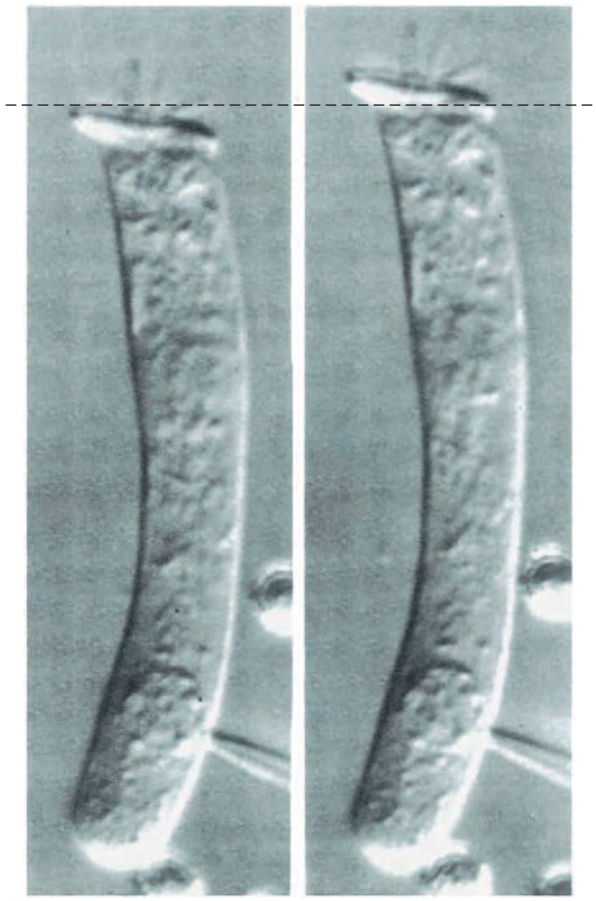

Figure 26–14 Voltage-induced motion of an outer hair cell. Depolarization of an isolated outer hair cell through the electrode at its base causes the cell body to shorten (*left*); hyperpolarization causes it to lengthen (*right*). The oscillatory motions of outer hair cells may provide the mechanical energy that amplifies basilar-membrane motion and thus enhances the sensitivity of human hearing. (Reproduced, with permission, from Holley and Ashmore 1988.)

Because sharp frequency selectivity, high sensitivity, and otoacoustic emissions are also observed in animal species that lack outer hair cells and lack high concentrations of prestin, electromotility cannot be the only form of mechanical amplification by hair cells. In addition to detecting stimuli, hair bundles are also mechanically active and contribute to amplification. Hair bundles can make spontaneous back-and-forth movements that have been shown in some nonmammals to underlie spontaneous otoacoustic emissions. Under experimental conditions, bundles can exert force against stimulus probes, performing mechanical work and thereby amplifying the input. In vitro experiments indicate that active hair-bundle motility

contributes to the cochlear active process even in the mammalian ear.

Active hair-bundle movements can be fast enough to mediate otoacoustic emissions at sound frequencies at least as high as a few kilohertz. However, it remains uncertain whether bundles can generate forces at the very high frequencies at which sharp frequency selectivity and otoacoustic emissions are observed in the mammalian cochlea. Active hair-bundle motility and somatic electromotility may function synergistically, with the former serving metaphorically as a tuner and preamplifier and the latter as a power amplifier. Alternatively, hair-bundle motility may dominate at relatively low frequencies but be superseded by electromotility at higher frequencies.

Cochlear Amplification Distorts Acoustic Inputs

When stimulated by two tones at nearby frequencies f_1 and f_2 ($f_1 < f_2$), the basilar membrane vibrates not only at these frequencies but also at additional frequencies—the distortion products—that are not present in the acoustic stimulus. As reported by the Italian violinist Giuseppe Tartini in the 18th century, distortion products can be heard as phantom tones in the auditory percept. Remarkably, the cubic difference tone $2f_1 - f_2$ is heard even at very low sound levels, and its magnitude grows in proportion to the stimulus. Correspondingly, the relative level of distortion remains practically constant over a broad range of sound levels. This phenomenon is explained by the particular form of the compressive nonlinearity associated with cochlear amplification. Clearly, the cochlea does not work as a high-fidelity sound receiver. Distorted cochlear vibrations are strong enough to be reemitted from the ear canal as *distortion-product otoacoustic emissions*. Because they are a property of healthy ears, these emissions are extensively used to screen hearing in newborns.

The Hopf Bifurcation Provides a General Principle for Sound Detection

Detailed in vivo and in vitro studies have revealed four cardinal features of auditory responsiveness. First, an active amplification process lowers the detection threshold. Second, because amplification operates only near a characteristic frequency, the input to the sensory system is actively filtered, which sharpens frequency selectivity. Third, for stimulation near the characteristic frequency, the response displays a compressive nonlinearity that represents a wide range of stimulus levels by a much narrower range of vibration amplitudes. Finally, even in the absence of a stimulus, mechanical activity can produce self-sustained oscillations that result in otoacoustic emissions.

These features have been recognized as signatures of an active dynamical system—a critical oscillator—that operates on the verge of an oscillatory instability termed the Hopf bifurcation (Box 26–1). They are generic: They do not depend on the subcellular and molecular details of the candidate mechanism that brings the system to the brink of spontaneous oscillation. The fact that active hair-bundle motility demonstrates a Hopf bifurcation in vitro provides further evidence that this mechanism contributes to cochlear amplification.

Within this framework, the characteristic frequency is set by that of the critical oscillator. The cochlear partition may be viewed as a set of active oscillatory modules that are hydrodynamically coupled by the cochlear fluids and with characteristic frequencies tonotopically distributed along the longitudinal axis of the cochlea. The hypothesis of critical oscillation facilitates modeling of the traveling wave and cochlear amplification. This is because the generic behaviors of a critical oscillator can be described by a single equation termed the "normal form" (Box 26–1). A critical oscillator is ideally suited for auditory detection, even if its inherent nonlinearity yields pronounced distortions in response to complex sound stimuli. Nonlinear interference between the frequency components of complex stimuli in fact appears as a necessary price to pay for the exquisite sensitivity, sharp frequency selectivity, and wide dynamic range of auditory detection afforded by a critical oscillator. The Hopf bifurcation provides generic properties that account for numerous disparate experimental observations at the level of a single hair bundle, of the basilar membrane, and even in psychoacoustics. This physical principle of auditory detection thus greatly simplifies our understanding of hearing. Although this chapter focusses primarily on mammalian hearing, the common necessity to hear with high sensitivity and sharp frequency selectivity poses similar physical constraints to the ears of all land vertebrates. These constraints have led to the independent evolution of ears that share similar structural features and whose operation is based on similar physical principles, including the use of critical oscillators to amplify sound (Box 26–2).

Hair Cells Use Specialized Ribbon Synapses

Being sensory receptors, hair cells form synapses with sensory neurons. The basolateral membrane of each cell contains several presynaptic active zones at which

Box 26–1 Generic Properties Near a Hopf Bifurcation

A dynamical system displays a Hopf bifurcation when it abruptly transits from quiescence to a state of spontaneous oscillation while subject to continuous variation of a control parameter C. If the system is poised in the vicinity of the critical point, at which $C = C_C$, its steady-state response to sinusoidal forces can be described by a single equation—the "normal form"—of a complex variable Z:

$$\Lambda \frac{dZ}{dt} \cong -\Lambda(C_c - C - 2i\pi f_c)Z - B|Z|^2 Z + F \qquad \textbf{(26–1)}$$

Here, the real part of Z may represent the position of the basilar membrane or of the hair bundle, Λ is a friction coefficient, and F is the external force provided by a sound stimulus. In the absence of an external force ($F = 0$), spontaneous oscillations emerge when the control parameter becomes larger than the critical value C_C (Figure 26-15A); the parameter f_C corresponds to the frequency of spontaneous oscillation at the critical point. A Hopf bifurcation must be driven by an active process, whereby the system mobilizes internal resources of energy to power spontaneous movements. A system operating precisely at the critical point is called a critical oscillator. The response of a critical oscillator to sinusoidal stimuli is endowed with generic properties (Figure 26–15B,C) that are characteristic of sound detection in the ear.

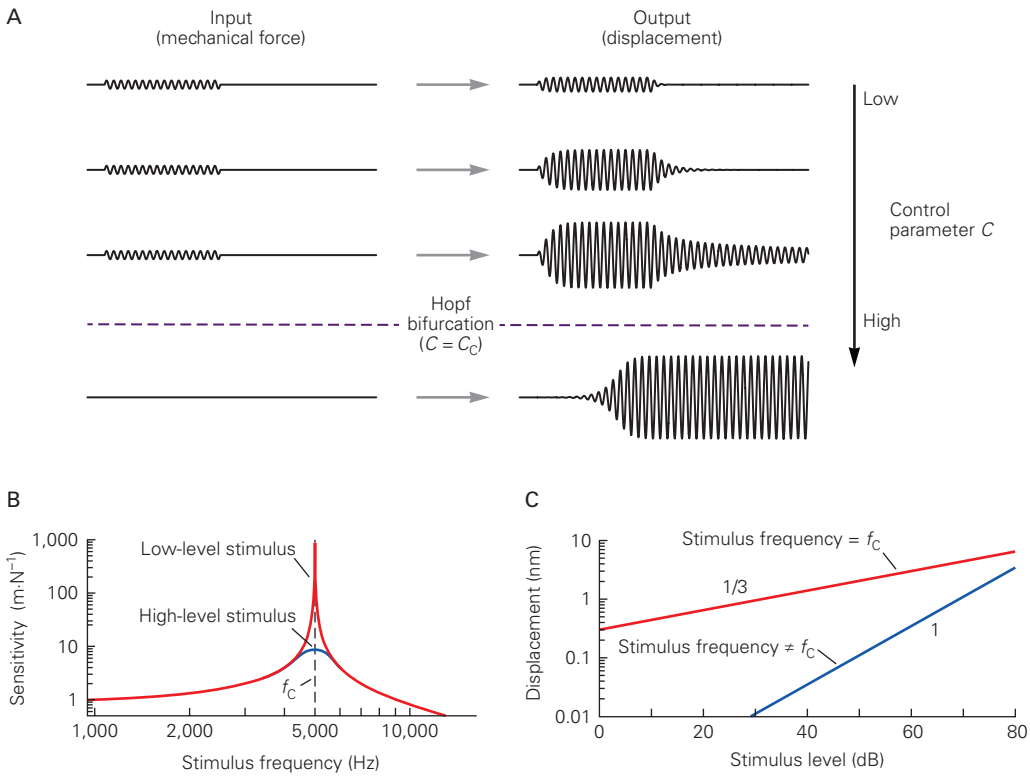

Figure 26–15 Frequency-selective amplification near a Hopf bifurcation.

A. As the control parameter C increases to approach the critical value C_C, the response to a sinusoidal stimulus of constant amplitude increases: The system gets more sensitive. For $C > C_C$, the system oscillates spontaneously at a constant amplitude and frequency, even if no stimulus is applied. The Hopf bifurcation corresponds to $C = C_C$. (Reproduced, with permission, from Hudspeth 2014.)

B. When the system is poised at the bifurcation ($C = C_C$), the sensitivity to a low-level stimulus is greatly enhanced near the characteristic frequency f_C (here 5000 Hz; **dashed line**), but drops rapidly if the stimulus is detuned from this frequency (**red line**). For a stimulus 60 dB more intense, the maximal sensitivity is 100-fold lower, and the peak in sensitivity is 100-fold broader (**blue line**): A critical oscillator enhances the weakest stimuli much more than the strongest and with much sharper frequency selectivity. (Adapted, with permission, from Hudspeth, Jülicher, and Martin 2010.)

C. At the characteristic frequency f_C, the response—here displacement—displays a compressive growth that corresponds to a line of slope 1/3 in this doubly logarithmic plot (**red line**): A large range of stimulus levels is represented by a much narrower range of response amplitudes. In contrast, when the frequency of the stimulus departs significantly from the characteristic frequency (**blue line**), the response is proportional to the input, corresponding to a line of slope unity. By amplifying weak inputs near its characteristic frequency, the critical oscillator lowers the stimulus level required to elicit a threshold vibration, here by 60 dB for a threshold of 0.3 nm. (Adapted, with permission, from Hudspeth, Jülicher, and Martin 2010.)

Box 26–2 The Evolutionary History of Hearing Resulted in Similarities Between Groups

Mammals are not alone in possessing sensitive and frequency-selective hearing. Amphibians and reptiles, including birds, also do. It is a remarkable fact that these various groups of land vertebrates actually acquired their good hearing systems largely independently. The small, dedicated auditory receptor organ was present in the inner ear of their common ancestor. Much later, the ancestors of modern lizards, birds, and mammals each independently evolved middle-ear systems with eardrums collecting sound from the outside world. Some species, such as birds and their relatives, even evolved two groups of sensory hair cells that have a division of labor similar to that of mammalian inner and outer hair cells. Comparison of middle-ear and inner-ear structures and functions across all living vertebrate groups has revealed that they share many common features and that hearing performance is largely comparable between them. Sound amplification associated with active hair-bundle motility was already present in the very first hair cells that evolved, even before the first fishes. This amplifying system was inherited by all groups and, as described earlier, plays a critical role in improving hearing sensitivity and sharpening frequency selectivity. The greatest difference between mammals and the other groups is that the upper frequency limit of hearing is generally higher in mammals. Nonmammalian ears are limited in response to frequencies lower than about 12 to 14 kHz, whereas some mammals can hear beyond 100 kHz.

In addition to active hair-bundle motility, the second mechanism that tunes individual hair cells to specific frequencies in many nonmammalian ears is electrical in nature. In many fishes, amphibians, and birds, the membrane potential of each hair cell resonates at a particular frequency. Several factors, including alternative splicing of the mRNA encoding cochlear K^+ channels and expression of these channels' auxiliary β subunit, tune the characteristic frequency of the resonance along the tonotopic axis of the auditory organ. Whether electrical resonance contributes to frequency tuning in the ears of mammals, including humans, remains uncertain. It is plausible that mammalian hair cells use instead an interplay between somatic electromotility, which seems absent in nonmammalian species, and the micromechanical environment, including hair-bundle motility, to actively amplify and filter their inputs.

The key signatures of a Hopf bifurcation have been recognized in spontaneous mechanical oscillations of the hair bundle, in electrical oscillations of the membrane potential, and in sound-evoked vibration of the basilar membrane. It is likely that the parallel evolution of hearing organs in different groups of vertebrates resulted in several ways of benefitting from the generic properties of critical oscillation.

chemical neurotransmitter is released. An active zone is characterized by four prominent morphological features (Figure 26–16).

A presynaptic dense body or synaptic ribbon lies in the cytoplasm adjacent to the release site. This fibrillar structure may be spherical, ovoidal, or flattened, and usually measures a few hundred nanometers across. The dense body resembles the synaptic ribbon of a photoreceptor cell and represents a specialized elaboration of the smaller presynaptic densities found at many other synapses. In addition to molecular components shared with conventional synapses, ribbon synapses contain large amounts of the protein ribeye.

The presynaptic ribbon is surrounded by clear synaptic vesicles, each 35 to 40 nm in diameter, which are attached to the dense body by tenuous filaments. Between the dense body and the presynaptic cell membrane lies a striking presynaptic density that comprises several short rows of fuzzy-looking material. Within the cell membrane, rows of large particles are aligned with the strips of presynaptic density. These particles include the Ca^{2+} channels involved in the release of transmitter as well as the K^+ channels that participate in electrical resonance in nonmammalian vertebrates.

Studies of nonmammalian experimental models show that, as with most other synapses (Chapter 15), the release of transmitter by hair cells is evoked by presynaptic depolarization and requires influx of Ca^{2+} from the extracellular medium. Hair cells lack synaptotagmins 1 and 2, however, and the role of those proteins as rapid Ca^{2+} sensors has probably been assumed by the protein otoferlin, which also promotes the replenishment of synaptic vesicles. Although glutamate is the principal afferent neurotransmitter, other substances are released as well.

The presynaptic apparatus of hair cells has several unusual features that underlie the signaling abilities of

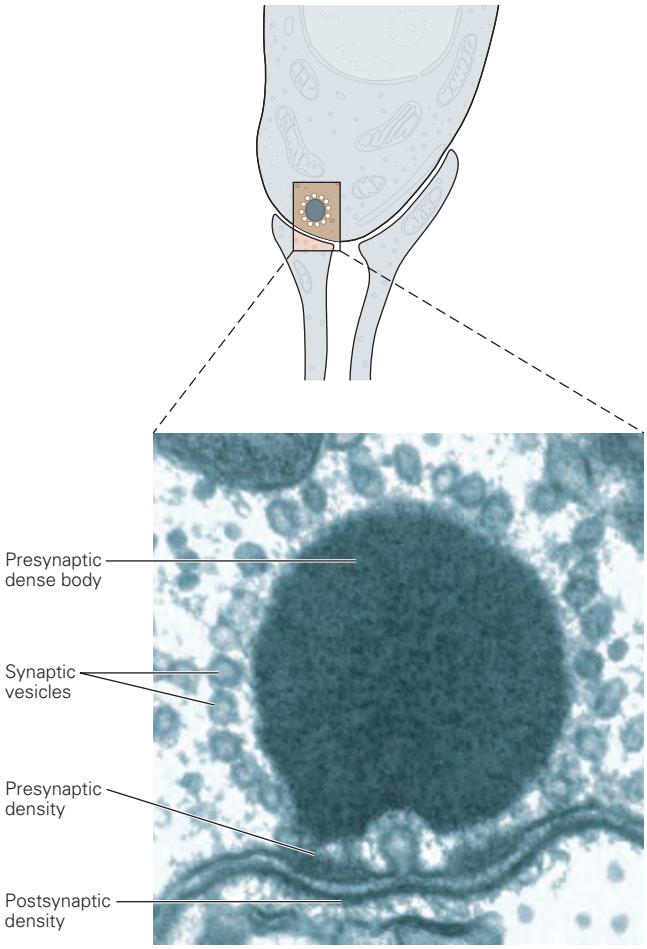

Figure 26–16 The presynaptic active zone of a hair cell. This transmission electron micrograph shows the spherical presynaptic dense body or synaptic ribbon that is characteristic of the hair cell's presynaptic active zone. It is surrounded by clear synaptic vesicles. Beneath the ribbon lies a presynaptic density, in the middle of which one vesicle is undergoing exocytosis. A modest postsynaptic density lies along the inner aspect of the plasmalemma of the afferent terminal. (Reproduced, with permission, from Jacobs and Hudspeth 1990.)

these cells. At rest, inner hair cells continuously release synaptic transmitter. The rate of transmitter release can be modulated upward or downward, depending on whether the hair cell is respectively depolarized or hyperpolarized. Consistent with this observation, some Ca^{2+} channels of hair cells are activated at the resting potential, providing a steady leak of Ca^{2+} that evokes transmitter release from unstimulated cells. Another unusual feature of the hair cell's synapses is that, like those of photoreceptors, they must be able to release neurotransmitter reliably in response to a threshold receptor potential of only 100 μV or so. This feature, too, depends on the fact that the presynaptic Ca^{2+} channels are activated at the resting potential.

Outer hair cells receive inputs from neurons in the brainstem in the form of large boutons on their basolateral surfaces (Figure 26–4). This efferent system desensitizes the cochlea by hyperpolarizing outer hair cells, which turns down the active process. The efferent terminals contain numerous clear synaptic vesicles about 50 nm in diameter, as well as a smaller number of larger, dense-core vesicles. The principal transmitter at these synapses is acetylcholine (ACh); calcitonin gene–related peptide (CGRP) also occurs in efferent terminals and may be co-released with ACh. ACh binds to nicotinic ionotropic receptors consisting of α9 and α10 subunits that have a substantial permeability to Ca^{2+} as well as to Na^+ and K^+. The Ca^{2+} that enters through these channels activates small-conductance Ca^{2+}-sensitive K^+ channels (SK channels), whose opening leads to a protracted hyperpolarization. The cytoplasm of a hair cell immediately beneath each efferent terminal holds a single cisterna of smooth endoplasmic reticulum. This structure may be involved in the reuptake of the Ca^{2+} that enters the cytoplasm in response to efferent stimulation, thus accelerating the return to the cell's resting potential.

Auditory Information Flows Initially Through the Cochlear Nerve

Bipolar Neurons in the Spiral Ganglion Innervate Cochlear Hair Cells

Information flows from cochlear hair cells to neurons whose cell bodies lie in the cochlear ganglion. The central processes of these bipolar neurons form the cochlear division of the vestibulocochlear nerve (eighth cranial nerve). Because this ganglion follows a spiral course around the bony core of the cochlea, it is also called the *spiral ganglion.* Approximately 30,000 ganglion cells innervate the hair cells of each inner ear.

The afferent pathways from the human cochlea reflect the functional distinction between inner and outer hair cells. At least 90% of the spiral ganglion cells terminate on inner hair cells (Figure 26–17). Each axon contacts only a single inner hair cell, but each cell directs its output to many nerve fibers, on average nearly 10. This arrangement has three important consequences.

First, the neural information from which hearing arises originates almost entirely at inner hair cells. Second, because the output of each inner hair cell is

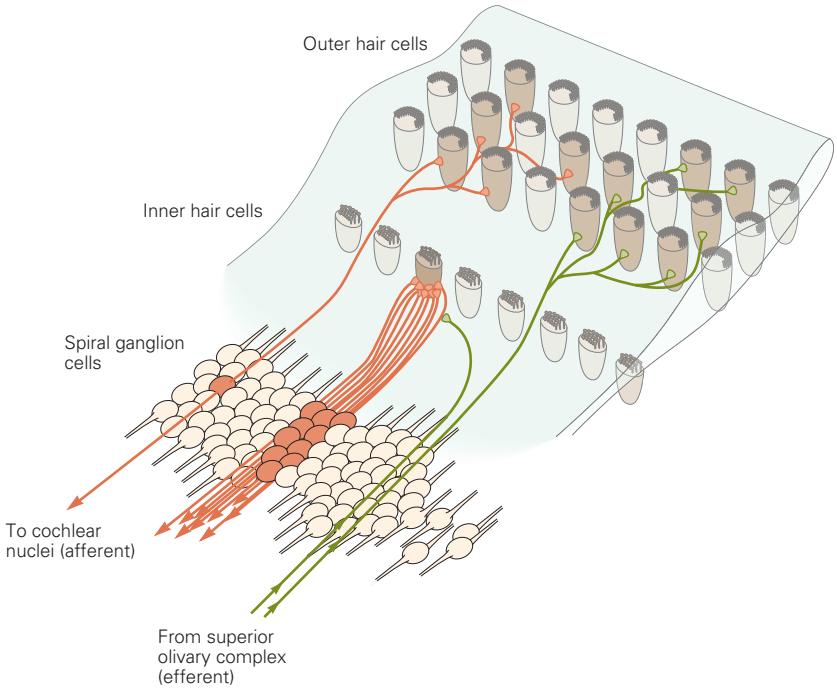

Figure 26–17 Innervation of cochlear hair cells. The great majority of sensory axons (**orange**) in the cochlea carry signals from inner hair cells, each of which constitutes the sole input to an average of 10 axons. A few sensory axons of small caliber transmit information from the outer hair cells. Efferent axons (**green**) largely innervate the outer hair cells and do so directly. In contrast, efferent innervation of inner hair cells is sparse and occurs on the sensory axon terminals. (Adapted, with permission, from Spoendlin 1974.)

sampled by many afferent nerve fibers, the information from one receptor is encoded independently in parallel channels. Third, at any point along the cochlear spiral, or at any position within the spiral ganglion, each ganglion cell responds best to stimulation at the characteristic frequency of the presynaptic hair cell. The tonotopic organization of the auditory neural pathways thus begins at the earliest possible site, immediately postsynaptic to inner hair cells.

Relatively few cochlear ganglion cells contact outer hair cells, and each such neuron extends branching terminals to numerous outer hair cells. Although the ganglion cells that receive input from outer hair cells are known to project into the central nervous system, these neurons are so few that it is not certain whether their projections contribute significantly to the analysis of sound.

The patterns of efferent and afferent connections of cochlear hair cells are complementary. Mature inner hair cells do not receive efferent input; just beneath these cells, however, are extensive axo-axonic synaptic contacts between efferent axon terminals and the endings of afferent nerve fibers. In contrast, other efferent nerves have extensive connections with outer hair cells on their basolateral surfaces. Each outer hair cell receives input from several large efferent terminals, which fill most of the space between the cell's base and the associated supporting cell, leaving little space for afferent terminals.

Cochlear Nerve Fibers Encode Stimulus Frequency and Level

The acoustic sensitivity of axons in the cochlear nerve mirrors the connection pattern of the spiral ganglion cells to the hair cells. Each axon is most responsive to a characteristic frequency. Stimuli of lower or higher frequency also evoke responses, but only when presented at greater levels. An axon's responsiveness may be characterized by a frequency selectivity, or tuning, curve, which is V-shaped like the curves for basilar-membrane motion and hair-cell sensitivity (Figure 26–11). The tuning curves for nerve fibers with different characteristic frequencies resemble one another but are shifted along the frequency axis.

The relationship between sound level in decibels SPL and firing rate in each fiber of the cochlear nerve is approximately linear. Because of the dependence of decibel level on sound pressure, this relation implies that sound pressure is logarithmically encoded by neuronal activity. At the upper end of a fiber's dynamic range, very loud sounds saturate the response. Because an action potential and the subsequent refractory period each last almost 1 ms, the greatest sustainable firing rate is about 500 spikes per second.

Even among nerve fibers with the same characteristic frequency, the threshold of responsiveness varies from axon to axon. The most sensitive fibers, whose response thresholds extend down to approximately

0 dB SPL, characteristically have high rates of spontaneous activity and produce saturating responses for stimulation at moderate intensities, approximately 30 dB SPL. At the opposite extreme, the least sensitive afferent fibers have very little spontaneous activity and much higher thresholds, but respond in a graded fashion to levels even in excess of 100 dB SPL. The activity patterns of most fibers range between these extremes.

The afferent neurons of lowest sensitivity contact the surface of an inner hair cell nearest the axis of the cochlear spiral. The most sensitive afferent neurons, on the other hand, contact the hair cell's opposite side. The multiple innervation of each inner hair cell is therefore not redundant. Instead, the output from a given hair cell is directed into parallel channels of differing sensitivity and dynamic range.

The firing pattern of fibers in the eighth cranial nerve exhibits both phasic and tonic components. Brisk firing occurs at the onset of a tone but, as adaptation occurs, the firing rate declines to a plateau level over a few tens of milliseconds. When stimulation ceases, there is usually a transitory cessation of activity with a similar time course to that of adaptation, before gradual resumption of the spontaneous firing rate (Figure 26–18).

When a periodic stimulus such as a pure tone is presented, the firing pattern of a cochlear nerve fiber encodes information about the periodicity of the stimulus. For example, a relatively low-frequency tone at a moderate intensity might produce one spike in a nerve fiber during each cycle of stimulation. The phase of firing is also stereotyped. Each action potential might occur, for example, during the compressive phase of the stimulus. As the stimulation frequency rises, the stimuli eventually become so rapid that the nerve fiber can no longer produce action potentials on a cycle-by-cycle basis. Up to a frequency in excess of 3 kHz, however, phase-locking persists; a fiber may produce an action potential only every few cycles of the stimulus, but its firing continues to occur at a particular phase in the stimulus cycle.

Periodicity in neuronal firing enhances the information about the stimulus frequency. Any pure tone of sufficient level evokes firing in numerous cochlear nerve fibers. Those fibers whose characteristic frequency coincides with the frequency of the stimulus respond at the lowest stimulus level, but respond still more briskly for stimuli of moderate intensity. Other nerve fibers with characteristic frequencies further from the stimulus also respond, although less vigorously. Regardless of their characteristic frequencies, however, all the responsive fibers may display phase

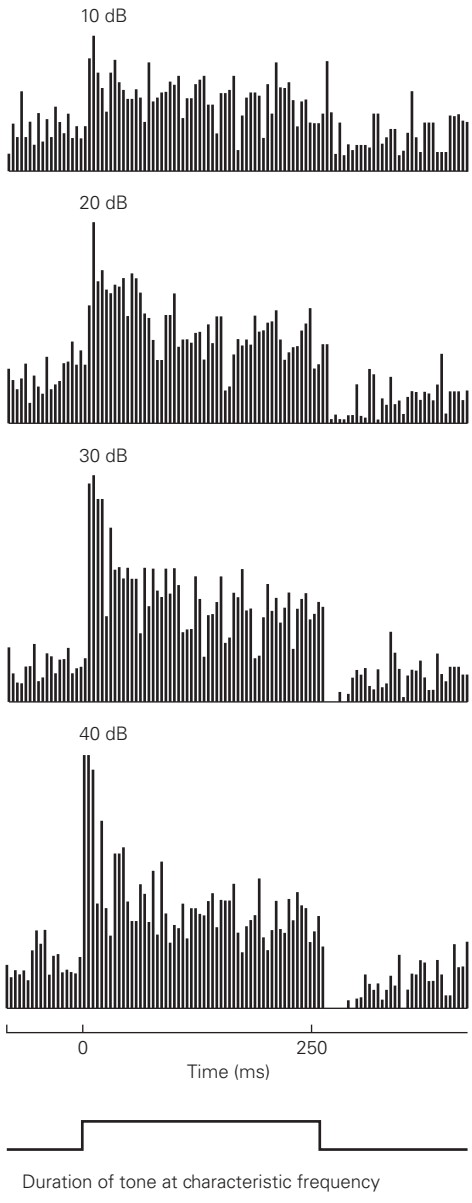

Figure 26–18 The firing pattern of a cochlear nerve fiber. A cochlear nerve fiber is stimulated for somewhat more than 250 ms with a tone burst at about 5 kHz, the cell's characteristic frequency. After a quiet period, the stimulus is repeated. Histograms show the average response patterns of the fiber as a function of stimulus level. The sample period is divided into discrete temporal bins, and the number of spikes occurring in each bin is displayed. An initial, phasic increase in firing is correlated with the onset of the stimulus. The discharge continues during the remainder of the stimulus during adaptation, but decreases following termination. This pattern is evident when the stimulus is 20 dB or more above threshold. Activity gradually returns to baseline during the interval between stimuli. (Adapted, with permission, from Kiang 1965.)

locking: Each tends to fire during a particular part of the stimulus cycle.

The central nervous system can therefore gain information about stimulus frequency in two ways. First, there is a *place code*: The fibers are arrayed in a tonotopic map in which the position is related to characteristic frequency. Second, there is a *frequency code*: The phase-locked firing of the fiber provides information about the frequency of the stimulus, at least for frequencies below 3 kHz.

Sensorineural Hearing Loss Is Common but Is Amenable to Treatment

Whether mild or profound, most deafness falls into the category of *sensorineural hearing loss,* often misnamed "nerve deafness." Although hearing loss can result from direct damage to the eighth cranial nerve, for example from an acoustic neuroma, deafness stems primarily from the loss of cochlear hair cells and their afferent fibers.

The 16,000 hair cells in each human cochlea are not replaced by cell division but must last a lifetime. However, in amphibians and birds, supporting cells can be induced to divide and their progeny to produce new hair cells. In the zebrafish and in birds, some hair cell populations are regenerated continually by the activity of stem or supporting cells. Researchers have recently succeeded in replenishing mammalian hair cells in vitro. Until we understand how hair cells can be restored to the organ of Corti, however, we must cope with hearing loss.

The past few decades have brought remarkable advances in our ability to treat deafness. For the majority of patients who have significant residual hearing, hearing aids can amplify sounds to a level sufficient to activate the surviving hair cells. A modern aid is custom-tailored to compensate for each individual's hearing loss, so that the device amplifies sounds at frequencies to which the wearer is least sensitive, while providing little or no enhancement to those that can still be heard well.

When most or all of a person's cochlear hair cells have degenerated, no amount of amplification can assist hearing. However, a degree of hearing can be restored by bypassing the damaged organ of Corti with a cochlear prosthesis or implant. A user wears a compact unit that picks up sounds, separates their frequency components, and forwards electronic signals representing these constituents along separate wires to small antennae situated just behind the auricle. The signals are then transmitted transdermally to receiving antennae implanted in the temporal bone. From there, fine wires bear the signals to appropriate electrodes implanted as an array in the cochlea at various positions along the scala tympani. Activation of the electrodes excites action potentials in any nearby axons that have survived the degeneration of the hair cells (Figure 26–19).

The cochlear prosthesis takes advantage of the tonotopic representation of stimulus frequency along the cochlea—the *place code* (Figure 26–11 and Chapter 28). The axons innervating each segment of the cochlea are concerned with a specific, narrow range of frequencies. Each electrode in a prosthesis can excite a cluster of nerve fibers that represent similar frequencies. The stimulated neurons then forward their outputs along the eighth nerve to the central nervous system, where these signals are interpreted as a sound of the frequency represented at that position on the basilar membrane. An array of approximately 20 electrodes can mimic a complex sound by appropriately stimulating several clusters of neurons.

The number of implanted cochlear prostheses worldwide is now approaching 350,000. Their effectiveness, however, varies widely from person to person. In the best outcome, an individual can, under quiet conditions, understand speech nearly as well as a normally hearing person and can even conduct telephone conversations. At the other extreme are patients who derive little benefit from prostheses, presumably because of extensive degeneration of the nerve fibers near the electrode array. Most patients find their prostheses of great value. Even if hearing is not completely restored, the devices help in lip reading and alert patients to noises in the environment.

Hearing loss is often accompanied by another distressing symptom, *tinnitus*, or "ringing in the ears." By interfering with concentration and disrupting sleep, tinnitus can exasperate, depress, and even madden its victims. Because on rare occasions tinnitus stems from lesions to the auditory pathways, such as acoustic neuromas, it is important in neurological diagnosis to exclude such causes. Most tinnitus, however, is idiopathic: Its cause is uncertain. More and more studies implicate stress as an important factor. Some drugs also trigger the condition; antimalarial drugs related to quinine and aspirin at the high dosages used in the treatment of rheumatoid arthritis are notorious for this. Often, however, tinnitus occurs at high frequencies to which a damaged ear is no longer sensitive. In these instances, tinnitus may reflect hypersensitivity in the deafferented central nervous system, a phenomenon analogous to phantom limb pain (Chapter 20).

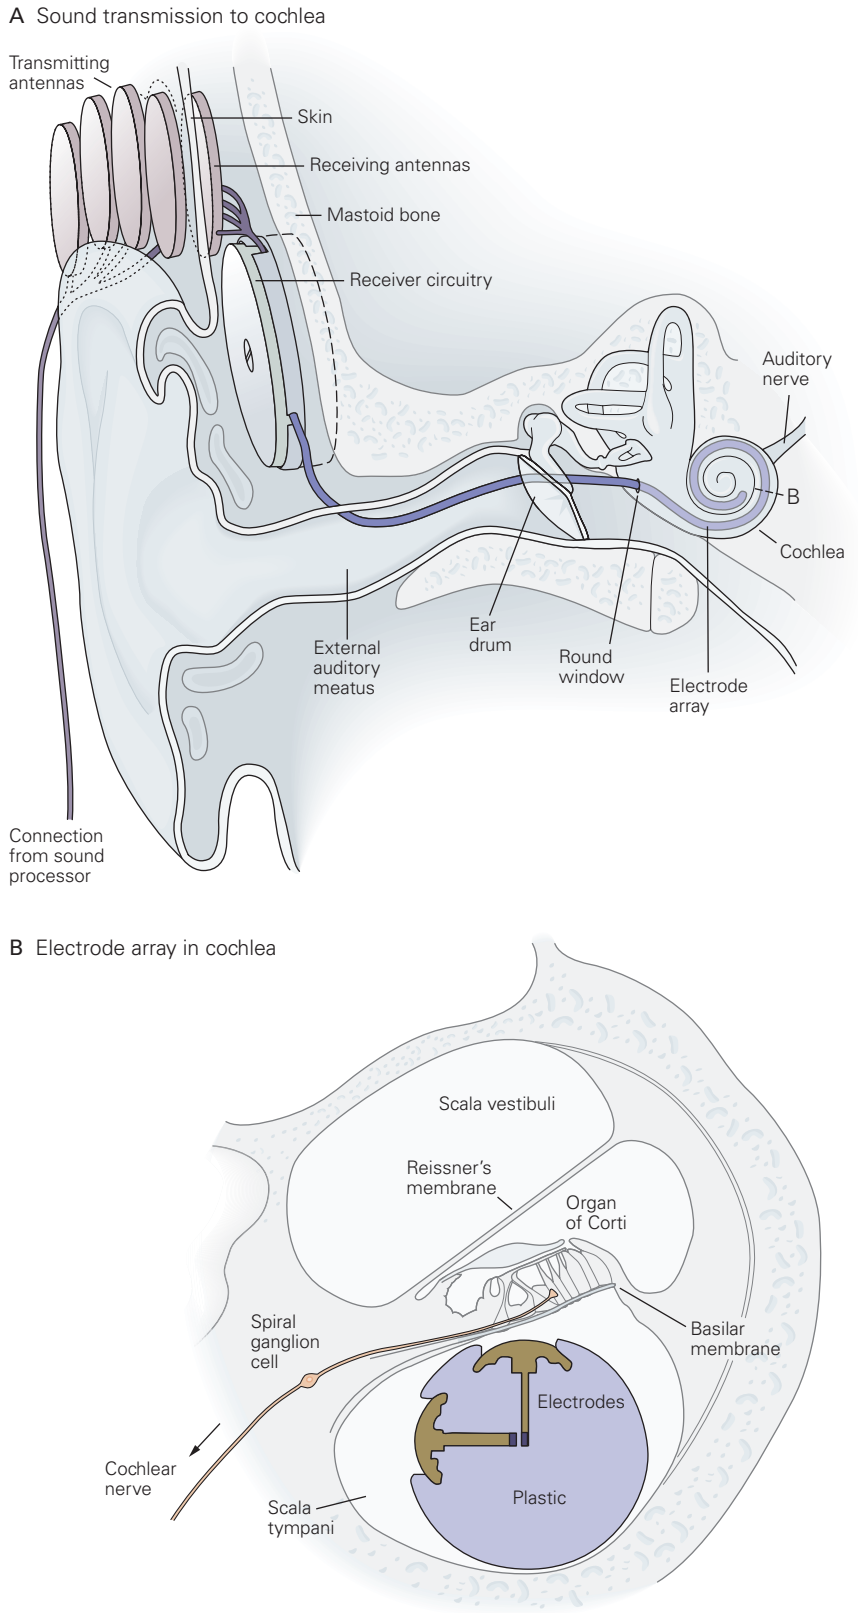

Figure 26–19 A cochlear prosthesis. (Reproduced, with permission, from Loeb et al. 1983.)

A. Transmitting antennas receive electrical signals from a sound processor, located behind the subject's auricle or on the frame of his eyeglasses, and transmit them across the skin to receiving antennas implanted subdermally behind the auricle. The signals are then conveyed in a fine cable (**dark purple**) to an electrode array in the cochlea.

B. This cross section of the cochlea shows the placement of pairs of electrodes in the scala tympani. A portion of the extracellular current passed between an electrode pair is intercepted by nearby cochlear nerve fibers, which are thus excited and send action potentials to the brain.

Highlights

1. Hearing begins with capture of sound by the ear. Mechanical energy captured by the outer ear flows through the middle ear to the cochlea, where it causes the elastic basilar membrane to oscillate.
2. The basilar membrane supports the receptor organ of the inner ear—the organ of Corti, an epithelial strip that contains approximately 16,000 mechanosensory hair cells. Hair cells transduce basilar-membrane vibrations into receptor potentials that cause sensory neurons to fire.
3. The frequency components of a sound stimulus are detected at different locations along the basilar membrane by different hair cells, following a tonotopic map. Mechanical gradients of the basilar membrane contribute to frequency analysis by the cochlea. In addition, each hair cell is tuned at a characteristic frequency according to its morphological, mechanical, and electrical properties, which vary continuously along the tonotopic axis of the cochlea.
4. Hair cells operate much more quickly than do other sensory receptors, which allows them to respond to sound frequencies beyond 100 kHz in some mammalian species. Accordingly, the mechanoelectrical transduction channels in the hair cell are activated directly by mechanical strain.
5. Each hair cell projects from its apical surface a tuft of cylindrical stereocilia—the hair bundle, which works as a mechanical antenna that vibrates in response to sound stimuli. The transduction channels occur at the stereociliary tips. Their open probability is modulated by tension changes in tip links that interconnect neighboring stereocilia.
6. Uniquely among sensory receptors, hair cells amplify their inputs to enhance their sensitivity, sharpen their frequency selectivity, and widen the range of stimulus levels that they can detect. Two forms of cellular motility contribute to this active process. First, receptor potentials evoke length changes of the somata of outer hair cells, a biological analog of piezoelectricity called electromotility. Second, the hair bundle—the mechanosensory antenna of the hair cell—can vibrate autonomously.
7. The ear not only receives sound but also emits sound called otoacoustic emissions. Spontaneous and evoked otoacoustic emissions result from the cochlea's active amplification processes.
8. The cochlea does not work as a high-fidelity sound receiver; instead, it introduces conspicuous distortions that contribute to sound perception. The auditory nonlinearity originates in the cochlea, which amplifies preferentially weak sound stimuli, and constitutes a hallmark of sensitive hearing that is used to screen hearing deficits in newborns.
9. A large variety of experimental observations at the level of a single hair bundle, of the basilar membrane, and in psychoacoustics are readily explained if the cochlea contains active mechanical modules that each operate on the verge of an oscillatory instability—the Hopf bifurcation. The Hopf bifurcation provides a general principle of auditory detection that simplifies our understanding of hearing.
10. The evolutionary history of hearing reveals that the various groups of land vertebrates acquired their hearing systems largely independently, but that their sensitivity and frequency selectivity are similar. In particular, both mammalian and nonmammalian ears benefit from mechanical amplification of sound inputs and show otoacoustic emissions. Mammals most notably differ from other groups in that their hearing range extends to frequencies beyond 12 to 14 kHz.
11. Analysis of the genetic forms of deafness has provided information on dozens of proteins key to the function of the hair cell, in particular those responsible for mechanoelectrical transduction and for synaptic transmission between hair cells and fibers of the auditory nerve. Although these genes may serve as potential targets for future therapies, sensorineural hearing loss is currently treated mostly with hearing aids or cochlear prostheses. New strategies, such as hair-cell replenishment via stem-cell differentiation or optogenetic stimulation of the spiral ganglion, provide promising avenues for research on hearing restoration.

The Vestibular System

Modern vehicular travel on earth and through extraterrestrial space relies upon sophisticated guidance systems that integrate acceleration, velocity, and positional information through transducers, computational algorithms, and satellite triangulation. Yet the principles of inertial guidance are ancient: Vertebrates have used analogous systems for 500 million years and invertebrates for even longer. In these animals, the inertial guidance system, termed the vestibular system, serves to detect and interpret motion through space as well as orientation relative to gravity.

Through extensive research over many decades, it is apparent that most, if not all, organisms on Earth have evolved to sense one of the most prevalent "forces" in our universe, gravity. The mechanisms for the sensory transduction are as diverse as nature could devise. Gravity is most precisely referenced as gravitoinertial acceleration (GIA), a distinct form of linear acceleration directed toward the core of our planet. In truth, gravity varies systematically by as much as 0.5% between the equator and the poles; it increases over mineral-dense regions and decreases over mineral-light regions of the Earth's surface. Yet every single behavior that animals perform is referenced to the GIA, and all of our actions and cognitive directives depend

upon knowledge of our motion and orientation relative to it. The first developments of what we refer to as a vestibular system were actually gravity sensors; as behavior became increasingly mobile, sensory organs evolved to process rotational accelerations as well.

In this chapter we will concentrate on the vestibular system of vertebrates, which has remained highly conserved across many species. Vestibular signals originate in the labyrinths of the internal ear (Figure 27–1B). The *bony labyrinth* is a hollow structure within the petrous portion of the temporal bone. Within it lies the *membranous labyrinth,* which contains sensors for both the vestibular and auditory systems.

The vestibular receptors consist of two parts: two otolith organs, the utricle and saccule, which measure linear accelerations, and three semicircular canals, which measure angular accelerations. Rotational motion (angular acceleration) is experienced during head turns, whereas linear acceleration occurs during walking, falling, vehicular travel (ie, translations), or head tilts relative to gravity. These receptors send vestibular information to the brain, where it is integrated into an appropriate signal regarding direction and speed of motion, as well as the position of the head relative to the GIA. Many of the central vestibular neurons at the first junction with receptor afferent fibers also

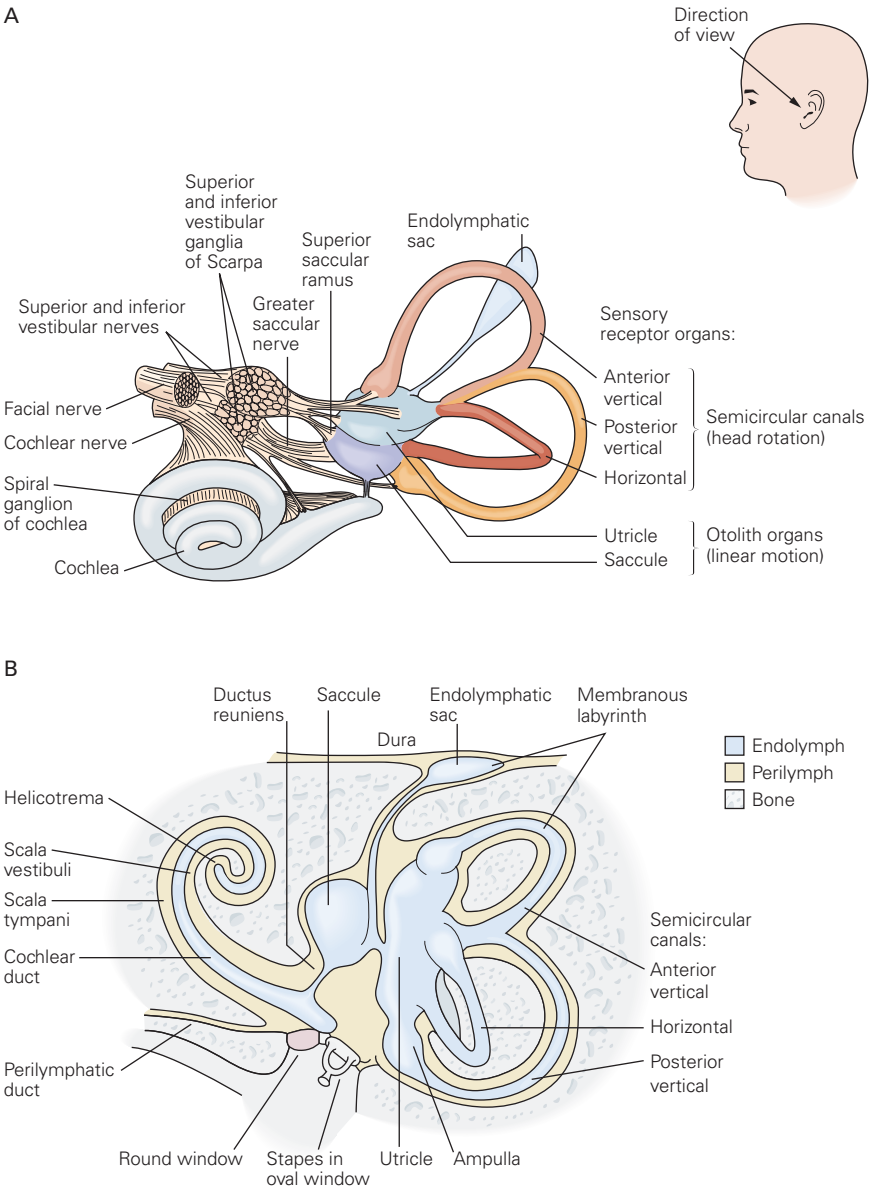

Figure 27–1 The vestibular apparatus of the inner ear.

A. The orientations of the vestibular and cochlear divisions of the inner ear are shown with respect to the head.

B. The inner ear is divided into bony and membranous labyrinths. The bony labyrinth is bounded by the petrosal portion of the temporal bone. Lying within this structure is the membranous labyrinth, which contains the receptor organs for hearing (the cochlea) and equilibrium (the utricle, saccule, and semicircular canals). The space between bone and membrane is filled with perilymph, whereas the membranous labyrinth is filled with endolymph. Sensory cells in the utricle, saccule, and ampullae of the semicircular canals respond to motion of the head. (Adapted from Iurato 1967.)

receive convergent signals from other systems such as proprioceptors, visual signals, and motor commands. Central processing of these multimodal signals occurs very rapidly to ensure adequate coordination of visual gaze and postural responses, autonomic responses, and awareness of spatial orientation.

The Vestibular Labyrinth in the Inner Ear Contains Five Receptor Organs

The membranous labyrinth is supported within the bony labyrinth by a filamentous network of connective tissue. The vestibular portion of the membranous labyrinth lies lateral and posterior to the cochlea. Vestibular receptors are contained in specialized enlarged regions of the membranous labyrinth, termed the ampullae for the semicircular canals and maculae for the otolith organs (Figure 27–1B). Both of the otolith organs lie in a central compartment of the membranous labyrinth, the vestibule, which is surrounded by the bony labyrinth of the same name.

The membranous labyrinth is filled with endolymph, a K^+-rich (150 mM) and Na^+-poor (16 mM) fluid whose composition is maintained by the action of ion pumps in specialized cells. Endolymph bathes the surface of the vestibular receptor cells. Surrounding the membranous labyrinth, in the space between the membranous labyrinth and the wall of the bony labyrinth, is *perilymph.* Perilymph is a high-Na^+ (150 mM), low-K^+ (7 mM) fluid similar in composition to cerebrospinal fluid, with which it is in communication through the cochlear duct. Perilymph bathes the basal surface of the receptor epithelia and the vestibular nerve fibers. Two fluid-tight partitions in the bony labyrinth, the oval and round windows (Figure 27–1B), connect the perilymphatic space to the middle ear cavity. The oval window is connected to the tympanic membrane by the middle ear ossicles. These windows are important for sound transduction (Chapter 26). The endolymph and perilymph are kept separate by a junctional complex of support cells that surrounds the apex of each receptor cell. Disruption of the balance between these two fluids (by trauma or disease) can result in vestibular dysfunction, leading to dizziness, vertigo, and spatial disorientation.

During development, the labyrinth progresses from a simple sac to a complex set of interconnected sensory organs, but retains the same fundamental topological organization. Each organ originates as an epithelium-lined pouch that buds from the otic cyst, and the endolymphatic spaces within the several organs remain continuous in the adult. The endolymphatic spaces of the vestibular labyrinth are also connected to the cochlear duct through the ductus reuniens (Figure 27–1B). In addition, the membranous labyrinth contains a small tube, the endolymphatic duct, which extends through a space in the sigmoid bone, the vestibular aqueduct, to end in a blind sac adjacent to the dura in the epidural space of the posterior cranial fossa. It is thought that the endolymphatic sac has both absorptive and excretive functions to maintain the ionic composition of the endolymphatic fluid.

Hair Cells Transduce Acceleration Stimuli Into Receptor Potentials

Each of the five receptor organs has a cluster of hair cells responsible for transducing head motion into vestibular signals. Hair cells are so named due to an array of nearly 100 staggered height stereocilia. The shortest stereocilia are at one end of the cell and the tallest at the other, ending with the only true cilium of the hair cell, termed the kinocilium. The kinocilium is typically the tallest of all stereocilia. Angular or linear acceleration of the head leads to a deflection of the stereocilia, which together compose the hair bundle (Figure 27–2).

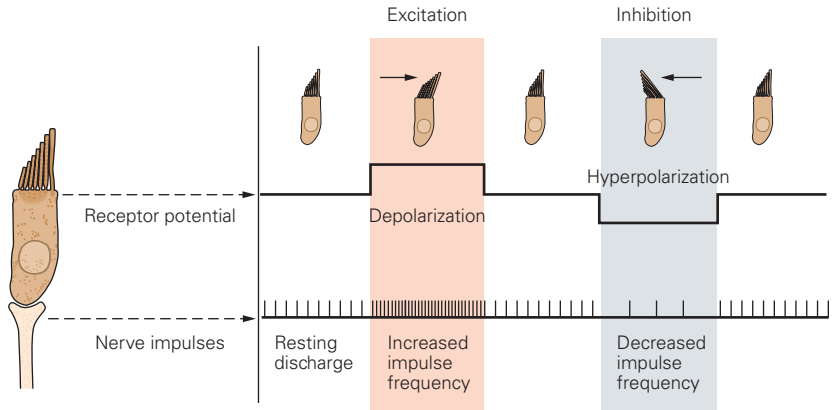

Figure 27–2 Hair cells in the vestibular labyrinth transduce mechanical stimuli into neural signals. At the apex of each cell are the stereocilia, which increase in length toward the single kinocilium. The membrane potential of the receptor cell depends on the direction in which the stereocilia are bent. Deflection toward the kinocilium causes the cell to depolarize and thus increases the rate of firing in the afferent fiber. Bending away from the kinocilium causes the cell to hyperpolarize, thus decreasing the afferent firing rate. (Adapted, with permission, from Flock 1965.)

Specialized ion channels in the tips of the hair bundle stereocilia allow K^+ to enter or be blocked from the surrounding endolymph (Chapter 26). This action allows hair cells to act as mechanoreceptors, where deflection of the stereocilia produces a depolarizing or hyperpolarizing receptor potential depending on which direction the hair bundle moves (Figure 27–2). These depolarizations and hyperpolarizations of the receptor membrane lead to excitation and inhibition, respectively, in the firing rate of the innervating afferent (Figure 27–2). In each vestibular receptor organ, hair cells are arranged so that movement directional specificity is defined by excitation in some cells and inhibition in other cells.

Vestibular signals are carried from the hair cells to the brain stem by branches of the vestibulocochlear nerve (cranial nerve VIII), which enter the brain stem and terminate in the ipsilateral vestibular nuclei, cerebellum, and reticular formation. Cell bodies of the vestibular nerve are located in Scarpa's ganglia within the internal auditory canal (Figure 27–1A). The *superior vestibular nerve* innervates the horizontal and anterior canals and the utricle, whereas the *inferior vestibular nerve* innervates the posterior canal and the saccule. The labyrinth's vascular supply, which arises from the anterior inferior cerebellar artery, travels with nerve VIII. The anterior vestibular artery supplies the structures innervated by the superior vestibular nerve, and the posterior vestibular artery supplies the structures innervated by the inferior vestibular nerve.

All vertebrate receptor hair cells receive efferent inputs from the brain stem. The function of the efferent innervation of vestibular receptors is still a subject of debate. Stimulation of the efferent fibers from the brain stem changes the sensitivity of the afferent axons from the hair cells. It increases the excitability of some afferents and hair cells while inhibiting others, and varies across species.

The Semicircular Canals Sense Head Rotation

An object undergoes angular acceleration when its rate of rotation about an axis changes. Therefore, the head undergoes angular acceleration when it turns or tilts, when the body rotates, and during active or passive locomotion. The three semicircular canals of each vestibular labyrinth detect these angular accelerations and report their magnitudes and motion directions to the brain.

Each semicircular canal is a semicircular tube of membranous labyrinth extending from the vestibule. One end of each canal is open to the vestibule, whereas at the other end, the ampulla, the entire lumen of the canal is traversed by a fluid-tight gelatinous diaphragm, the cupula. The stereocilia and the kinocilium protrude into the gelatinous cupula, while the hair cells are located below in a receptor epithelium, the crista, along with the innervating afferent terminals (Figure 27–3).

The vestibular organs detect accelerations of the head because the inertia of endolymph and cupula results in forces acting on the stereocilia. Consider the simplest situation, a rotation in the plane of a semicircular canal. When the head begins to rotate, the membranous and bony labyrinths move along with it. Because of its inertia, however, the endolymph lags behind the surrounding membranous labyrinth, thus pushing the cupula in a direction opposite that of the head (Figure 27–3B).

The motion of endolymph in a semicircular canal can be demonstrated with a cup of coffee. While gently twisting the cup about its vertical axis, observe a particular bubble near the fluid's outer boundary. As the cup begins to turn, the coffee tends to maintain its initial orientation in space and thus counter-rotates in the cup. If you continue rotating the cup at the same speed, the coffee (and the bubble) eventually catches up to the cup and rotates with it. When the cup decelerates and stops, the coffee keeps rotating, moving in the opposite direction relative to the cup.

In the ampulla, this relative motion of the endolymph creates pressure on the cupula, bending it toward or away from the adjacent vestibule, depending on the direction of endolymph flow. The resulting deflection of the stereocilia alters the membrane potential of the hair cells, thereby changing the firing rates of the associated sensory fibers. Each semicircular canal is maximally sensitive to rotations in its plane. The horizontal canal is oriented approximately 30° elevated above the naso-occipital axis (roughly in the horizontal plane as a person walks and looks at the ground ahead) and thus is most sensitive to rotations in the horizontal plane. The stereocilia are arranged so that leftward rotational motion is excitatory for the left horizontal canal and inhibitory for the right horizontal canal. The anterior and posterior canals are oriented more vertically in the head, at an angle of approximately 45 degrees from the sagittal plane (Figure 27–4). Similar rotational motion downward in the plane of the anterior canals is excitatory for anterior canal hair cells, while upward head motion is excitatory for posterior canals.

Because there is approximate mirror symmetry of the left and right labyrinths, the six canals effectively operate as three coplanar pairs. The two horizontal canals form one pair; each of the other pairs consists of one anterior canal on one side of the head and the contralateral posterior canal. Further, the three

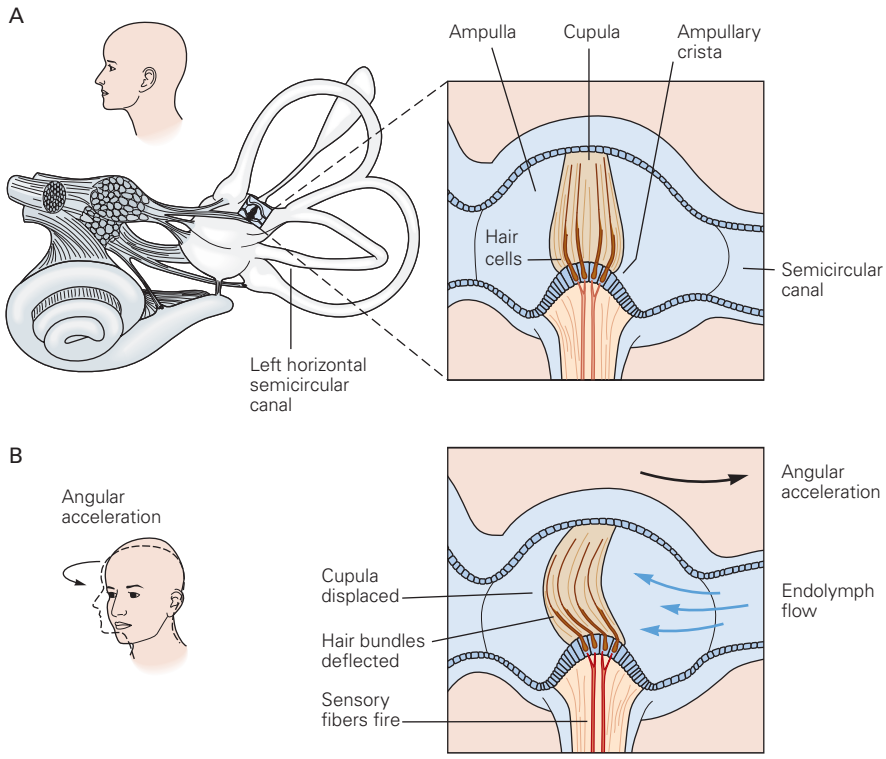

Figure 27–3 The ampulla of a semicircular canal.

A. A thickened zone of epithelium, the ampullary crista, contains the hair cells. The stereocilia and the kinocilia of the hair cells extend into a gelatinous diaphragm, the cupula, which stretches from the crista to the roof of the ampulla.

B. The cupula is displaced by the relative movement of endolymph when the head turns. As a result, the hair bundles are also displaced. Their movement is greatly exaggerated in the diagram.

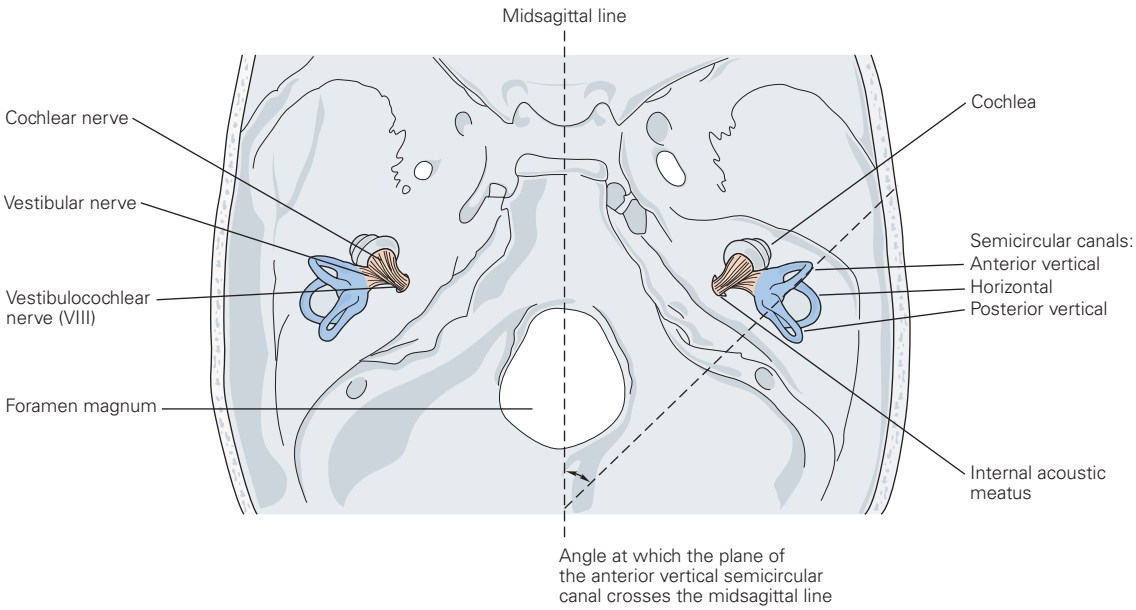

Figure 27–4 The bilateral symmetry of the semicircular canals. The horizontal canals on both sides lie in approximately the same plane and therefore are functional pairs. The bilateral vertical canals have a more complex relationship. The anterior canal on one side and the posterior canal on the opposite side lie in parallel planes and therefore constitute a functional pair. The vertical semicircular canals lie nearly 45° from the midsagittal plane. Each of the semicircular canals on one side of the head lie in approximately orthogonal planes to each other.

semicircular canals on each side of the head lie roughly orthogonal to each other (Figure 27–4). When the head moves toward the receptor hair cells (eg, leftward head turns for the left horizontal semicircular canal), the stereocilia are bent toward the tall kinocilium, thus exciting (depolarizing) the cell. Head motion in the opposite direction causes bending away from the kinocilum and toward the smallest stereocilia, thus closing the channels and inhibiting (hyperpolarizing) the cell.

The left and right ear semicircular canals have opposite polarity; thus, when you turn your head to the left, the receptors in the left horizontal semicircular canal will be excited (increased firing rate), whereas right horizontal canal receptors will be inhibited (decreased firing rate; Figure 27–5). The same relationship is true for the vertical semicircular canals. The canal planes are also roughly aligned to the pulling planes of specific eye muscles. The pair of horizontal canals lies in the pulling plane of the lateral and medial rectus muscles. The left anterior and right posterior canal pair lie in the pulling plane of the left superior and inferior rectus and right superior and inferior oblique muscles. The right anterior and left posterior pair occupies the pulling plane of the left superior and inferior oblique and right superior and inferior rectus muscles.

The Otolith Organs Sense Linear Accelerations

The vestibular system must compensate not only for head rotations but also for linear motion. The two otolith organs, the utricle and saccule, detect linear motion as well as the static orientation of the head relative to gravity, which is itself a linear acceleration. Each organ consists of a sac of membranous labyrinth approximately 3 mm in the longest dimension. The hair cells of each organ are arranged in a roughly elliptical patch called the *macula*. The human utricle contains approximately 30,000 hair cells, whereas the saccule contains some 16,000.

The hair bundles of the otolithic hair cells extend into a gelatinous sheet, the *otolithic membrane*, which

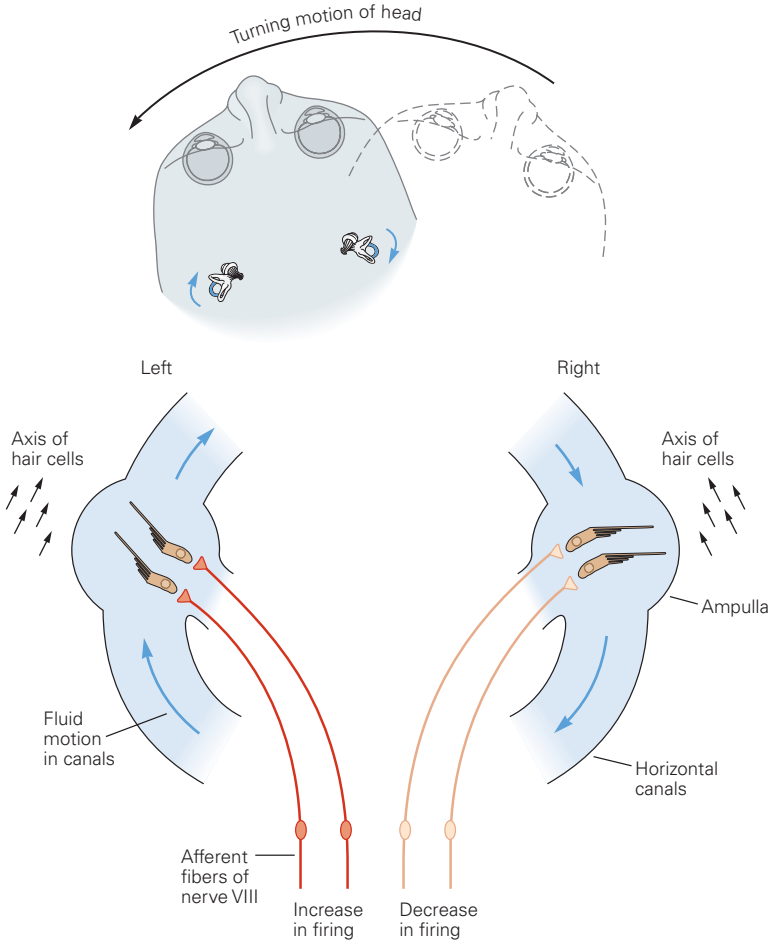

Figure 27–5 The left and right horizontal semicircular canals work together to signal head movement. Because of inertia, rotation of the head in a counterclockwise direction causes endolymph to move clockwise with respect to the canals. This deflects the stereocilia in the left canal in the excitatory direction, thereby exciting the afferent fibers on this side. In the right canal, the afferent fibers are hyperpolarized so that firing decreases.

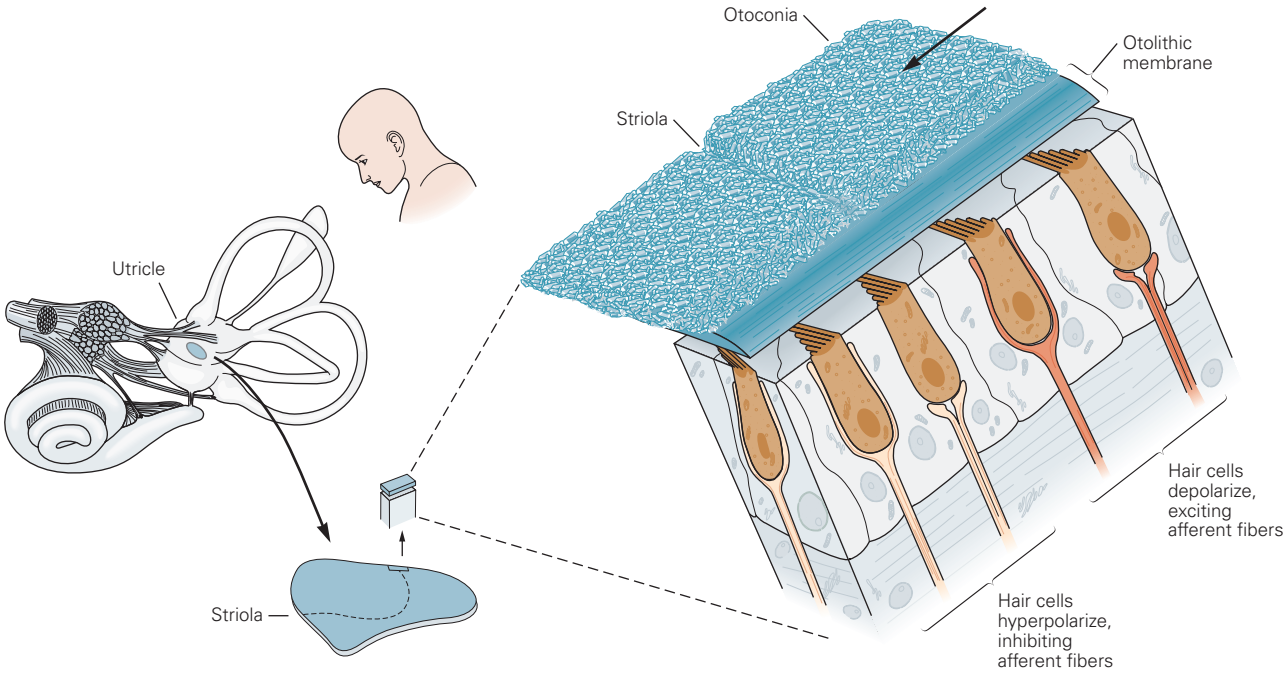

Figure 27–6 The utricle detects tilt of the head. Hair cells in the epithelium of the utricle have apical hair bundles that project into the otolithic membrane, a gelatinous material that is covered by millions of calcium carbonate particles (otoconia). The hair bundles are polarized but are oriented in different directions. The directional polarity of each hair cell is organized relative to a reversal region running through the center of the utricle, termed the striola (see Figure 27–7). Thus, when the head is tilted, the gravitational force on the otoconia bends each hair bundle in a particular direction. When the head is tilted in the direction of a hair cell's axis of polarity, that cell depolarizes and excites the afferent fiber. When the head is tilted in the opposite direction, the same cell hyperpolarizes and inhibits the afferent fiber. (Adapted from Iurato 1967.)

covers the entire macula (Figure 27–6). Embedded on the surface of this membrane are fine, dense particles of calcium carbonate called *otoconia* (Greek root translates to "ear dust"), which give the otolith ("ear stone") organs their name. Otoconia are typically 0.5 to 30 µm long; thousands of these particles are attached to the otolithic membranes of the utricle and saccule.

Gravity and other linear accelerations exert shear forces on the otoconial matrix and the gelatinous otolithic membrane, which can move relative to the membranous labyrinth. This results in a deflection of the hair bundles, altering activity in the vestibular nerve to signal linear acceleration owing to translational motion or gravity. The orientations of the otolith organs and the directional sensitivity of individual hair cells are such that a linear acceleration along any axis can be sensed. For example, with the head in its normal position, the macula of each utricle is raised above the naso-occipital axis by approximately 30°, similar to the horizontal semicircular canal. In normal resting head position, the utricle is deviated to bring the utricle approximately equal to an Earth horizontal plane. Any acceleration in the horizontal plane excites some hair cells in each utricle and inhibits others, according to their orientations (Figures 27–6 and 27–7).

The operation of the paired saccules resembles that of the utricles. The hair cells represent all possible

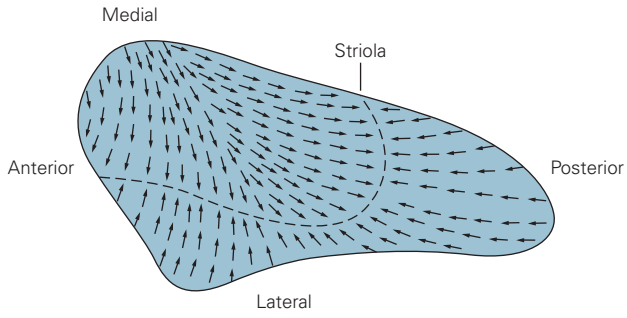

Figure 27–7 The axis of mechanical sensitivity of each hair cell in the utricle is oriented toward the striola. The striola curves across the surface of the macula containing the hair cells, resulting in a characteristic variation in the axes of mechanosensitivity (**arrows**) in the population of hair cells. Because of this arrangement, tilt in any direction depolarizes some cells and hyperpolarizes others, while having no effect on the remainder. (Adapted, with permission, from Spoendlin 1966.)

orientations within the plane of each saccular macula, but the maculae are oriented vertically in nearly parasagittal planes. The saccules are therefore especially sensitive to vertical accelerations. Certain saccular hair cells also respond to accelerations in the horizontal plane, in particular those along the anterior–posterior axis.

Central Vestibular Nuclei Integrate Vestibular, Visual, Proprioceptive, and Motor Signals

The vestibular nerve projects ipsilaterally from the vestibular ganglion mainly to four vestibular nuclei (medial, lateral, superior, and descending) in the dorsal part of the pons and medulla, in the floor of the fourth ventricle. Many vestibular nerve fibers also bifurcate, sending a direct projection to the fastigial nucleus, the nodulus and uvula, and the reticular formation (Figure 27–8A). These nuclei integrate signals from the vestibular organs with signals from the spinal cord, cerebellum, and visual system.

The vestibular nuclei project, in turn, to many central targets, including the oculomotor nuclei, reticular and spinal centers concerned with gaze and postural movement, and the thalamus (Figure 27–9). Many vestibular nuclei neurons have reciprocal connections with the cerebellum, primarily in the floculo-nodular lobe, that form important regulatory mechanisms for eye movements, head movements, and posture (Figures 27–8 and 27–9). The vestibular nuclei receive inputs from the premotor cortex, the accessory optic system (nucleus of the optic tract), the neural integrator nuclei (nucleus prepositus hypoglossi and interstitial nucleus of Cajal), and the reticular formation (Figure 27–8). Further projections from the vestibular nuclei reach the rostral and caudal lateral medulla nuclei that are involved in regulation of blood pressure, heart rate, respiration, and bone remodeling, as well as the parabrachial nucleus for homeostasis modulation. Finally, there are projections from the vestibular nuclei to the medial geniculate (auditory) nuclei, as well as the supragenual nucleus and dorsal tegmental nucleus, which contribute to spatial orientation (Figure 27–9).

The superior and medial vestibular nuclei receive fibers predominantly from the semicircular canals in the medial regions and some otolith input in the lateral regions (Figure 27–8). They send fibers predominantly to the cerebellum, reticular formation, thalamus, oculomotor centers, and spinal cord (Figure 27–9). Oculomotor center outputs include the three oculomotor nuclei (abducens, oculomotor, trochlear), as well as the neural integrators for converting head velocity into head position signals in the nucleus hypoglossi (horizontal eye movements) and interstitial nucleus of Cajal (vertical eye movements). These nuclei are described in some detail later.

Another major output pathway concerned with gaze control arises from the medial vestibular nucleus (as well as lesser projections from the descending and lateral vestibular nuclei) and projects bilaterally to the cervical spinal cord through the medial vestibulospinal tract (Figure 27–9; see Chapter 35). There are two categories of medial vestibulospinal fibers. Vestibulospinal neurons project only to the spinal cord to control neck musculature. Vestibulo-ocular neurons project to both the spinal cord and the oculomotor nuclei and are involved in coordinated eye and head movements to maintain gaze stability.

The lateral vestibular nucleus (Deiters' nucleus) receives fibers from the semicircular canals medially and the otolith organs laterally. There is a major output to all levels of the ipsilateral spinal cord through the lateral vestibulospinal tract that is concerned principally with postural reflexes through modulation of limb and axial musculature (Figure 27–9). Lateral vestibular nuclei neurons also project heavily to the reticular formation. The descending vestibular nucleus receives predominantly otolithic input, but also receives semicircular canal fibers medially, and projects to the cerebellum, reticular formation, and spinal cord (medial vestibulospinal tract). The primary neurotransmitters for excitatory vestibular nuclear projections include glutamate, whereas the inhibitory projections are either glycine or γ-aminobutyric acid (GABA). Vestibular projections to the spinal systems are discussed in more detail in Chapter 36.

The Vestibular Commissural System Communicates Bilateral Information

Many of these vestibular nuclei neurons receive convergent motion information from the opposite ear through an inhibitory commissural pathway that uses GABA as a neurotransmitter (Figure 27–8B). The commissural pathway is highly organized according to the type of receptor from which information is received. For example, cells receiving signals from the ipsilateral horizontal excitatory canal will also receive signals from the contralateral horizontal canal through an inhibitory interneuron. Due to the directional selectivity of the receptors in each ear, the contralateral horizontal canal input will always be decreased during an ipsilateral head turn, in effect "disinhibiting" the inhibitory input from the contralateral side.

The effect of the commissural system is to increase the response of the vestibular nuclei neuron and

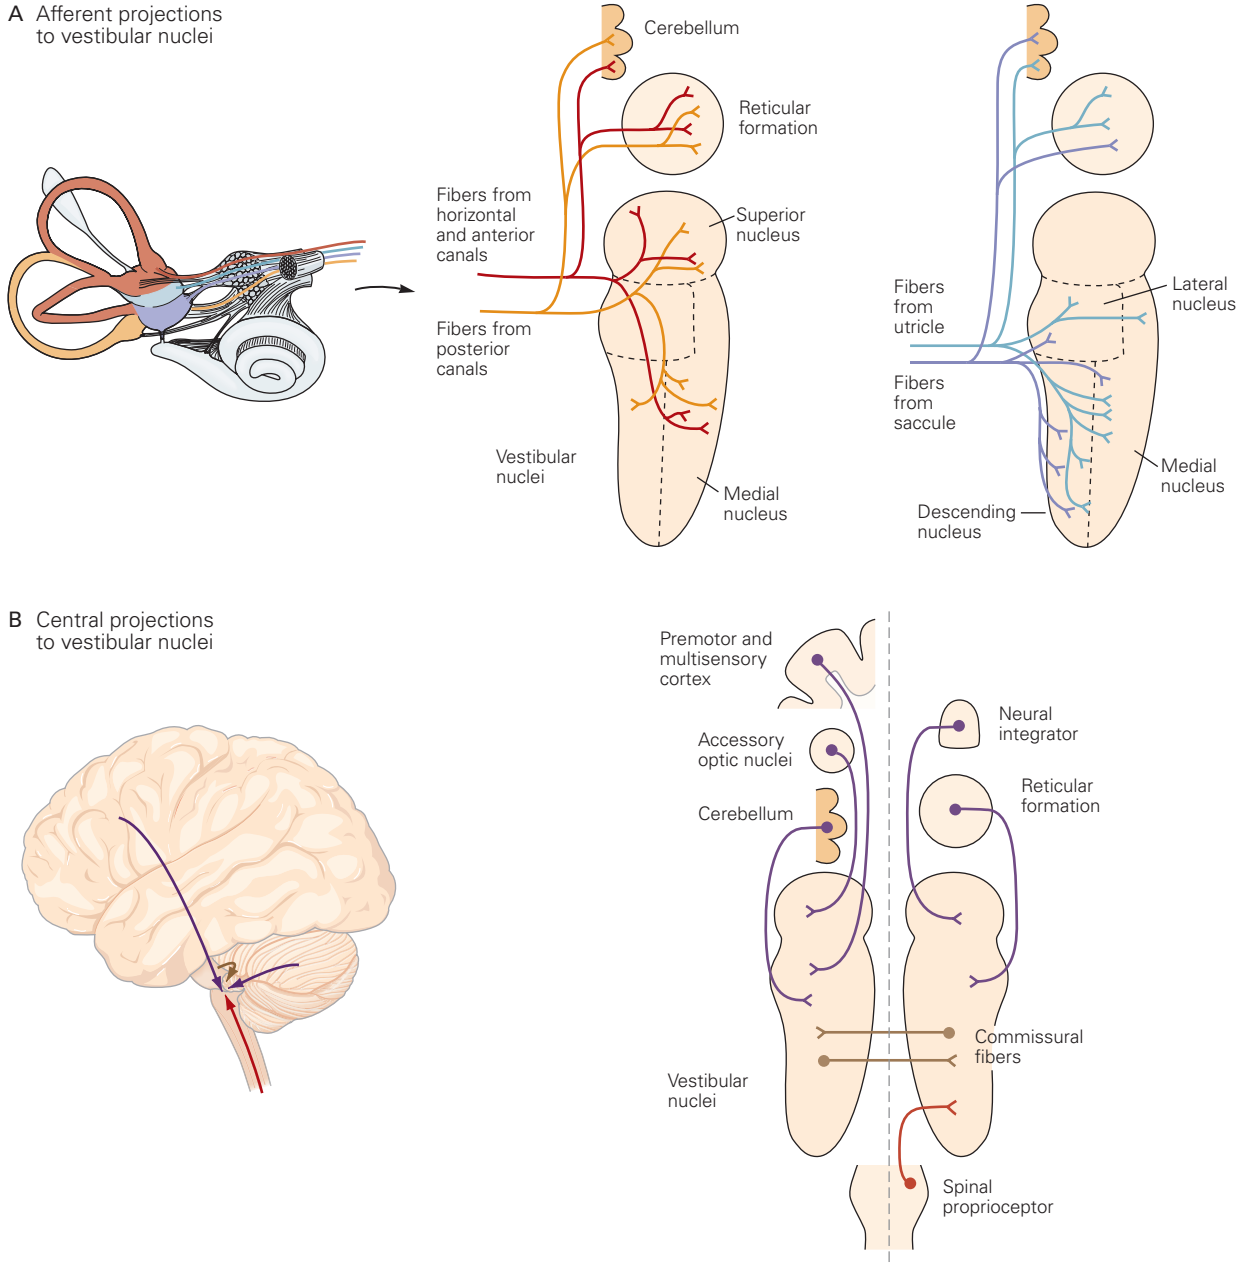

Figure 27–8 Afferent fiber and central projections to the vestibular nuclei.

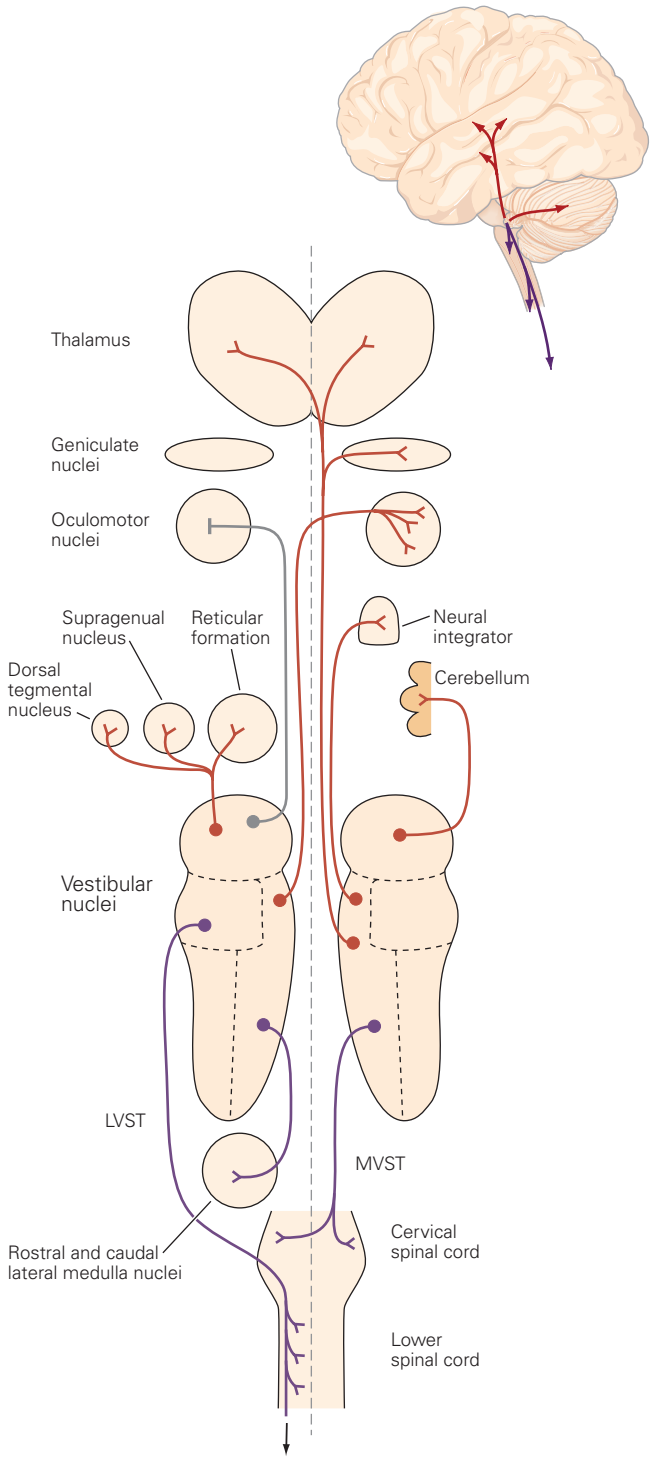
A. Afferent fibers from vestibular receptors terminate in the brain stem and cerebellum. Fibers from semicircular canals project primarily to the medial portions of the superior and medial vestibular nuclei, the descending vestibular nucleus, the cerebellum (nodulus and uvula), and the reticular formation. Fibers from the otoliths primarily project to the lateral portions of all vestibular nuclei, the nodulus and uvula, and the reticular formation. (Adapted, with permission, from Gacek and Lyon 1974.)

B. Central projections to the vestibular nuclei arise from a number of cortical, brain stem, and spinal cord regions. These include the premotor and multisensory cortices, accessory optic nuclei, cerebellum, neural integrator nuclei, reticular formation, spinal cord, and commissural fibers from the contralateral vestibular nuclei.



decrease noise from the incoming afferent signal, giving rise to a "push-pull" vestibular function. From an engineering point of view, the "push-pull" set point in the nuclei neurons constantly updates canal signals from the opposing ear to act as a comparator junction and can explain the relatively high spontaneous firing rate of canal afferents at nearly 100 spikes/s. For example, during a leftward head turn, left brain stem nuclei neurons receive high firing rate signals from the left horizontal canal and low firing rate signals from the right horizontal canal. The comparison of activity is interpreted as a left head turn (Figure 27–5). Similar comparisons between signals also occur for inputs from the anterior semicircular canal on one side and the posterior semicircular canal on the opposite ear side. Thus, for rotational motion in any head plane, the comparator is able to determine the direction of movement with great specificity.

Any disruption of the normal balance between left and right ear canal inputs (eg, from trauma or disease in the receptor organs or nerve) will be interpreted by the brain as a head rotation, even though the head is stationary. These effects often lead to illusions of spinning or rotating that can be quite upsetting and may produce nausea or vomiting. However, over time, the commissural fibers provide for vestibular compensation, a process by which the loss of unilateral vestibular receptor function is partially restored centrally and behavioral responses such as the vestibulo-ocular reflex mostly recover.

Combined Semicircular Canal and Otolith Signals Improve Inertial Sensing and Decrease Ambiguity of Translation Versus Tilt

In some instances, the vestibular input from a single receptor may be ambiguous. For example, Einstein (1908) showed that linear accelerations are equivalent whether they arise from translational motion or tilts of the head relative to gravity. The otolith receptors cannot

Figure 27–9 (Left) Output projections from the vestibular nuclei. The vestibular nuclei project to a number of brain regions below the cortical level. Two separate descending pathways project through the lateral and medial vestibulospinal tracts (**LVST, MVST**) to terminate in the spinal cord. The vestibular nuclei also project to the reticular formation and the lateral medullary nuclei in the brain stem. Ascending projections to the supragenual nucleus, the dorsal tegmental nucleus, the oculomotor nuclei (abducens, oculomotor, and trochlear), and the neural integrator nuclei are very prominent (**red line**, excitatory; **gray line**, inhibitory), as are projections to the cerebellum (nuclei, nodulus, and uvula). Other prominent vestibular projections terminate in the geniculate nuclei and the thalamus (ventral lateral, posterior, and intralaminar thalamic regions).

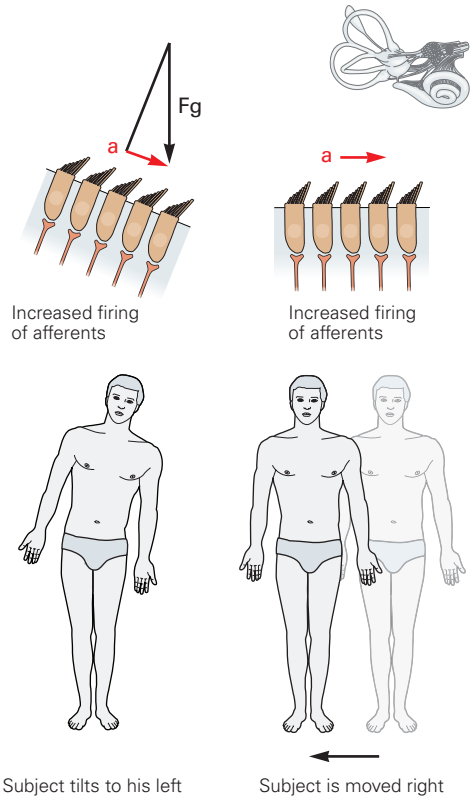


Figure 27–10 Vestibular inputs signaling body posture and motion can be ambiguous. The postural system cannot distinguish between tilt and linear acceleration of the body based on otolithic inputs alone. The same shearing force acting on vestibular hair cells can result from tilting of the head (*left*), which exposes the hair cells to a portion of the acceleration (**a**) owing to gravity (**Fg**), or from horizontal linear acceleration of the body (*right*).

discriminate between the two: So how is it that we can tell the difference between translating rightward and tilting leftward, where the linear acceleration signaled by the otolith afferents is the same (Figure 27–10)?

It is now well established that convergent vestibular nuclei and cerebellar neurons use combined signals from both the semicircular canals and the otolith receptors and some simple computations to discriminate between tilt and translation. As a result, some central vestibular and cerebellar cells encode head tilt, whereas other cells encode translational motion, which, as we will see, is extremely important for the control of head and eye movements.

Vestibular Signals Are a Critical Component of Head Movement Control

An important discovery is the differing responses in some vestibular nuclei neurons to actively versus passively generated head movements. Specifically, in contrast to vestibular afferents, some neurons in the vestibular nuclei and cerebellum well known for responding to vestibular stimuli during passive movement lose or reduce their sensitivity during self-generated movement. The preferential response to passive motion, or to the passive components of combined active and passive motion, has been interpreted as sensory prediction error signals: The brain predicts how self-generated motion activates the vestibular organs and subtracts these predictions from afferent signals. Such error signals are important for the on-line control of head movement, as well as head movement estimation.

Computationally, these properties have been interpreted quantitatively using concepts common to all sensorimotor systems; that is, active and passive motion signals are processed by internal models of the motion sensor (ie, the canals, otolith organs, and neck proprioceptors). The brain uses an internal representation of the laws of physics and sensory dynamics (which can be elegantly modeled as forward internal models of the sensors) to process vestibular signals. Without such error signals, accurate self-motion estimation would be severely compromised. These computational insights suggest that, unlike early interpretations, vestibular signals remain critically important when coupled to self-motion estimation and head movement control during actively generated head movements.

Vestibulo-Ocular Reflexes Stabilize the Eyes When the Head Moves

In order to see clearly and maintain focus on visual objects during head motion, the eyes maintain foveal fixation through a series of vestibulo-ocular reflexes (VORs). If you shake your head back and forth while reading, you can still discern words because of the VORs. If instead you move the book at a similar speed while holding your head steady, you can no longer read the words.

In the latter instance, vision provides the brain with the only corrective feedback for stabilizing of the image on the retina, and visual processing in vertebrates is much slower (around 100 ms latency) and less effective than vestibular processing (around 10 ms) for image stabilization. The vestibular apparatus signals how fast the head is rotating, and the oculomotor system uses this information to stabilize the eyes to fix visual images on the retina.

There are two components of VORs. The *rotational VOR* compensates for head rotation and receives its input predominantly from the semicircular canals. The *translational VOR* compensates for linear head movement. These two VOR responses arise from connections from vestibular nuclei neurons to the abducens, oculomotor, and trochlear nuclei (Figure 27–9).

The Rotational Vestibulo-Ocular Reflex Compensates for Head Rotation

When the semicircular canals sense head rotation in one direction, the eyes rotate in the opposite direction at equal velocity in the orbits (Figure 27–11). This compensatory eye rotation is called the vestibular slow phase, although it is not necessarily slow: The eyes may reach speeds of more than 200 degrees per second if the head's rotation is fast. During fast head movements, the VOR must act quickly to maintain stable gaze. A trisynaptic pathway, the three-neuron arc, connects each semicircular canal to the appropriate eye muscle (Figure 27–11).

The rotational VOR represents a phylogenetically old reflex. Many invertebrates and all vertebrate species, from amphibians, reptiles, fish, and birds to nonhuman primates, have the ability to reflexively rotate their eyes opposite to the direction of head rotation, thus keeping the visual world stable on the retina. Primary afferents from the horizontal semicircular canals send excitatory signals through the vestibular nuclei and the medial longitudinal fasciculus to the contralateral abducens nucleus (Figure 27–11). Abducens motor neurons send impulses via cranial nerve VI to excite the ipsilateral lateral rectus muscle. At the same time, abducens interneurons send excitatory signals to motor neurons in the contralateral oculomotor nucleus, which innervates the medial rectus muscle (see Chapter 35 for details on other projections).

The three-synapse pathway illustrated in Figure 27–11 is not sufficient to elicit appropriate compensatory eye movements. This is because the afferent signal from the semicircular canals is proportional to head velocity, while the compensatory eye movement requires eye position changes. To convert velocity to position requires temporal integration (simple calculus) that occurs through neural networks in the brain stem nuclei for most head motion speeds. However, at high rotation frequencies, the viscoelastic properties of the eyeball, eye muscles, and surrounding tissues provide an additional integration step. Thus, the rotational VOR is thought to consist of two parallel processes.

The first process consists of the direct neural pathway known as the three-neuron arc (Figure 27–11). The second neural integrator process consists of additional parallel pathways that ensure that the correct proportion of velocity and position commands are delivered to the oculomotor nuclei to move the eye appropriately (Figure 27–9 and see Chapter 35). Without this second indirect integrator pathway, the response to a head rotation would initially bring the eye to the correct position, but the eye would drift away from that position since the oculomotor neurons would lack the tonic input to compensate for the elastic restoring forces of the eyeball (Chapter 35). This is exactly what happens after lesions of brainstem and cerebellar structures that are thought to participate in this neural integration (eg, the prepositus hypoglossi and the interstitial nucleus of Cajal; Figure 27–9). It is generally thought that the integrator pathway is shared by all conjugate eye movement systems (saccades, smooth pursuit, and the VOR), although the direct pathway is at least partly segregated for different types of eye movements (ie, VOR, smooth pursuit, saccades).

With continued head rotation, the eyes eventually reach the limit of their orbital range and stop moving. To prevent this, a rapid saccade-like movement called a quick phase displaces the eyes to a new point of fixation in the direction of head rotation.

If rotation is prolonged, the eyes execute alternating slow and quick phases called *nystagmus* (Figure 27–12). Although the slow phase is the primary response of the rotational VOR, the direction of nystagmus is defined in clinical practice by the direction of its quick phase. Since prolonged rightward rotation excites the right horizontal canal and inhibits the left horizontal canal, leftward slow phases and a *right-beating nystagmus* result.

If the angular velocity of the head remains constant, the inertia of the endolymph is eventually overcome, as in the earlier coffee cup example. The cupula relaxes and vestibular nerve discharge returns to its baseline rate. As a consequence, slow-phase velocity decays and the nystagmus stops, although the head is still rotating.

In fact, the nystagmus lasts longer than would be expected based on cupular deflection. By a process called *velocity storage*, a brain stem network provides a velocity signal to the oculomotor system, although the vestibular nerve no longer signals head movement. Eventually, however, the nystagmus does decay and the sense of motion vanishes in darkness. Further, the same rotation in the presence of a visual surround activates the optokinetic reflex (Chapter 35) and elicits a steady-state nystagmus pattern that is sustained indefinitely. The interactions between canal and optokinetic

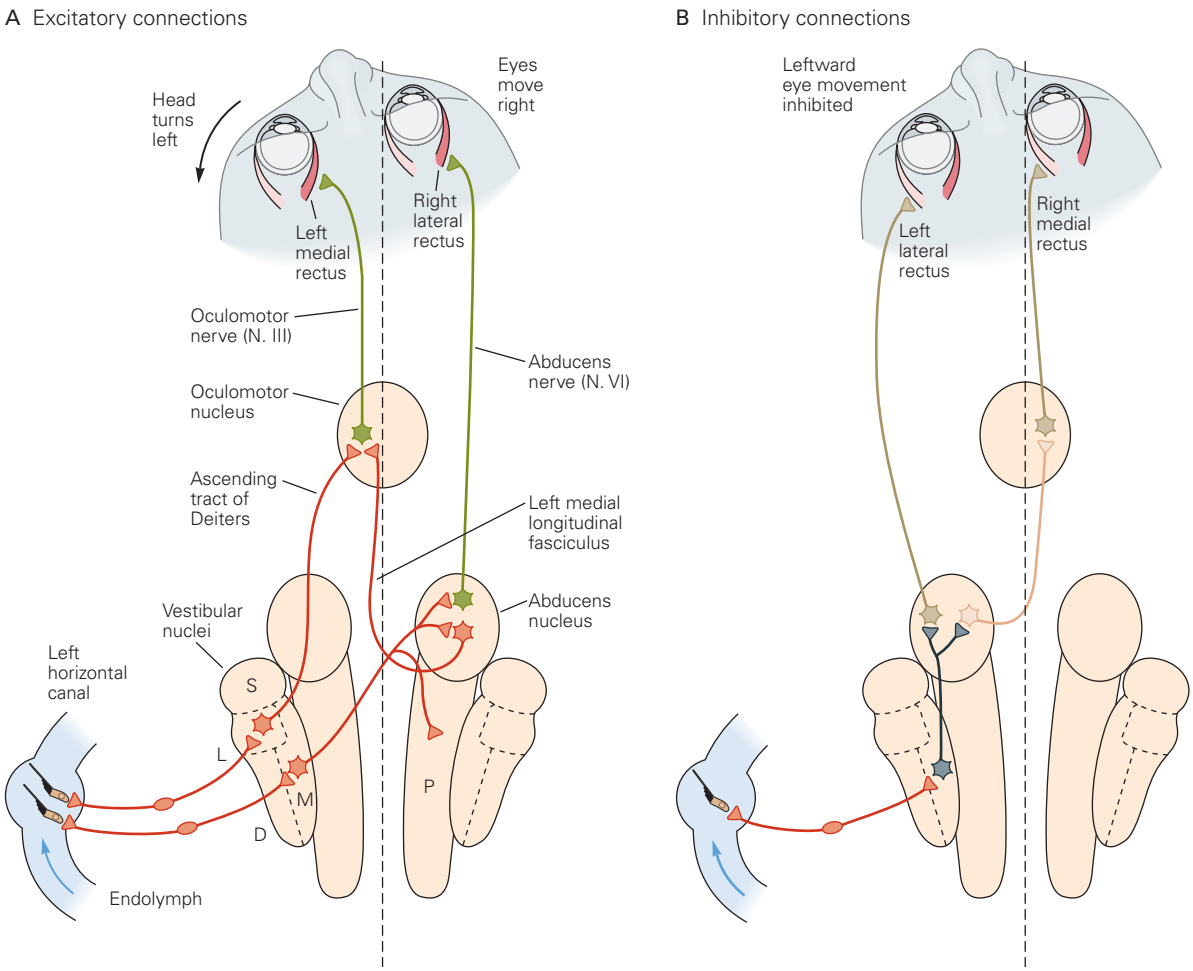

Figure 27–11 The horizontal vestibulo-ocular reflex. Similar pathways connect the anterior and posterior canals to the vertical recti and oblique muscles.

A. Leftward head rotation excites hair cells in the left horizontal canal, thus exciting neurons that evoke rightward eye movement. The vestibular nuclei include two populations of first-order neurons. One lies in the medial vestibular nucleus (**M**); its axons cross the midline and excite neurons in the right abducens nucleus and nucleus prepositus hypoglossi (**P**). The other population is in the lateral vestibular nucleus (**L**); its axons ascend ipsilaterally in the tract of Deiters and excite neurons in the left oculomotor nucleus, which project in the oculomotor nerve to the left medial rectus muscle.

The right abducens nucleus has two populations of neurons. A set of motor neurons projects in the abducens nerve and excites the right lateral rectus muscle. The axons of a set of interneurons cross the midline and ascend in the left medial longitudinal fasciculus to the oculomotor nucleus, where they excite the neurons that project to the left medial rectus muscle. These connections facilitate the rightward horizontal eye movement that compensates for leftward head movement. Other nuclei shown are the superior (**S**) and descending (**D**) vestibular nuclei.

B. During counterclockwise head movement, leftward eye movement is inhibited by sensory fibers from the left horizontal canal. These afferent fibers excite neurons in the medial vestibular nucleus that inhibit motor neurons and interneurons in the left abducens nucleus. This action reduces the excitation of the motor neurons for the left lateral and right medial rectus muscles. The same head movement results in a decreased signal in the right horizontal canal (not shown), which has similar connections. The weakened signal results in decreased inhibition of the right lateral and left medial rectus muscles and decreased excitation of the left lateral and right medial rectus muscles. (Adapted from Sugiuchi et al. 2005.)

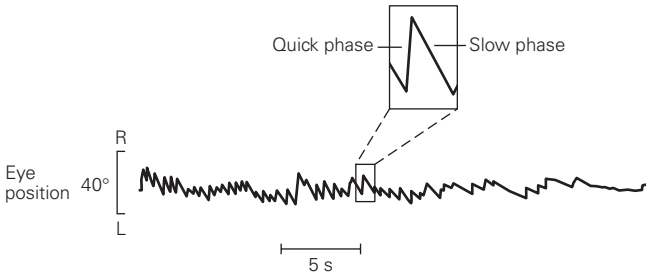

Figure 27–12 Vestibular nystagmus. The trace shows the eye position of a subject in a chair rotated counterclockwise at a constant rate in the dark. At the beginning of the trace, the eye moves slowly at the same speed as the chair (slow phase) and occasionally makes rapid resetting movements (quick phase). The speed of the slow phase gradually decreases until the eye no longer moves regularly. (Reproduced, with permission, from Leigh and Zee 2015.)

signals during rotation occurs through the velocity storage network.

If head rotation stops abruptly, the endolymph continues to be displaced in the same direction that the head had formerly rotated. With rightward rotation, this inhibits the right horizontal canal and excites the left horizontal canal, resulting in a sensation of leftward rotation and a corresponding left-beating nystagmus. However, this occurs only in darkness. In the light, optokinetic reflexes suppress postrotatory nystagmus since there is no visual motion stimulus.

The Translational Vestibulo-Ocular Reflex Compensates for Linear Motion and Head Tilts

When the head rotates, all images move with the same velocity on the retina. When the head moves sideways, however, the image of a close object moves more rapidly across the retina than does the image of a distant object. This can be understood easily by considering what happens when a person looks out the side window of a moving car. Objects near the side of the road move out of view almost with the speed of the car, whereas distant objects disappear more slowly. To compensate for linear head movement, the vestibular system must take into account the distance to the object being viewed—the more distant the object, the smaller the needed eye movement. During linear movements that do not involve head rotation, an appropriate translational VOR is elicited, driven by input from the otolith organs. Neurons in the vestibular nuclei, including some different from those providing the main drive to the rotational VOR, carry this signal to the extraocular motor neuron pools.

Side-to-side head movements result in a horizontal eye movement in a direction opposite to the head movement. Vertical displacements of the body, such as during walking or running, elicit oppositely directed vertical eye movements to stabilize gaze. However, in contrast to the rotational VOR where a head rotation is compensated by an equal but opposite eye rotation, horizontal displacement must be compensated by an eye rotation that depends on the viewed object distance, a nontrivial computation. For example, during a lateral head displacement, nearby objects move on the retina more rapidly than distant ones. So, in order to stabilize a nearby object on the retina, the eyes need to rotate by a larger amount than is needed for a distant object. Thus, the horizontal compensatory eye movements that are elicited during lateral motion scale with target distance; the closer the target, the larger is the compensatory eye movement. Similarly, as in the rotational VOR, compensatory responses to translation occur at relatively short latency (10–12 ms).

Fore-aft translations produce converging and diverging eye movements that bring the eyes together or move them apart. The amount of convergence or divergence is also dependent upon visual target distance, such that close visual objects produce large eye movements and distant visual objects produce little eye movements. Further, the amount of relative left and right eye movement is dependent upon visual object eccentricity relative to straight ahead. Unlike the rotational VOR that is a full-field image stabilization reflex, the goal of the translational VOR is to selectively stabilize visual objects on the fovea. In general, the two eyes move disjunctively, consisting of either a pure vergence movement or a combination of vergence and conjugate eye movements. In practice, although the direction of the evoked eye movement is typically consistent with geometrical predictions, the primate/human translational VOR typically undercompensates for near-target viewing, with gains of only about 0.5.

The translational VOR differs from the rotational VOR in the ability to generate compensatory eye movements during translation that optimize visual acuity on the central retina. These abilities appear to be specific to frontal-eyed animals, such as primates. Many lateral-eyed species, like the rabbit, do not generate eye movements that compensate for the visual consequences of translation during self-motion.

Because gravity exerts a constant linear acceleration force on the head, the otolith organs also sense the orientation of the head relative to gravity. When the head tilts away from the vertical in the roll plane—around the axis running from the occiput to the nose—the eyes rotate in the opposite direction to reduce the

tilt of the retinal image. This ocular counter-rolling reflex—the ability to use a gravity-sensing mechanism to maintain gaze relative to the horizon—is of paramount importance for lateral-eyed, afoveate species that typically lack a well-developed saccadic system. But such functional utility for these tilt responses has lost its advantage in the primate oculomotor system, where static ocular counter-rolling and counter-pitching in humans have a gain of less than 0.1.

Vestibulo-Ocular Reflexes Are Supplemented by Optokinetic Responses

The VORs compensate for head movement imperfectly. They are best at sensing the onset or abrupt change of motion; they compensate poorly for sustained motion at constant speed during translation or constant angular velocity during rotation. In addition, they are insensitive to very slow rotations or low-amplitude linear accelerations.

Thus, vestibular responses during prolonged motion in the light are supplemented by visual stabilization reflexes that maintain nystagmus when vestibular input ceases: optokinetic nystagmus, a full-field stabilization system, and ocular following, a foveal stabilization system. Although the two classes of reflexes are distinct, their pathways overlap.

The Cerebellum Adjusts the Vestibulo-Ocular Reflex

As we have seen, the VOR keeps the gaze constant when the head moves. There are times, however, when the reflex is inappropriate. For example, when you turn your head while walking, you want your gaze to follow. The rotational VOR, however, would prevent your eyes from turning with your head. To prevent this sort of biologically inappropriate response, the VOR is under the control of the cerebellum and cortex, which suppress the reflex during volitional head movements.

In addition, the VOR must be continuously calibrated to maintain its accuracy in the face of changes within the motor system (fatigue, injury to vestibular organs or pathways, eye-muscle weakness, or aging) and differing visual requirements (wearing corrective lenses). Indeed, the VOR is a highly modifiable reflex. The brain continuously monitors its performance by evaluating the clarity of vision during head movements. When head turns are consistently associated with image motion across the retina, the VOR undergoes gain changes in the direction appropriate to improve the compensatory ability of the reflex. For example, when viewing the world through spectacles that magnify or miniaturize the visual scene, the rotational VOR gain (in darkness) increases or decreases accordingly. The reflex behavior can adapt over several minutes, hours, and days. This is accomplished by sensory feedback that modifies the motor output. If the reflex is not working properly, the image moves across the retina. The motor command to the eye muscles must be adjusted until the gaze is again stable, rotational retinal image motion is zero, and there is no error.

Anyone who wears eyeglasses depends on this plasticity of the VOR. Because lenses for nearsightedness shrink the visual image, a smaller eye rotation is needed to compensate for a given head rotation, and the gain of the VOR must be reduced. Conversely, glasses for farsightedness magnify the image, so the VOR gain must increase during their use. More complicated is the instance of bifocal or progressive spectacles, in which the reflex must use different gains for the different magnifications. In the laboratory, the reflex can be conditioned by altering the visual consequences of head motion. For example, if a subject is rotated for a period of time while wearing magnifying glasses, the reflex gain gradually increases (Figure 27–13A).

This process requires changes in synaptic transmission in both the cerebellum and the brain stem. If the flocculus and paraflocculus of the cerebellum are lesioned, the gain of the VOR can no longer be modulated. Mossy fibers carry vestibular, visual, and motor signals from the pontine and vestibular nuclei to the cerebellar cortex; the granule cells, with their parallel fiber axons, relay these signals to the Purkinje cells (Figure 27–13B). The synaptic efficacy of parallel fiber input to a Purkinje cell could be modified by the concurrent action of climbing fiber input. Indeed, the climbing fiber input to the cerebellum carries a retinal error signal, thought to serve as a "teaching" signal enabling the cerebellum to correct the error in the VOR. This adaptation requires long-term plasticity of multiple mechanisms through multiple sites (Chapter 37).

In addition to the Purkinje cell, plasticity is also found in the vestibular nuclei, in a particular class of neurons known as flocculus target neurons, which receive GABAergic inhibitory input from Purkinje cells in the flocculus as well as direct inputs from vestibular sensory fibers. During adaptation of the VOR, these neurons change their sensitivity to the vestibular inputs in the appropriate way, and after adaptation, they can maintain those changes without further input from the cerebellum. The importance of the cerebellum in calibrating eye movements is also evident in patients with cerebellar disease, who are often characterized by a VOR response of abnormal amplitude or direction.

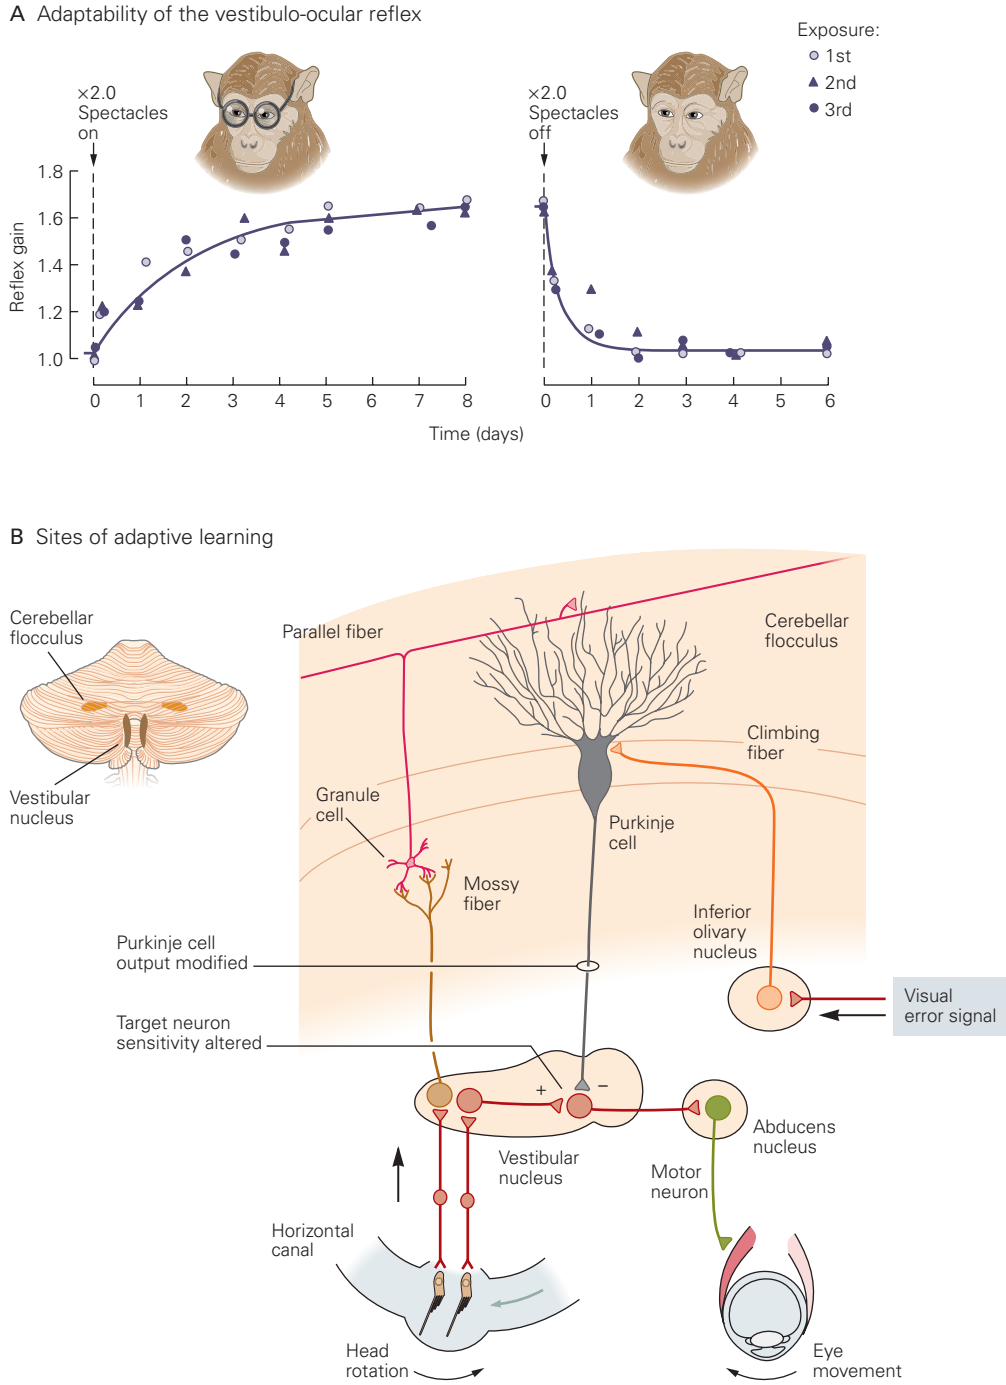

Figure 27–13 The vestibulo-ocular reflex is adaptable.

A. For several days, the monkey continuously wears magnifying spectacles that double the speed of the retinal-image motion evoked by head movement. Each day, the gain of the vestibulo-ocular reflex—the amount the eyes move for a given head movement—is tested in the dark so that the monkey cannot use retinal motion as a clue to modify the reflex. Over a period of 4 days, the gain increases gradually (*left*). It quickly returns to normal when the spectacles are removed (*right*). (Adapted, with permission, from Miles and Eighmy 1980.)

B. Adaptation of the vestibulo-ocular reflex occurs in cerebellar and brain stem circuits. A visual error signal, triggered by motion of the retinal image during head movement, reaches the inferior olivary nucleus. The climbing fiber transmits this error signal to the Purkinje cell, affecting the parallel fiber–Purkinje cell synapse. The Purkinje cell transmits changed information to the floccular target cell in the vestibular nucleus, changing its sensitivity to the vestibular input. After the reflex has been adapted, the Purkinje cell input is no longer necessary.

The Thalamus and Cortex Use Vestibular Signals for Spatial Memory and Cognitive and Perceptual Functions

For decades, vestibular function has been studied primarily in relation to reflexes, both vestibulo-ocular and vestibulospinal. Yet, in the past decade, it has become increasingly clear that the function of the vestibular system is as important for cognitive processes as for reflexes. The difficulty in understanding the vestibular system's role in spatial cognition stems from the fact that these functions are inherently multisensory, arising through convergence of vestibular, visual, somatosensory, and motor cues, following principles that remain poorly understood. Some of these perceptual functions of the vestibular system include tilt perception, visual-vertical perception, and visuospatial constancy.

Tilt perception. Vestibular information is critical for spatial orientation—the perception of how our head and body are positioned relative to the outside world. Nearly all species orient themselves using gravity, which provides a global, external reference. Thus, spatial awareness is governed by our orientation relative to gravity, collectively typically referred to as tilt.

Visual-vertical perception. We commonly experience the visual scene as perceptually oriented relative to earth-vertical orientation, regardless of our spatial orientation in the world. This ability has been studied psychophysically in humans and monkeys using tasks in which a subject is turned ear-down in the dark and asked to orient a dimly lit bar vertically in space (to align it with gravity). The results suggest that the neural representation of the visual scene is modified by static vestibular and proprioceptive signals that indicate the orientation of the head and body.

Visuospatial constancy. Vestibular signals are also important for the perception of a stable visual world despite constantly changing retinal images caused by movement of the eyes, head, and body. The projection of the scene onto the retina continuously changes because of these movements. Despite the changing retinal image, the percept of the scene as a whole remains stable; this stability is critical not only for vison but also for sensorimotor transformations (eg, to update the motor goal of an eye or arm movement).

Vestibular Information Is Present in the Thalamus

Vestibular projections to the thalamus are complicated and overall less clear, partly because of the strong multisensory nature of the responses in these cells and the difficulty in comparing thalamic regions and nomenclature across studies and species. Some neurons in all vestibular nuclei and likely the fastigial cerebellar nuclei project bilaterally to the thalamus, but most fibers terminate in the contralateral thalamic nuclei (Figure 27–9).

Several major thalamic regions receive vestibular projections, including the ventral posterolateral and ventral lateral thalamic nuclei and, to a lesser extent, the ventral posteroinferior nuclei, the posterior group, and the anterior pulvinar. These nuclei are traditionally thought to also receive somatosensory input and project to the primary and secondary somatosensory cortices, as well as the posterior parietal cortex (areas 5 and 7) and the insula of the temporal cortex.

Vestibular Information Is Widespread in the Cortex

A number of cortical areas receiving short-latency vestibular signals either alone or more commonly in concert with proprioceptive, tactile, oculomotor, visual, and auditory signals have been identified (Figure 27–14). Although vestibular signals are widely distributed to a number of cortical regions, all such regions are multimodal and none seems to represent a purely vestibular cortex, similar to other modalities such as vision, proprioception, and audition.

Vestibular modulation has been established in the lateral sulcus (parietoinsular vestibular cortex), somatosensory cortex (areas 3a and 2v), oculomotor cortex (frontal and supplementary eye fields), extrastriate visual motion cortex (dorsal medial superior temporal area), and parietal cortex (ventral intraparietal area and area 7a). In the primary somatosensory cortex, area 2v lies at the base of the intraparietal sulcus just posterior to the areas of the postcentral gyrus representing the hand and mouth. Electrical stimulation of area 2v in humans produces sensations of whole-body motion. Area 3a lies at the base of the central sulcus, adjacent to the motor cortex. Many cells in the parietoinsular vestibular cortex are multisensory, responding to body motion, somatosensory, proprioceptive, and visual motion stimuli. Patients with lesions in this region report episodes of vertigo, unsteadiness, and a loss of perception for visual vertical. Neurons in the medial intraparietal and medial superior temporal areas respond to both visual (optic flow) and vestibular signals. These cells utilize multisensory cue integration (Bayesian) frameworks to assist in the cognitive perception of motion through space.

Imaging studies reveal an even larger portion of cerebral cortex involved in processing vestibular information, including the temporoparietal cortex and the insula, the superior parietal lobe, the

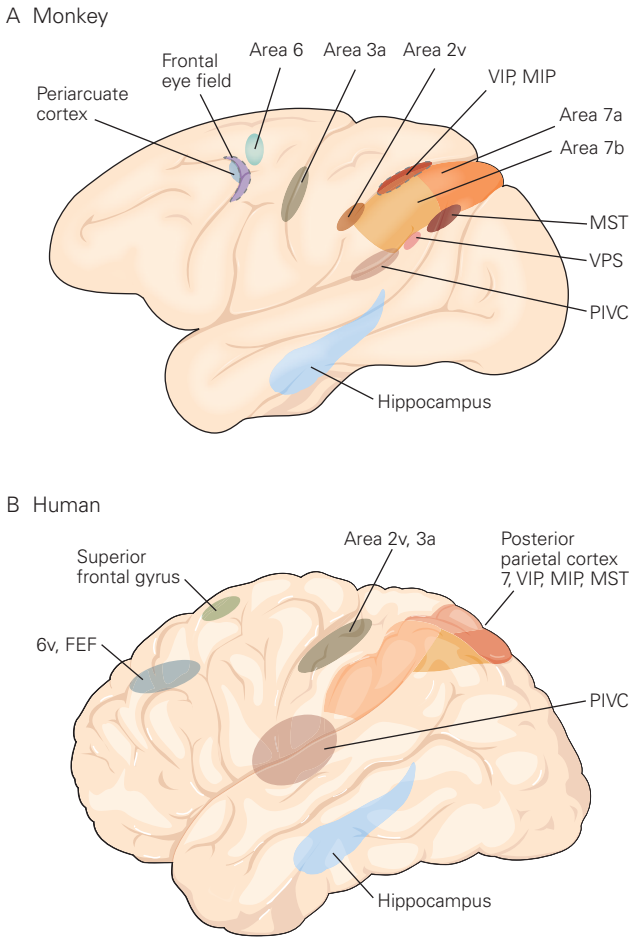

Figure 27–14 The vestibular cortex.

A. This lateral view of a monkey's brain shows the areas of cerebral cortex in which vestibular responses have been recorded. Areas in monkey cortex include periarcuate cortex, area 6, frontal eye fields, areas 3a and 2v, ventral intraparietal area (**VIP**), medial intraparietal area (**MIP**), area 7, visual posterior sylvian area (**VPS**), medial superior temporal area (**MST**), parieto-insular vestibular cortex (**PIVC**), and the hippocampal formation.

B. In the human cortex, areas recording vestibular activity include 6v, frontal eye fields (**FEF**), superior frontal gyrus, 2v, 3a, posterior parietal cortex, PIVC, and the hippocampal formation.

pre- and postcentral gyri, anterior cingulate and posterior middle temporal gyri, premotor and frontal cortices, inferior parietal lobule, putamen, and hippocampal regions. Using electrical stimulation of the vestibular nerve in patients activates the prefrontal lobe and anterior portion of the supplementary motor area at relatively short latencies. However, imaging and, to a lesser extent, single-cell recording studies may overstate the range of vestibular representations. In particular, vestibular stimuli often co-activate the somatosensory and proprioceptive systems, as well as evoke postural and oculomotor responses, which might in turn result in increased cortical activations.

Vestibular Signals Are Essential for Spatial Orientation and Spatial Navigation

Our ability to move about depends on a stable directional orientation. Certain cells in the thalamus, hippocampal region, entorhinal cortex, and subiculum are involved in navigation tasks. Damage to these areas impairs a variety of spatial and directional abilities. At least six cell types contributing to spatial orientation have been identified, including place cells, grid cells, head direction cells, border cells, speed cells, and conjunctive cells. In the hippocampus, place cells discharge relative to the animal's location in the environment (Chapter 54). Head direction cells in the dorsal thalamus, parahippocampal regions, and several regions of the cortex indicate the animal's heading direction like a compass. Grid cells in the entorhinal cortex respond to multiple spatial locations in a unique triangular grid pattern. Border cells in the entorhinal cortex signal environmental boundaries, speed cells discharge in proportion to the animal's running speed, and conjunctive cells exhibit a combination of several of these properties.

These regions are intimately connected and appear to work together in a "navigation network" to provide for spatial orientation, spatial memory, and our ability to move through our surroundings. Think of walking through your house, driving to the store, or knowing which direction to go in a new city. Lesions of central vestibular networks disrupt head direction, place, and grid responses. Patients with disease or trauma to the vestibular system, hippocampus, and anterior thalamus regions often exhibit severe deficits in their ability to orient in familiar environments or even find their way home.

All of these cells depend on a functioning vestibular system to maintain their spatial orientation properties. The pathway by which vestibular signals reach the navigation network and the computational principles determining how vestibular cues influence these spatially tuned cells is not well understood. We know that there are at least three different influences: Semicircular canal signals contribute to the estimate of head direction; gravity signals influence the three-dimensional properties of head direction cells; and translation signals influence the estimate of linear speed, which controls both grid cell properties and the magnitude and frequency of theta oscillations in the hippocampal network. What is clear is that there is no evidence

linking vestibular nuclei response properties directly to head direction or other spatially tuned cell types, and no direct projections from the vestibular nuclei to the brain areas thought to house these spatially tuned neurons have been identified. Furthermore, vestibular nuclei responses are inappropriate for driving these spatially tuned cells, as these signals need to encompass the total head movement, rather than individual components during active or passive head movement.

It has long been recognized that proprioceptive and motor efference cues should participate, together with vestibular signals, to track head direction over time. It has been proposed that internally generated information from vestibular, proprioceptive, and motor efference cues can be utilized to keep track of changes in directional heading. More recent insights have started to shed light on how each of these cues contributes to the final self-motion estimate that can be precisely predicted and quantitatively estimated based on a Bayesian framework. Although as yet difficult to define, quantitative internal models govern the relationship of vestibular and other multisensory self-motion cues for computing the spatial properties of navigation circuit cells.

Clinical Syndromes Elucidate Normal Vestibular Function

As we have seen, rotation excites hair cells in the semicircular canal whose hair bundles are oriented in the direction of motion and inhibits those in the canals oriented away from the motion direction. This imbalance in vestibular signals is responsible for the compensatory eye movements and the sensation of rotation that accompanies head movement. It can also originate from disease of one labyrinth or vestibular nerve, which results in a pattern of afferent vestibular signaling analogous to that stemming from rotation away from the side of the lesion, that is, more discharge from the intact side. There is accordingly a strong feeling of spinning, called vertigo.

Caloric Irrigation as a Vestibular Diagnostic Tool

Nystagmus can be used as a diagnostic indicator of vestibular system integrity. In patients complaining of dizziness or vertigo, the function of the vestibular labyrinth is typically assessed by a caloric test (Figure 27–15). Either warm (44°C) or cold (30°C) water is introduced into the external auditory canal. In normal persons, warm water induces nystagmus that beats toward the ear into which the water has been introduced, whereas cold water induces nystagmus that beats away from the ear into which the water has been introduced. This relationship is encapsulated in the mnemonic COWS: **C**old water produces nystagmus beating to the **O**pposite side; **W**arm water produces nystagmus beating to the **S**ame side. In normal persons, the two ears give equal responses. If there is a unilateral lesion in the vestibular pathway, however, nystagmus will be induced and directed toward the side opposite the lesion.

The vertigo and nystagmus resulting from an acute vestibular lesion typically subside over several days, even if peripheral function does not recover. This is because central compensatory mechanisms restore the balance in vestibular signals in the brain stem, even when peripheral input is permanently lost or unbalanced.

The loss of input from one labyrinth also means that all vestibular reflexes must be driven by a single labyrinth. For the VOR, this condition is quite effective at low speeds because the intact labyrinth can be both excited and inhibited. However, during rapid, high-frequency rotations, inhibition is not sufficient, such that the gain of the reflex is reduced when the head rotates toward the lesioned side. This is the basis of an important clinical test of canal function, the head-impulse test. In this test, the head is moved rapidly one time along the axis of rotation of a single canal. If there is a significant decrease in gain owing to canal dysfunction, the movement of the eyes will lag behind that of the head, and there will be a visible catch-up saccade.

Bilateral Vestibular Hypofunction Interferes With Normal Vision

Vestibular function is sometimes lost simultaneously on both sides, for example, from ototoxicity owing to aminoglycoside antibiotics such as gentamicin or cancer treatment medications such as cisplatin. The symptoms of bilateral vestibular hypofunction are different from those of unilateral loss. First, vertigo is absent because there is no imbalance in vestibular signals; input is reduced equally from both sides. For the same reason, there is no spontaneous nystagmus. In fact, these patients may have no symptoms when they are at rest and the head is still.

In humans, receptor and nerve fiber loss due to disease, trauma, or ototoxicity is permanent. However, in other animal classes such as amphibians, reptiles, and birds, spontaneous regeneration does occur over time. Although the differences in regeneration between animal groups is not yet understood, recent

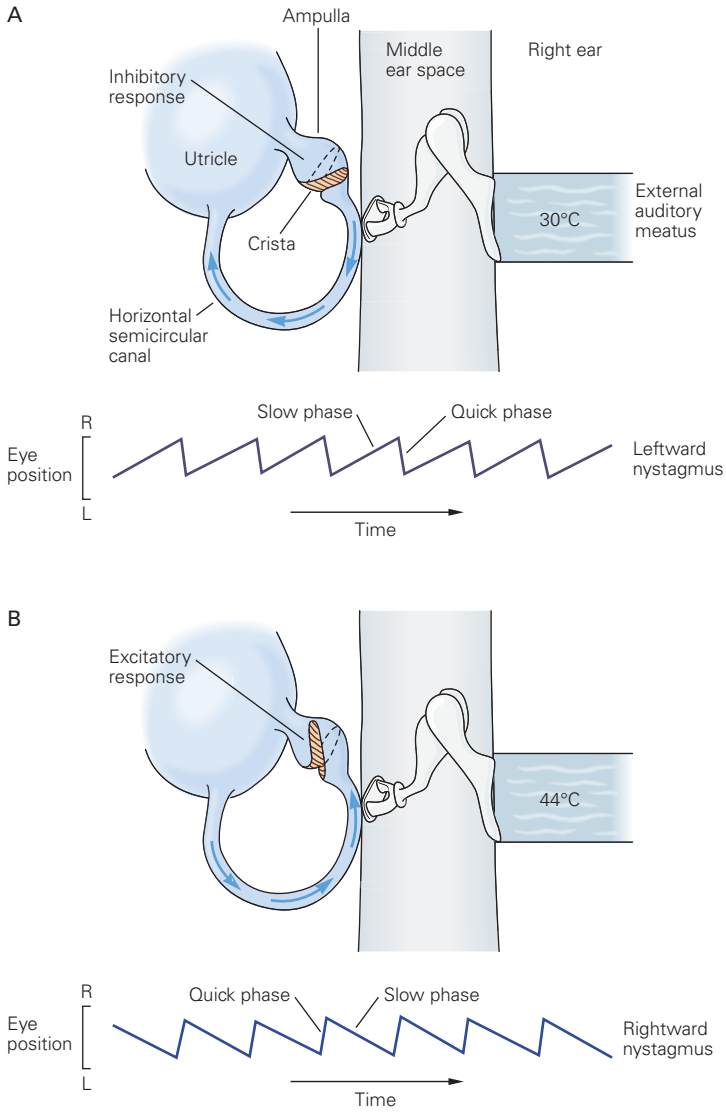

Figure 27–15 **Bithermal caloric test of the vestibulo-ocular reflex.** The vestibular caloric test remains the primary test used today in clinics around the world to determine if there is system dysfunction. The head is elevated 30° to align the horizontal semicircular canals with gravity.

A. Cold water or air introduced into the right ear causes a downward convection current in the endolymph, producing an inhibitory response in the right ear hair cells and afferent fibers. The result is a leftward (opposite side) beating nystagmus (as determined by fast phase direction).

B. Warm water or air introduced into the right ear produces an upward endolymph movement, producing an excitatory response in the hair cells and afferents. The result is a rightward (same side) beating nystagmus.

research shows promise for the future development of regenerative treatments in humans.

For the present, the loss of vestibular reflexes is devastating. A physician who lost his vestibular hair cells because of a toxic reaction to streptomycin wrote a dramatic account of this loss. Immediately after the onset of streptomycin toxicity, he could not read without steadying his head to keep it motionless. Even after partial recovery, he could not read signs or recognize friends while walking in the street; he had to stop to see clearly. Some patients may even "see" their heartbeat if the VOR fails to compensate for the miniscule head movements that accompany each arterial pulse.

Highlights

1. The vestibular system provides the brain with a rapid estimate of head movement. Vestibular signals are used for balance, visual stability, spatial orientation, movement planning, and motion perception.
2. Vestibular receptor hair cells are mechanotransducers that sense rotational and linear accelerations. Through kinematic and neural processing mechanisms, movements are transformed into acceleration, velocity, and position signals. These signals are used throughout the brain efficiently and quickly to guide behavior and cognition.

3. Receptor cells are polarized to detect the direction of motion. Three semicircular canals in each inner ear detect rotational motion and work in bilateral synergistic pairs through convergent commissural pathways in the vestibular nuclei. Two otolith organs in each ear detect linear translations and tilts relative to gravity.
4. Vestibular nuclei neurons receive converging multisensory and motor signals from visual, proprioceptive, cerebellar, and cortical sources. The multisensory integration allows for discrimination between active and passive body motion, as well as appropriate motor responses for reactive or volitional behavior.
5. Projections from the vestibular nuclei to the oculomotor system allow eye muscles to compensate for head movement through the vestibulo-ocular reflex to hold the image of the external world motionless on the retina. Cortical projections to the vestibular and oculomotor nuclei allow volitional eye movements to be separated from reflex eye movements but work through a final common pathway. Motor learning through vestibulocerebellar networks provides compensatory changes in eye movement responses to changing visual conditions through the use of spectacles, disease, or aging.
6. Projections from the vestibular nuclei to motor areas and the spinal cord facilitate postural stability. Gaze stability coordinates eye and neck movements through the medial vestibulospinal pathway. Postural control is exerted through the lateral vestibulospinal pathway.
7. Projections from the vestibular nuclei to the rostral and caudal medulla nuclei are involved in regulation of blood pressure, heart rate, respiration, bone remodeling, and homeostasis.
8. Projections from the vestibular nuclei to thalamus and cortex ensure spatial orientation and influence spatial perception more generally.
9. Vestibular signals processed in the hippocampal regions are crucial for spatial location and navigation functions.
10. Vestibular signals are combined with visual signals in several cortical regions through Bayesian cue integration to provide motion perception.
11. Disease or trauma to the vestibular system can produce nausea, vertigo, dizziness, balance disorders, visual instability, and spatial confusion.
12. We are only beginning to appreciate the role of the vestibular system in cognition. However, it is clear that vestibular signals contribute to our perception of self, conception of body presence, and memory.
13. New approaches in computation and theory promise to provide the lapidary keys needed to unlock our understanding of how vestibular signals contribute to the essence of brain function.

Auditory Processing by the Central Nervous System

Hearing is crucial for localizing and identifying sound; for humans, it is particularly important because of its role in the understanding and production of speech. The auditory system has several noteworthy features. Its subcortical pathway is longer than that of other sensory systems. Unlike the visual system, sounds can enter the auditory system from all directions, day and night, when we are asleep as well as when we are awake. The auditory system processes not only sounds emanating from outside the body (environmental sounds, sounds generated by others) but also self-generated sounds (vocalizations and chewing sounds). The location of sound stimuli in space is not conveyed by the spatial arrangement of

sensory afferent neurons but is instead computed by the auditory system from representations of the physical cues.

Sounds Convey Multiple Types of Information to Hearing Animals

Hearing helps to alert animals to the presence of unseen dangers or opportunities and, in many species, also serves as a means for communication. Information about where sounds arise and what they mean must be extracted from the representations of the physical characteristics of sound at each of the ears. To understand how animals process sound, it is useful first to consider which cues are available.

Most vertebrates take advantage of having two ears for localizing sounds in the horizontal plane. Sound sources at different positions in that plane affect the two ears differentially: Sound arrives earlier and is more intense at the ear nearer the source (Figure 28–1A). Interaural time and intensity differences carry information about where sounds arise.

The size of the head determines how interaural time delays are related to the location of sound sources; the neuronal circuitry determines the precision with which time delays are resolved. Because air pressure waves travel at roughly 340 m/s in air, the maximal interaural delay in humans is approximately 600 μs; in small birds, the greatest delay is only 35 μs. Humans can resolve the location of a sound source directly ahead to within approximately 1 degree, corresponding to an interaural time difference of 10 μs. Interaural time differences are particularly well conveyed by neurons that encode relatively low frequencies. These neurons can fire at the same position in every cycle of the sound and in this way encode the interaural time difference as an interaural phase difference. Sounds of high frequencies produce *sound shadows* or intensity differences between the two ears. For many mammals with small heads, high-frequency sounds provide the primary cue for localizing sound in the horizontal plane.

Mammals can localize sounds in the vertical plane and with a single ear using spectral filtering. High-frequency sounds, with wavelengths that are close to or smaller than the dimensions of the head, shoulders, and external ears, interact with those parts of the body to produce constructive and destructive interference, introducing broad spectral peaks and deep, narrow spectral notches whose frequency changes with the location of the sound (Figure 28–1B). High-frequency sounds from different origins are filtered differently because in mammals the shape of the external ear differs back-to-front as well as top-to-bottom. Animals learn to use these spectral cues to locate sound sources. If the shape of the ear is experimentally altered, even adult humans can learn to make use of a new pattern of spectral cues. If animals lose hearing in one ear, they lose interaural timing and intensity cues and must depend completely on spectral cues for localizing sounds.

How do we make sense of the complex and changing sounds that we hear? Most natural sounds contain energy over a wide range of frequencies and change rapidly with time. The information used to recognize sounds varies among animal species, and depends on listening conditions and experience. Human speech, for example, can be understood in the midst of noise, over electronic devices that distort sounds, and even through cochlear implants. One reason for its robustness is that speech contains redundant cues: The vocal apparatus produces sounds in which multiple parameters covary. At the same time, this makes the task of understanding how animals recognize patterns a complicated one. It is not clear which cues are used by animals under various conditions.

Music is a source of pleasure to human beings. Musical instruments and human voices produce sounds that have energy at the fundamental frequency that corresponds to its perceived pitch, as well as at multiples of that frequency, giving sounds a quality that allows us, for example, to distinguish a flute from a violin when their pitch is the same. Musical pitches are largely in the low-frequency range in which auditory nerve fibers fire in phase with sounds. In music, sounds are combined simultaneously to produce chords and successively to produce melodies. Euphonious, pleasant chords elicit regular, periodic firing in cochlear nerve fibers. In dissonant sounds, there is less regularity both in the sound itself and in the firing of auditory nerve fibers; the component frequencies are so close that they interfere with one another instead of periodically reinforcing one another.

The Neural Representation of Sound in Central Pathways Begins in the Cochlear Nuclei

The neural pathways that process acoustic information extend from the ear to the brain stem, through the midbrain and thalamus, to the cerebral cortex (Figure 28–2). Acoustic information is conveyed from cells in the cochlear ganglion (see Figure 26–17) to the cochlear nuclei in the brain stem. There information is received by several different types of neurons, most of which are arranged tonotopically.

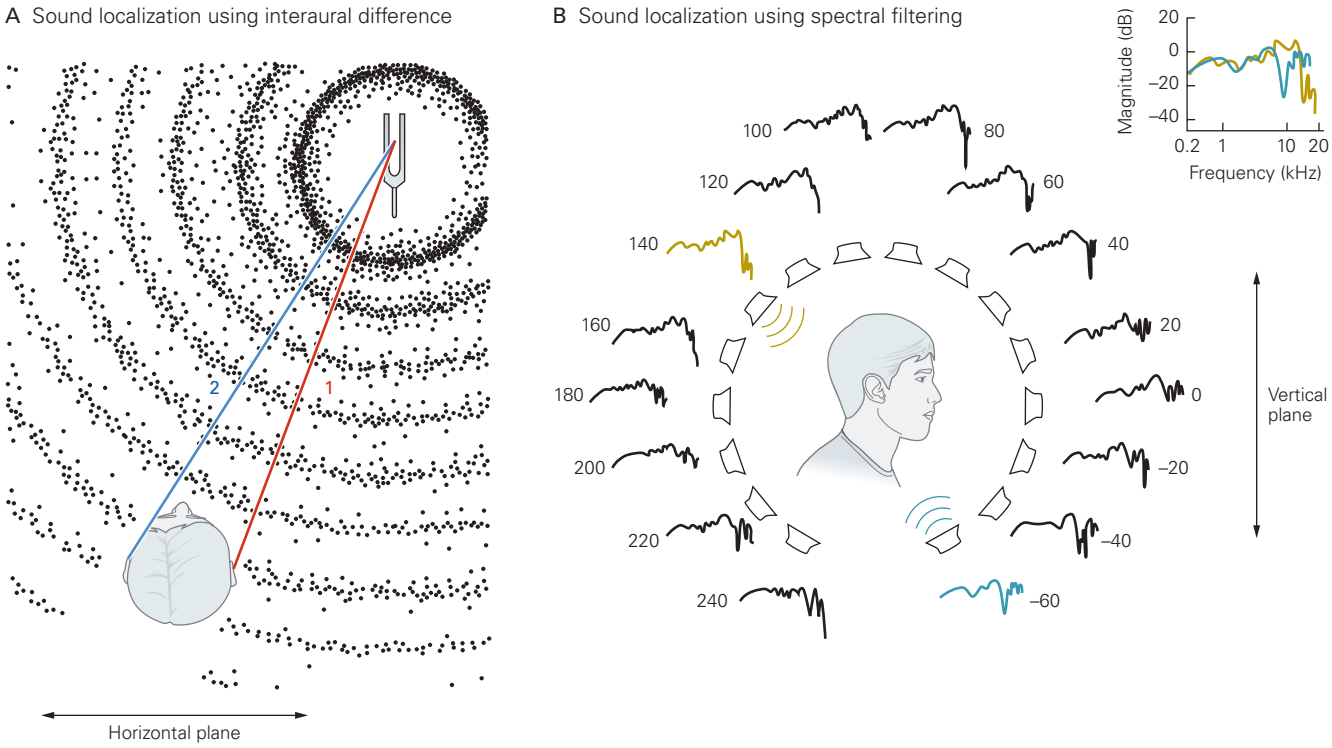

Figure 28–1 Cues for localizing sound sources in the horizontal plane.

A. Interaural time and intensity differences are cues for localizing sound sources in the horizontal plane, or azimuth. A sound arising in the horizontal plane arrives differently at the two ears: Sounds arrive earlier and are louder at the ear nearer the source. A sound that arises directly in the front or back travels the same distance to the right and left ears and thus arrives at both ears simultaneously. Interaural time and intensity do not vary with the movement of sound sources in the vertical plane, so it is impossible to localize a pure sinusoidal tone in the vertical plane. In humans, the maximal interaural time difference is approximately 600 μs. High-frequency sounds, with short wavelengths, are deflected by the head, producing a sound shadow on the far side. (Adapted, with permission, from Geisler 1998.)

B. Mammals can localize broadband sounds in both the vertical and horizontal planes on the basis of spectral filtering. When a noise that has equal energy at all frequencies over the human hearing range (*white noise*) is presented through a speaker, the ear, head, and shoulders cancel energy at some frequencies and enhance others. The white noise that is emitted from the speaker has a flat power spectrum, but by the time the noise has reached the bottom of the ear canal, its spectrum is no longer flat.

In the figure, the sound energy at each frequency at the eardrum relative to that of the white noise is shown by the traces beside each speaker; these traces plot the relative sound magnitude in decibels against spectral frequency (*head-related transfer function*). The small plot in the upper right compares two head-related transfer functions: one for a noise that arises low and in front of a listener (**blue**) and one for a noise from behind the listener's head (**brown**). Head-related transfer functions have deep notches at frequencies greater than 8 kHz, whose frequencies vary depending on where the sounds arose. Sounds that lack energy at high frequencies and narrowband sounds are difficult to localize in the vertical plane. Since spectral filtering also varies in the horizontal plane, it provides the only location cue to animals that have lost hearing in one ear.

You can test the salience of these spectral cues with a simple experiment. Close your eyes as a friend jingles keys directly in front of you at various elevations. Compare your ability to localize sounds under normal conditions and when you distort the shape of both ears by pushing them with your fingers from the back. (Data from D. Kistler and F. Wightman.)

The axons of the different types of neurons take different routes to the brain stem and midbrain, where they terminate on separate targets. Some of the pathways from the cochlear nuclei to the contralateral inferior colliculus are direct; others involve one or two synaptic stages in brain stem auditory nuclei. From the bilateral inferior colliculi, acoustic information flows two ways: to the ipsilateral superior colliculus, where it participates in orienting the head and eyes in response to sounds, and to the ipsilateral thalamus, the relay to auditory areas of the cerebral cortex. The afferent auditory pathways from the periphery to higher brain regions include efferent feedback at many levels.

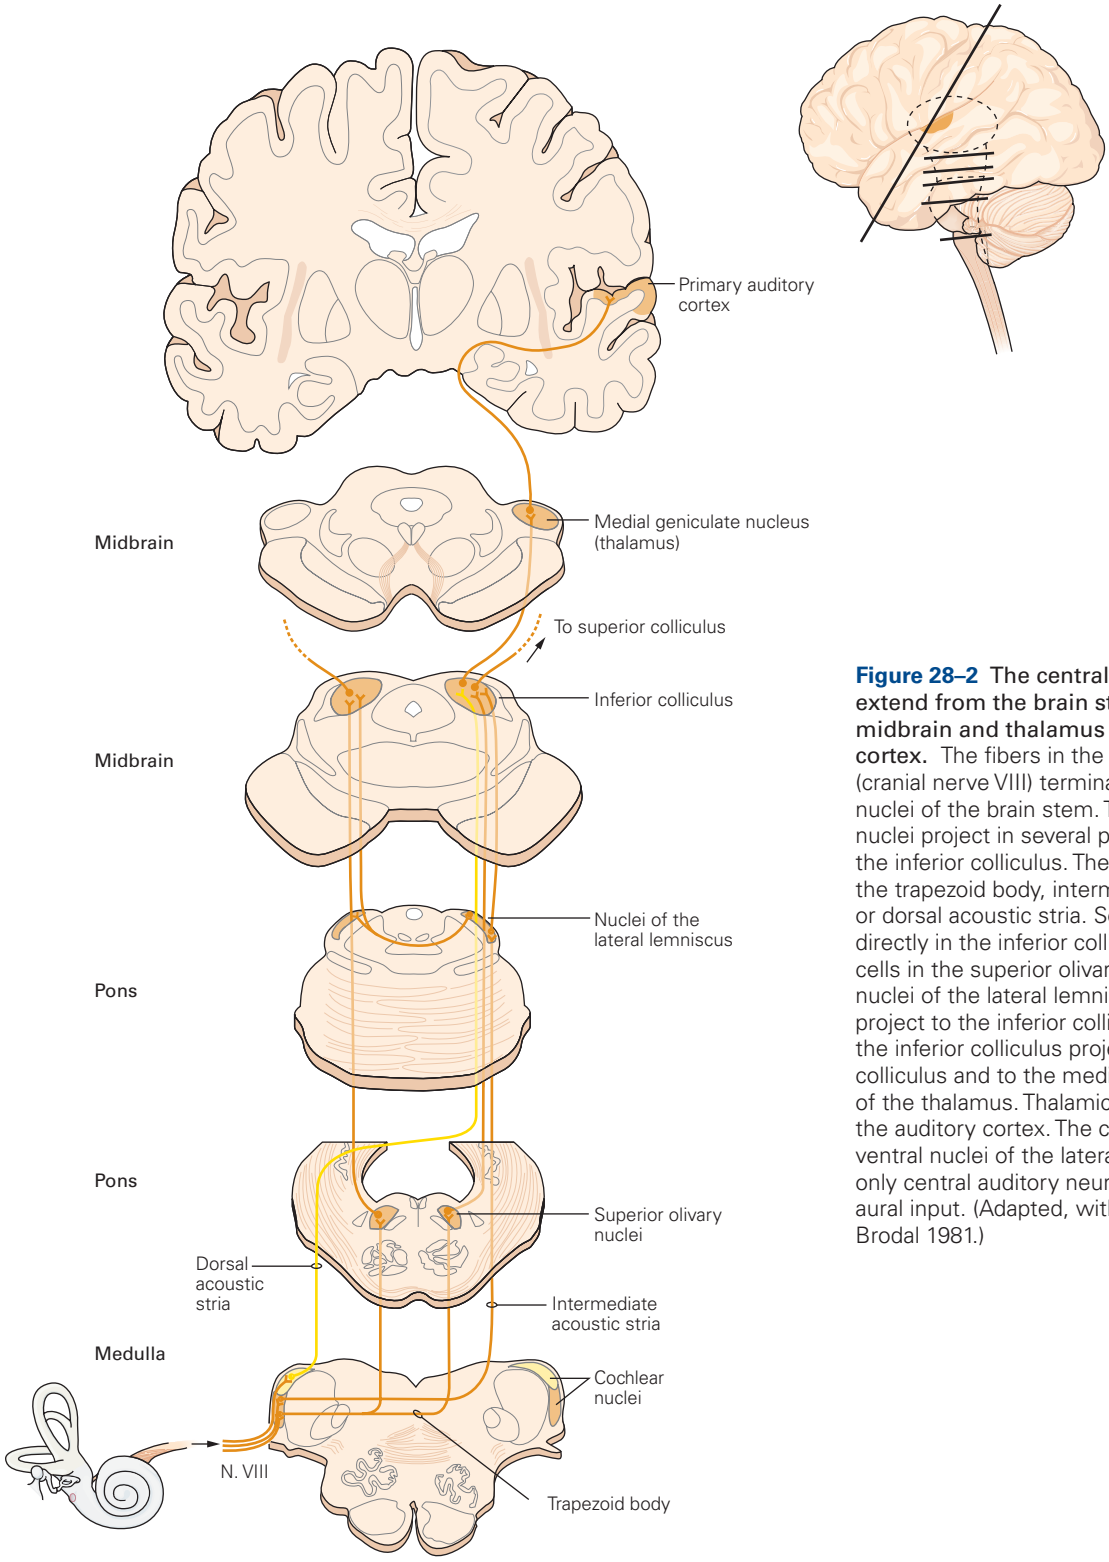

Figure 28–2 **The central auditory pathways extend from the brain stem through the midbrain and thalamus to the auditory cortex.** The fibers in the cochlear nerve (cranial nerve VIII) terminate in the cochlear nuclei of the brain stem. The neurons of these nuclei project in several parallel pathways to the inferior colliculus. Their axons exit through the trapezoid body, intermediate acoustic stria, or dorsal acoustic stria. Some cells terminate directly in the inferior colliculus. Others contact cells in the superior olivary complex and in the nuclei of the lateral lemniscus, which in turn project to the inferior colliculus. Neurons of the inferior colliculus project to the superior colliculus and to the medial geniculate nucleus of the thalamus. Thalamic neurons project to the auditory cortex. The cochlear nuclei and the ventral nuclei of the lateral lemniscus are the only central auditory neurons that receive monaural input. (Adapted, with permission, from Brodal 1981.)

The Cochlear Nerve Delivers Acoustic Information in Parallel Pathways to the Tonotopically Organized Cochlear Nuclei

The afferent nerve fibers from cochlear ganglion cells are bundled in the cochlear or auditory component of the vestibulocochlear nerve (cranial nerve VIII) and terminate exclusively in the cochlear nuclei. The cochlear nerve in mammals contains two groups of fibers: a large number (95%) of myelinated fibers that receives input from inner hair cells and a small number (5%) of unmyelinated fibers that receive input from outer hair cells.

The larger, more numerous, myelinated fibers are much better understood than the unmyelinated fibers. Each type detects energy over a narrow range of frequencies; the tonotopic array of cochlear nerve fibers thus carries detailed information about how the frequency content of sounds varies from moment to moment. The unmyelinated fibers terminate both on the large neurons in the ventral cochlear nuclei and also on the small granule cells that surround the ventral cochlear nuclei. Because it is difficult to record from these tiny fibers, the information they convey to the brain is not well understood. The unmyelinated fibers integrate information from a relatively wide region of the cochlea but are not responsive to sound. It has been suggested that these fibers respond to cochlear damage and contribute to hyperacusis—pain after exposure to loud sounds that damages the cochlea.

Two features of the cochlear nuclei are important. First, these nuclei are organized tonotopically. Fibers that carry information from the apical end of the cochlea, which detects low frequencies, terminate ventrally in the ventral and dorsal cochlear nuclei; those that carry information from the basal end of the cochlea, which detects high frequencies, terminate dorsally (Figure 28–3). Second, each cochlear nerve fiber innervates several different areas within the cochlear nuclei, contacting various types of neurons that have distinct projection patterns to higher auditory centers. As a result, the auditory pathway comprises at least four parallel ascending pathways that simultaneously extract different acoustic information from the signals carried by cochlear nerve fibers. Parallel circuits are a general feature of vertebrate sensory systems.

The Ventral Cochlear Nucleus Extracts Temporal and Spectral Information About Sounds

The principal cells of the unlayered ventral cochlear nucleus sharpen temporal and spectral information and convey it to higher centers of the auditory pathway. Three types of neurons are intermingled and form separate pathways through the brain stem (Figure 28–4).

Bushy cells project bilaterally to the superior olivary complex. This pathway has two parts. One courses through the medial superior olive and compares the time of arrival of sounds at the two ears; the other travels through the medial nucleus of the trapezoid body and the lateral superior olive and compares interaural intensity. Large spherical bushy cells sense low frequencies and project bilaterally to the medial superior olive, forming a circuit that detects interaural time delay and contributes to the localization of low-frequency sounds in the horizontal plane. The small spherical bushy cells and globular bushy cells sense higher frequencies. Small spherical bushy cells excite the lateral superior olive ipsilaterally. The globular bushy cells, through calyceal endings, excite neurons in the contralateral medial nucleus of the trapezoid body that in turn inhibit principal cells of the lateral superior olive. Neurons in the lateral superior olive integrate the ipsilateral excitation and contralateral inhibition to measure interaural intensity and to localize sources of high-frequency sounds in the horizontal plane (see Figure 28–6).

Stellate cells terminate widely. They excite neurons in the ipsilateral dorsal cochlear nucleus, the medial olivocochlear efferent neurons in the ventral nucleus of the trapezoid body, the periolivary nuclei in the vicinity of the ipsilateral lateral superior olive, and the contralateral ventral nucleus of the lateral lemniscus, inferior colliculus, and thalamus. The tonotopic array of stellate cells encodes the spectrum of sounds.

Octopus cells excite targets in the contralateral paraolivary nucleus and terminate in large excitatory calyceal endings on neurons of the ventral nucleus of the lateral lemniscus, which in turn provide sharply timed glycinergic inhibition to the inferior colliculus. Octopus cells detect onsets of sounds that allow animals to detect brief gaps. They mark the spectral components that come from one source that necessarily start together.

The differences in the integrative tasks performed by these pathways through the ventral cochlear nucleus are reflected in cell morphology. The shapes of their dendrites reflect the way they collect information from cochlear nerve fibers. The dendrites of the sharply tuned bushy and stellate cells receive input from relatively few cochlear nerve fibers, whereas those of the broadly tuned octopus cells, in contrast, lie perpendicular to the path of cochlear nerve fibers, poised to receive input from many cochlear nerve fibers. Many of the inputs to bushy cells are from unusually large

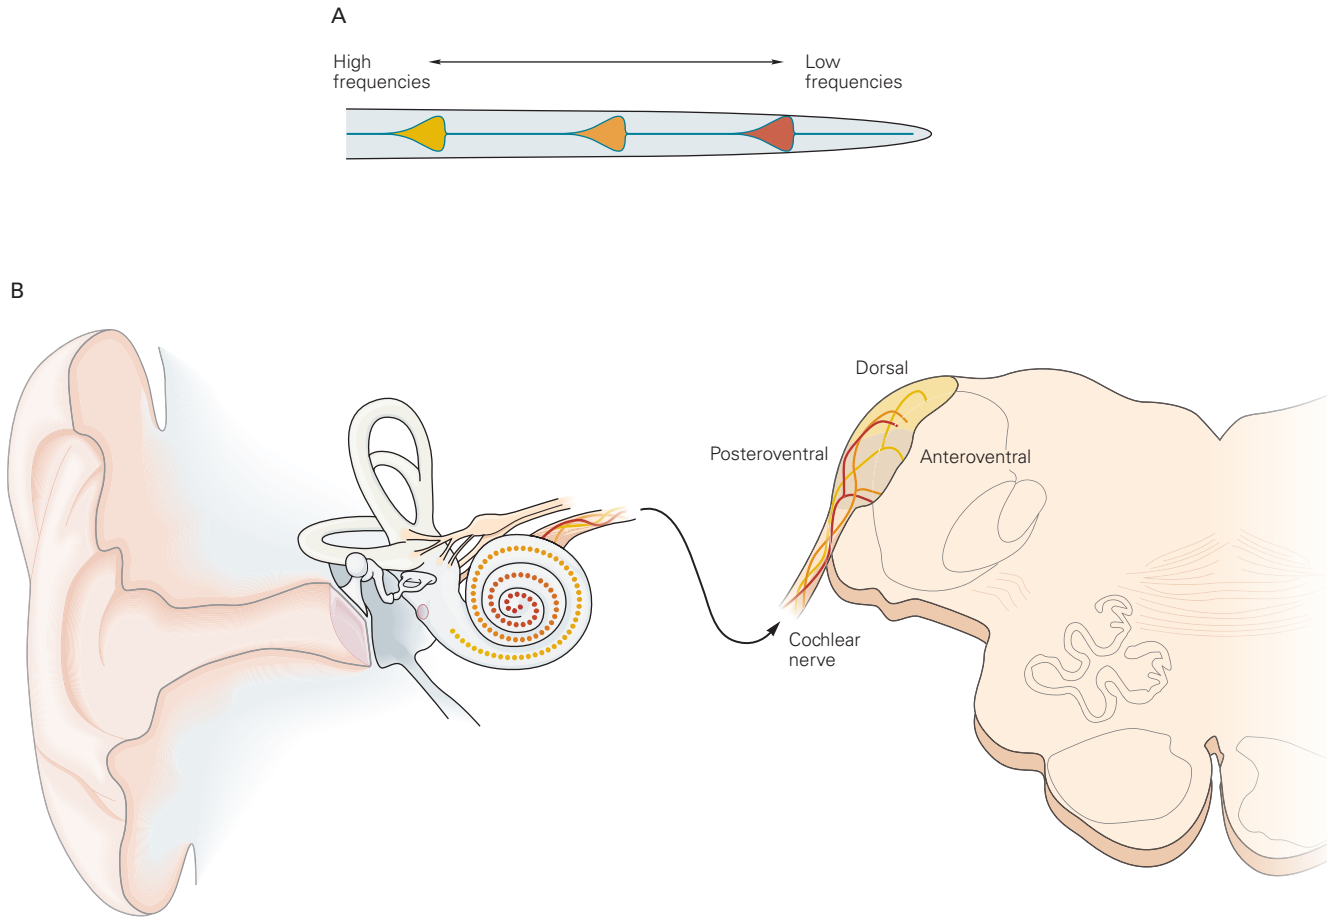

Figure 28–3 The dorsal and ventral cochlear nuclei.

A. Stimulation with three frequencies of sound vibrates the schematically uncoiled basilar membrane at three positions, exciting distinct populations of hair cells and their afferent nerve fibers.

B. Cochlear nerve fibers project in a tonotopic pattern to the cochlear nuclei. Those encoding the lowest frequencies (**red**) terminate most ventrally, whereas those encoding higher frequencies (**yellow**) terminate more dorsally. The cochlear nuclei include the ventral and dorsal nuclei. Each afferent fiber enters at the nerve root and splits into branches that run anteriorly (the ascending branch) and posteriorly (the descending branch). The ventral cochlear nucleus is thus divided functionally into anteroventral and posteroventral divisions.

terminals that envelop the bushy cell bodies, meeting their need for large synaptic currents. The need for large synaptic currents in octopus cells is met by summing inputs from large numbers of small terminals.

The biophysical properties of neurons determine how synaptic currents are converted to voltage changes and over how long a time synaptic inputs are integrated. Octopus and bushy cells in the ventral cochlear nucleus are able to respond with exceptionally rapid and precisely timed synaptic potentials. These neurons have a prominent, low-voltage-activated K^+ conductance that confers a low input resistance and rapid responsiveness and prevents repetitive firing (Figure 28–4C). The large synaptic currents that are required to trigger action potentials in these leaky cells are delivered through rapidly gated, high-conductance, AMPA-type (α-amino-3-hydroxy-5-methylisoxazole-4-propionate) glutamate receptors at many synaptic release sites. In contrast, stellate cells, in which even relatively small depolarizing currents produce large protracted voltage changes, generate slower excitatory postsynaptic potentials (EPSPs) in response to synaptic currents, and *N*-methyl-D-aspartate (NMDA)-type glutamate receptors enhance those responses.

The Dorsal Cochlear Nucleus Integrates Acoustic With Somatosensory Information in Making Use of Spectral Cues for Localizing Sounds

Among vertebrates, only mammals have dorsal cochlear nuclei. The dorsal cochlear nucleus receives input from two systems of neurons that project to different

layers (Figure 28–4A,B). Its principal cells, fusiform cells, integrate those two systems of inputs and convey the result directly to the contralateral inferior colliculus.

The outermost molecular layer is the terminus of a system of parallel fibers, the unmyelinated axons of granule cells that are scattered in and around the cochlear nuclei. This system transmits somatosensory, vestibular, and auditory information from widespread regions of the brain to the molecular layer.

The deep layer receives acoustic information. Not only cochlear nerve fibers but also stellate cells of the ventral cochlear nucleus terminate in the deep layer. Acoustic inputs are tonotopically organized in isofrequency laminae that run at right angles to parallel fibers.

Fusiform cells, the principal cells of the dorsal cochlear nucleus, integrate the two systems of inputs. Parallel fibers in the molecular layer excite fusiform cells through spines on apical dendrites in the molecular layer. Parallel fibers also terminate on spines of dendrites of cartwheel cells, interneurons that bear a strong resemblance to cerebellar Purkinje cells, which in turn inhibit fusiform cells. Cochlear nerve fibers and stellate cells in the ventral cochlear nucleus excite fusiform cells and inhibitory interneurons via synapses on the smooth basal dendrites in the deep layer.

Recent experiments suggest that the circuits of the dorsal cochlear nucleus distinguish between unpredictable and predictable sounds. An animal's own chewing or licking sounds, for example, are predictable and canceled through these circuits. The changes in spectral cues that arise when animals move their heads or ears or shoulders, changing the angle of incidence of sounds to the ears, are unpredictable, especially when an external sound source is moving. Somatosensory and vestibular information about the position of the head and ears, as well as descending information from higher levels of the nervous system about the animal's own movements, pass through the molecular layer to modulate acoustic information that arrives in the deep layer.

The Superior Olivary Complex in Mammals Contains Separate Circuits for Detecting Interaural Time and Intensity Differences

In many vertebrates, including mammals and birds, neurons in the superior olivary complex compare the activity of cells in the bilateral cochlear nuclei to locate sound sources. Separate circuits detect interaural time and intensity differences and project to the inferior colliculi.

The Medial Superior Olive Generates a Map of Interaural Time Differences

Differences in arrival times at the ears are not represented at the cochlea. Instead, they are first represented in the medial superior olive where a map of interaural phase is created by a comparison of the timing of action potentials in the responses to sounds from the two ears. Sounds arrive at the near ear before they arrive at the far ear, with interaural time differences being directly related to the location of sound sources in the horizontal plane (Figure 28–5A).

Cochlear nerve fibers tuned to frequencies below 4 kHz and their bushy cell targets encode sounds by firing in phase with the pressure waves. This property is known as *phase-locking.* Although individual neurons may fail to fire at some cycles, some set of neurons fires with every cycle. In so doing, these neurons carry information about the timing of inputs with every cycle of the sound. Sounds arriving from one side evoke phase-locked firing that is consistently earlier at the near ear than at the far ear, resulting in consistent interaural phase differences (Figure 28–5A).

In 1948, Lloyd Jeffress suggested that an array of detectors of coincident inputs from the two ears, transmitted through *delay lines* comprised of axons with systematically differing lengths, could form a map of interaural time differences and thus a map of the location of sound sources (Figure 28–5B). In such a circuit, conduction delays compensate for the earlier arrival at the near ear. Interaural time delays increase systematically as sounds move from the midline to the side, resulting in coincident firing further toward the edge of the neuronal array.

Such neuronal maps have been found in the barn owl in the homolog of the medial superior olivary nucleus. Mammals and chickens use a variant of this input arrangement. The principal neurons of the medial superior olive form a sheet of one or a few cells' thickness on each side of the midline. Each neuron has two tufts of dendrites, one extending to the lateral face of the sheet, and the other projecting to the medial face of the sheet (Figure 28–5C). The dendrites at the lateral face are contacted by the axons of large spherical bushy cells from the ipsilateral cochlear nucleus, whereas the dendrites at the medial face are contacted by large spherical bushy cells of matching best frequency from the contralateral cochlear nucleus. The axons of bushy cells terminate in the contralateral

medial superior olive with delay lines just as Jeffress had suggested, but the branches that terminate in the ipsilateral medial superior olive are of equal length (see Figure 28–5C).

The conduction delays are such that each medial superior olive receives coincident excitatory inputs from the two ears only when sounds come from the contralateral half of space. As sound sources move from the midline to the most lateral point on the contralateral side of the head, the earlier arrival of sounds at the contralateral ear needs to be compensated by successively longer delay lines. This results in inputs from the two ears coinciding at successively more posterior and lateral regions of the medial superior olive. Inhibition superimposed on these excitatory inputs plays a significant role in sharpening the map of interaural phase.

In encoding interaural phase, individual neurons in the medial superior olive provide ambiguous information about interaural time differences. Phase ambiguities are resolved when sounds have energy at multiple frequencies, as natural sounds almost always do. The sheet of neurons of the medial superior olive forms a representation of interaural phase along the rostrocaudal and lateromedial dimensions. The array of bushy cell inputs also imposes a tonotopic organization in the dorsoventral dimension. Sounds that contain energy at multiple frequencies evoke maximal coincident firing in a single dorsoventral column of neurons that localizes sound sources unambiguously. The beauty of using interaural phase to encode interaural time disparities is that the brain receives information about interaural time differences not just at the beginning and end of the sound but with every cycle of an ongoing sound.

Principal cells of the medial superior olive also receive sharply timed inhibition driven by sounds from both the ipsilateral and contralateral sides through the lateral and medial nuclei of the trapezoid body, respectively. Remarkably, the inhibition through pathways from both sides precedes the arrival of excitation and sharpens the summation of excitation even though inhibition is mediated through a pathway that has an additional synapse. The great conduction speed through the disynaptic pathway through the medial nucleus of the trapezoid body is made possible by the large axons of globular bushy cells and the large calyceal terminals of Held that activate neurons in the medial nucleus of the trapezoid body with short and consistently timed delays. The pathway that brings ipsilateral inhibition through the lateral nucleus of the trapezoid body is less well understood.

Each medial superior olive thus forms a map of the location of sound sources in the contralateral hemifield. The striking difference between this spatial representation of stimuli and those in other sensory systems is that it is not the result of the spatial arrangement of inputs, like retinotopic or somatosensory maps, but is inferred by the brain from computations made in the afferent pathways.

The Lateral Superior Olive Detects Interaural Intensity Differences

Sounds with wavelengths that are similar to or smaller than the head are deflected by the head, causing the

Figure 28–4 (Opposite) Different types of cells in the cochlear nuclei extract distinct types of acoustic information from cochlear nerve fibers.

A. The differing sizes and shapes of terminals along the length of each cochlear nerve fiber in the ventral cochlear nucleus of a newborn dog reflect differences in their postsynaptic targets. The large end bulbs form synapses on bushy cells; smaller boutons contact stellate and octopus cells. The nerve fibers shown here are color-coded as in Figure 28–3: the **yellow** fiber encodes the highest frequencies and the **red** fiber the lowest. (Adapted, with permission, from Cajal 1909.)

B. A layer of mouse granule cells (**light brown**) separates the unlayered ventral cochlear nucleus (**pink**) from the layered dorsal nucleus (**tan and light brown**). In the dorsal cochlear nucleus, the cell bodies of fusiform and granule cells are intermingled in a region between the outermost molecular layer and the deep layer. Cochlear nerve fibers, color-coded for frequency as in Figure 28–3, terminate in both nuclei but with different patterns of convergence on the principal cells. Each bushy, stellate, and fusiform cell receives input from a few auditory nerve fibers and is sharply tuned, whereas individual octopus cells are contacted by many auditory nerve fibers and are broadly tuned.

C. Differences in the intrinsic electrical properties of the principal cells of mouse cochlear nuclei are reflected in the patterns of voltage change in the cells. When steadily depolarized, stellate and fusiform cells fire repetitive action potentials, whereas repetitive firing in bushy and octopus cells is prevented by low-voltage-activated conductances. The low input resistance of bushy and octopus cells in the depolarized voltage range makes depolarizing voltage changes rapid but also small; the rise and fall of voltage changes in stellate and fusiform cells is slower. Synaptic potentials, too, are different. The brief synaptic potentials in bushy and octopus cells require larger synaptic currents but encode the timing of auditory nerve inputs more faithfully than do the longer-lasting synaptic potentials in stellate or fusiform cells. C Bilateral medial superior olivary nuclei

intensity at the near ear to be greater than that at the far ear. In humans, interaural intensities can differ in sounds that have frequencies greater than about 2 kHz. Interaural intensity differences produced by such *head shadowing* are detected by a neuronal circuit that includes the medial nucleus of the trapezoid body and the lateral superior olive.

Although the lateral superior olive does not form a map of the location of sounds in the horizontal plane, it performs the first of several integrative steps that use interaural intensity differences to localize sounds. Neurons in this nucleus balance ipsilateral excitation with contralateral inhibition. Excitation comes from small spherical bushy cells and stellate cells in the ipsilateral ventral cochlear nucleus. Inhibition comes from a disynaptic pathway that includes globular bushy cells in the contralateral ventral cochlear nucleus and principal neurons of the ipsilateral medial nucleus of the trapezoid body (Figure 28–6A). Sounds that arise ipsilaterally generate relatively strong excitation and relatively weak inhibition, whereas those that arise contralaterally generate stronger inhibition than excitation. Neurons in the lateral superior olive are activated more strongly by sounds from the ipsilateral than from the contralateral hemifield. The firing of lateral superior olivary neurons is a function of the location of the sound source and thus carries information about where sounds arise in the horizontal plane (Figure 28–6B).

In order to balance excitation and inhibition stimulated by one sound, the ipsilateral excitation and contralateral inhibition must arrive at neurons in the lateral superior olive at the same time. Thus, excitation that arises monosynaptically from the ipsilateral ventral cochlear nucleus must arrive at the same time as inhibition that arises disynaptically from the contralateral ventral cochlear nucleus. The inhibition comes from the medial nucleus of the trapezoid body whose inputs through large axons of globular bushy cells and large calyces of Held produce synaptic responses

Figure 28–5 (Opposite) Interaural differences in the arrival of a sound help localize sound in the horizontal plane.

A. When a sound such as a pure tone arises from the right, the right ear detects the sound earlier than the left ear. The difference in the time of arrival at the two ears is the interaural time delay (**ITD**). Cochlear nerve fibers and their bushy cell targets fire in phase with pressure changes. Although individual bushy cells may fail to fire at some cycles, a set of cells will encode the timing of a low-frequency sound and its frequency with every cycle. Comparison of the onset of action potentials in the bushy cells at the two sides reveals the ITDs (**slanted black lines**).

B. Interaural time differences can be measured by an array of neurons whose inputs from the two ears are delay lines as proposed by Lloyd Jeffress (1948). Action potentials propagate to reach the nearest terminals before they reach the farthest ones; thus, in the delay line from the right, terminals will generate synaptic potentials sequentially from right to left, and in the delay line from the left, terminals will generate synaptic potentials sequentially from left to right. Suppose that such postsynaptic neurons are coincidence detectors, firing only when they receive excitatory postsynaptic potentials (EPSPs) simultaneously from the right and left. Sounds that arise at the midline reach the right and left ears simultaneously with no interaural time disparity (ITD = 0). The neuron in the middle of the array that receives input from equally long axons from the two sides will thus receive simultaneous EPSPs from the two sides. When sounds come from the right, signals from the right ear arrive at the central nervous system earlier than those from the left ear (ITD >0). Sound from the right generates synchronous EPSPs in the (**yellow**) neuron because the earlier arrival of sound from the right (**red**) is compensated by a longer conduction delay relative to that from the left (**blue**). Likewise, when sound arises from the left, the ITD <0 and conduction delays from the left (**blue**) compensate for the early arrival at the left. Such a neuronal circuit produces a map of interaural time disparities in the coincidence detectors; as sounds move from the right to left, they activate coincidence detectors sequentially from left to right. Such an arrangement of delay lines has been found in the nucleus laminaris of the barn owl, the homolog of the mammalian medial superior olivary nucleus.

C. Mammals use delay lines only in the nucleus contralateral to a sound source to form a map of interaural time differences. The bitufted neurons of the medial superior olivary nucleus form a sheet that is contacted on its lateral face by bushy cells from the ipsilateral cochlear nucleus and on the medial face by bushy cells from the contralateral cochlear nucleus. (Although it is depicted here schematically in a coronal section of the brain stem, the encoding of interaural disparities is in a sheet of neurons that also has a rostrocaudal dimension.) On the ipsilateral side, the branches of the bushy cell axon are of equal length and thus initiate synaptic currents in their targets in the medial superior olive simultaneously. On the contralateral side, the branches deliver synaptic currents sequentially first to the regions closest to the midline, and then to progressively more lateral regions. Neurons of the medial superior olive detect synchronous excitation from the two ears only when sounds arise from the contralateral half of space. When sounds arise from the right side, their early arrival at the right ear is compensated by progressively longer conduction delays to activate neurons more and more toward the lateral end of the left medial superior olive (the **yellow cell** is activated by a sound from the far right, as in part **B**). When sounds arise from the front and there is no interaural time difference, neurons in the anterior end of the medial superior olive are activated synchronously from both sides. Each medial superior olive forms a map of where sounds arise in the contralateral hemifield. (Adapted, with permission, from Yin 2002.)

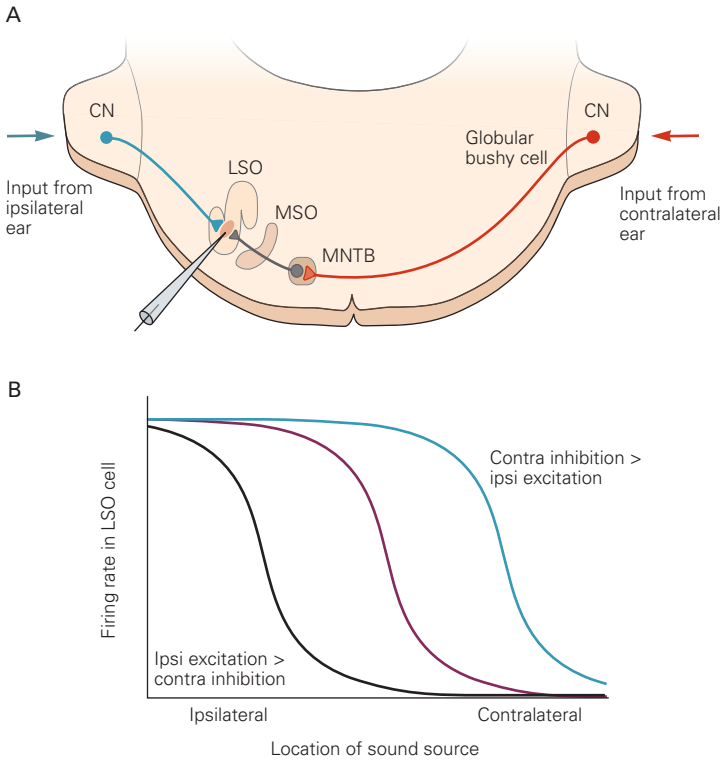

Figure 28–6 Interaural differences in the intensity of a sound also help localize sound in the horizontal plane.

A. Principal cells of the lateral superior olivary nucleus (**LSO**) receive excitatory input from the ipsilateral cochlear nucleus (**CN**) and inhibitory input from the contralateral cochlear nucleus. A coronal section through the brain stem of a cat illustrates the anatomical connections. Small spherical bushy cells and stellate cells in the ipsilateral ventral cochlear nucleus provide direct excitation. Globular bushy cells in the contralateral ventral cochlear nucleus project across the midline and excite neurons in the medial nucleus of the trapezoid body (**MNTB**) via large terminals, the calyces of Held. Cells of the medial nucleus of the trapezoid body inhibit neurons in the lateral superior olive as well as in the medial superior olive (**MSO**). For neurons of the lateral superior olive to compare intensities of the same sound, the timing of the ipsilateral excitatory input must be matched with the timing of the contralateral inhibitory input. To this end, globular bushy cells have particularly large axons that terminate in a calyx of Held in the medial nucleus of the trapezoid body where synaptic transmission is strong and thus the synaptic delay is short and invariant in its timing.

B. The firing of neurons in the lateral superior olive reflects a balance of ipsilateral excitation and contralateral inhibition. When sounds arise from the ipsilateral side, excitation is relatively stronger and inhibition is relatively weaker than when sounds arise from the contralateral side. The transition between the dominance of excitation and inhibition reflects the location of the sound source.

with short and consistently timed delays. The axons of small spherical bushy cells and stellate cells that carry ipsilateral excitation conduct more slowly than those of globular bushy cells.

The terminals of the globular bushy cells, the calyces of Held, engulf the cell bodies of trapezoid-body neurons so dramatically that they caught the attention of early anatomists and modern biophysicists. A single somatic terminal releases neurotransmitter at numerous release sites and generates large synaptic currents. The reliability of pre- and postsynaptic recordings at this synapse makes the site ideal for detailed studies of the mechanisms of synaptic transmission (Chapter 15).

The Superior Olivary Complex Provides Feedback to the Cochlea

Although sensory systems are largely afferent, bringing sensory information to the brain, recent studies have led to an appreciation of the importance of efferent signaling at many levels of the auditory system. Olivocochlear neurons form a feedback loop from the superior olivary complex to hair cells in the cochlea. Their cell bodies lie around the major dense clusters of cell bodies in the olivary nuclei. In mammals, two groups of olivocochlear neurons have been functionally distinguished. The medial olivocochlear neurons' axons terminate on the outer hair cells bilaterally; the lateral olivocochlear neuron axons terminate ipsilaterally on the afferent fibers associated with inner hair cells.

Most medial olivocochlear neurons, with cell bodies that lie ventral and medial within the olivary complex, send their axons to the contralateral cochlea (Figure 28–7), but many also project to the ipsilateral cochlea. These cholinergic neurons act on hair cells through a special class of nicotinic acetylcholine receptor-channels formed from α9 and α10 subunits. The influx of Ca^{2+} through these channels leads to the opening of K^+ channels that hyperpolarize outer hair cells. These neurons thus mediate tuned negative feedback and are binaural, being driven predominantly but not exclusively by stellate cells of the contralateral

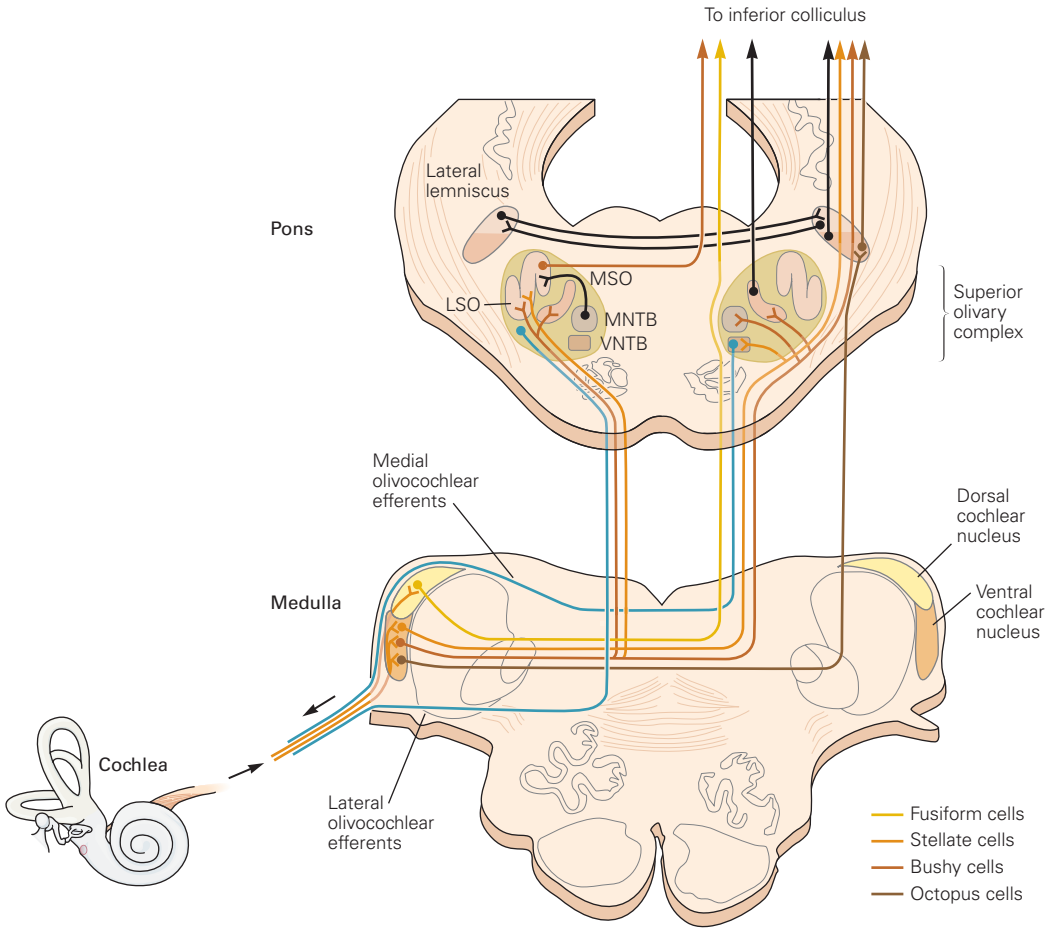

Figure 28–7 **Major components of the ascending and descending auditory pathways.** The auditory pathway is bilaterally symmetrical; the major connections among the nuclei that form the early auditory pathway are shown. The ascending pathway begins in the cochlea and progresses through several parallel pathways through the cochlear nuclei: the cochlear nuclei, the superior olivary nuclei, and the ventral and dorsal nuclei of the lateral lemniscus. These signals converge in the inferior colliculus, which projects to the medial geniculate body of the thalamus and thence to the cerebral cortex (see Figure 28–2). Some of the connections are through excitatory pathways (**colored lines**) and others through inhibitory pathways (**black lines**). These same nuclei are also interconnected through descending pathways (**blue lines**) and bilaterally through commissural projections. (**LSO**, lateral superior olivary nucleus; **MNTB**, medial nucleus of the trapezoid body; **MSO**, medial superior olive; **VNTB**, ventral nucleus of the trapezoid body).

ventral cochlear nucleus. Activity in these efferent fibers reduces the sensitivity of the cochlea and protects it from damage by loud sounds. Collateral branches of medial olivocochlear neurons terminate on stellate cells in the cochlear nucleus, acting on conventional nicotinic and muscarinic acetylcholine receptors, forming an excitatory feedback loop.

Lateral olivocochlear neurons, with cell bodies that lie in and around the lateral superior olive, send their axons exclusively to the ipsilateral cochlea, where they terminate on the afferent fibers from inner hair cells. Charles Liberman and his colleagues demonstrated that these efferents balance the excitability of cochlear nerve fibers at the two ears.

Ventral and Dorsal Nuclei of the Lateral Lemniscus Shape Responses in the Inferior Colliculus With Inhibition

Fibers from the cochlear and superior olivary nuclei run in a band, or lemniscus, along the lateral edge of the brain as they ascend from the brainstem to the inferior colliculus. Along this band of fibers are groups of neurons that form the dorsal and ventral nuclei of the

lateral lemniscus. Neurons in the ventral nuclei of the lateral lemniscus receive input from all major groups of principal cells of the ventral cochlear nuclei and respond predominantly to monaural input, driven by the contralateral ear, while neurons in the dorsal nucleus receive input from the lateral and medial superior olivary nuclei and respond to inputs from both ears. Neurons in both subdivisions are inhibitory and project to the inferior colliculus. Their roles are intriguing but not fully understood.

Since understanding the meaning of sounds is not greatly compromised by the loss of one ear, it would make sense that the largely monaural functions of the ventral nuclei of the lateral lemniscus involve the processing of the meaning of sounds. Furthermore, mammals vary in the information they extract from their acoustic environments, which may account for differences between species in the structure and function of the ventral nuclei of the lateral lemniscus.

A border that is more distinct in some mammalian species than in others separates the ventral and intermediate nuclei and the subdivisions of the ventral nucleus of the lateral lemniscus. Neurons differ in their shapes, biophysical properties, and pattern of convergence of cochlear nuclear inputs. One group of glycinergic neurons is innervated by large calyceal terminals from octopus cells. These could generate inhibitory temporal reference signals in the inferior colliculus. Some broadly tuned neurons fire almost exclusively at the onset of tones with sharply timed action potentials but convey periodicity in complex sounds, raising the question of whether these neurons might have a role in encoding pitch in music and speech. Others respond by firing as long as a tone is present; these neurons track the fluctuations in intensity or the envelopes of sounds, a feature that is useful for understanding the meaning of sounds including speech. Tuning curves of the neurons are variable, with many being broad or W-shaped.

Neurons in the dorsal nucleus are predominantly binaural, receiving input from the ipsilateral medial superior olive and from the lateral superior olive, primarily from the contralateral side. These neurons are GABAergic, targeting the inferior colliculi on both sides and also targeting the contralateral dorsal nucleus of the lateral lemniscus. Excitation in neurons of the dorsal nucleus is amplified by NMDA-type glutamate receptors so that the inhibition they generate in their targets outlasts sound stimuli for tens of milliseconds and thus has been termed persistent inhibition. To localize sounds accurately, animals must ignore the reflections of sounds from surrounding surfaces that arrive after the initial direct wave front. Psychophysical experiments have shown that mammals suppress all but the first-arriving sound, a phenomenon termed the *precedence effect.* It has been proposed that persistent inhibition in the inferior colliculus from the dorsal nucleus of the lateral lemniscus serves to suppress spurious localization cues such as echoes and thus that it contributes to the precedence effect.

Afferent Auditory Pathways Converge in the Inferior Colliculus

The inferior colliculus occupies a central position in the auditory pathway of all vertebrate animals because all auditory pathways ascending through the brain stem converge there (Figure 28–7). The most important sources of excitation are stellate cells from the contralateral ventral cochlear nucleus, fusiform cells from the contralateral dorsal cochlear nucleus, principal cells of the ipsilateral medial superior olive and of the contralateral lateral superior olive, principal cells of ipsilateral and contralateral dorsal nuclei of the lateral lemniscus, commissural connections from the contralateral inferior colliculus, and pyramidal cells in layer V of the auditory cortex. Important sources of inhibition include the nuclei of the lateral lemniscus, the ipsilateral lateral superior olive, the superior paraolivary nucleus, and the contralateral inferior colliculus.

The inferior colliculus of mammals is subdivided into the central nucleus, dorsal cortex, and external cortex. The central nucleus is tonotopically organized. Low frequencies are represented dorsolaterally and high frequencies ventromedially in laminae that have similar best frequencies. Fine mapping has shown that the tonotopic organization is discontinuous; the separation between best frequencies corresponds to psychophysically measured critical bands of approximately one-third octave. Although the central nucleus is organized tonotopically, the spectral range of inputs to these neurons is broader than at earlier stages in the auditory pathway. Inhibition can be broad and narrows the responses of excitatory neurons. Furthermore, tuning can be modulated by descending inputs from the cortex.

Many neurons in the central nucleus carry information about the location of sound sources. The majority of these cells are sensitive to interaural time and intensity differences, essential cues for localizing sounds in the horizontal plane. Neurons are also sensitive to spectral cues that localize sounds in the vertical plane. Physiological correlates of the precedence effect have been measured in the inferior colliculus, where inhibition suppresses simulated reflections of sounds.

The inferior colliculus is not only a convergence point but also a branch point for ascending or outflow pathways. Neurons of the central nucleus project to the external cortex of the inferior colliculus and also to the thalamus and the nucleus of the brachium of the inferior colliculus, both of which then project to the superior colliculus (or the optic tectum in birds).

Sound Location Information From the Inferior Colliculus Creates a Spatial Map of Sound in the Superior Colliculus

The inferior colliculus is not only a convergence point but also a branch point for ascending or outflow pathways. Central nucleus neurons project to the thalamus and also to the external cortex of the inferior colliculus and the nucleus of the brachium of the inferior colliculus, both of which then project to the superior colliculus (or the optic tectum in birds).

The superior colliculus is critical for reflexive orienting movements of the head and eyes to acoustic and visual cues in space. By the time the binaural sound cues and the monaural spectral cues that underlie mammalian sound localization reach the superior colliculus, they have been merged to create a spatial map of sound in which neurons are unambiguously tuned to specific sound directions. This convergence is critical since binaural differences in level and timing alone cannot unambiguously code for a single position in space. The spectral cues that provide information about vertical location must be taken into account, as different locations in the vertical plane can give rise to identical interaural differences in time or intensity. Such unambiguous spatial mapping occurs both in birds and in some mammals (Figure 28–8). In ferrets and guinea pigs, it occurs in the external cortex and the nucleus of the brachium of the inferior colliculus.

Within the superior colliculus, the auditory map is aligned with maps of visual space and the body surface. Unlike the visual and somatosensory spatial maps, the auditory spatial map does not reflect the peripheral receptor surface; instead, it is computed from a combination of cues that identify the specific position of a sound source in space.

Auditory, visual, and somatosensory neurons in the superior colliculus all converge on output pathways in the same structure that controls orienting movements of the eyes, head, and external ears. The motor circuits of the superior colliculus are mapped with respect to motor targets in space and are aligned with the sensory maps. Such sensory-motor correspondence facilitates the sensory guiding of movements.

The Inferior Colliculus Transmits Auditory Information to the Cerebral Cortex

Auditory information ascends from the inferior colliculus to the medial geniculate body of the thalamus and from there to the auditory cortex. The pathways from the inferior colliculus include a lemniscal or core pathway and extralemniscal or belt pathways. Descending projections from the auditory cortex to the medial geniculate body are prominent both anatomically and functionally.

Stimulus Selectivity Progressively Increases Along the Ascending Pathway

A marked feature of auditory neurons at structures along the ascending pathway is their progressively increased stimulus selectivity. An auditory nerve fiber is primarily selective to one stimulus dimension, the frequency of a pure tone. The stimulus selectivity of neurons in the central auditory system may be multidimensional, such as frequency, spectral bandwidth, sound intensity, modulation frequency, and spatial location. In this multidimensional acoustic space, neurons become more selective at successive auditory areas along the ascending pathway.

Many neurons in the auditory cortex (especially those in upper cortical layers) are highly selective to acoustic stimuli, such that the preferred (nearly optimal) stimulus of a neuron occupies only a small region of its receptive field in the multidimensional acoustic space. The region of the preferred stimulus becomes increasingly smaller at structures along the path to the auditory cortex (Figure 28–9A). Pure tones and broadband noises are two extreme cases of a wide range of acoustic stimuli that could preferentially drive auditory cortex neurons. The majority of neurons in the auditory cortex are preferentially driven by stimuli with greater spectral and temporal complexity than pure tones and broadband noises.

The increased stimulus selectivity is also accompanied by changes in a neuron's firing pattern. When neurons are driven by their preferred stimuli, they respond not only with higher firing rates but also with sustained firing throughout the stimulus duration (Figure 28–9B). The receptive field of a cortical neuron contains a "sustained firing region" (corresponding to preferred stimuli) within a larger "onset firing region" (corresponding to nonpreferred stimuli). This explains why it is common for experimenters to observe onset (phasic) responses in auditory cortex when a continuous sound is played.

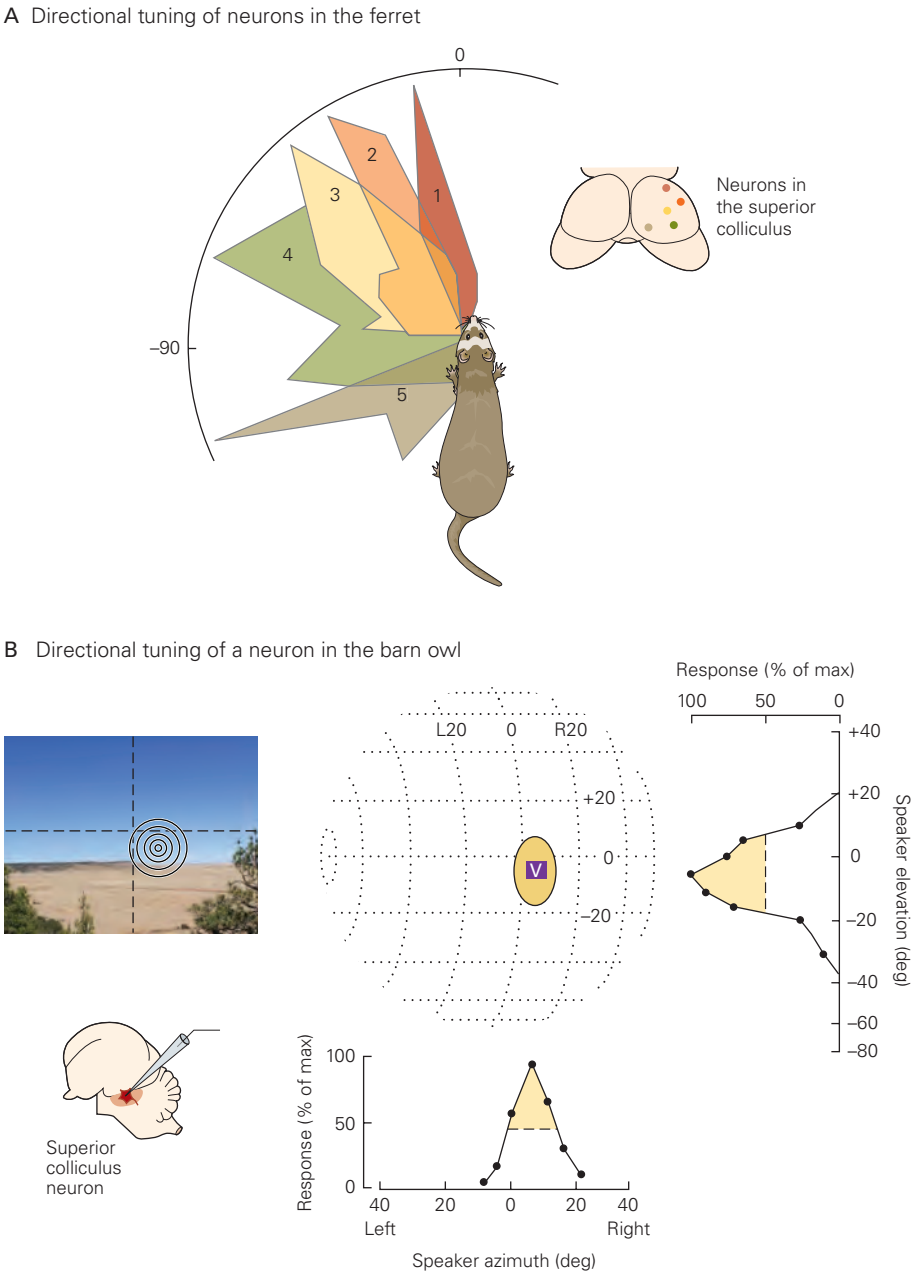

Figure 28–8 A spatial map of sound is formed in the superior colliculus.

A. Neurons in the ferret's superior colliculus are directionally tuned to sound in the horizontal plane. The illustration shows the firing rate profiles of collicular neurons 1 through 5 as a function of where the sounds are located, plotted in polar coordinates centered on the head. The drawing on the right shows the location of the recorded neurons in the colliculus. Note that neuron 1 responds best to sounds in front of the animal, whereas neurons that are located progressively more caudally in the colliculus gradually shift their responses to sounds that originate farther contralaterally. (Adapted, with permission, from King 1999.)

B. The normalized responses of a neuron in the superior colliculus of a barn owl to noise bursts presented at various locations along the horizon are plotted below (*bottom right*). The **yellow areas** in these tuning curves indicate where responses exceed 50% of the maximum. The sensitivity of the neuron to a particular location along the horizon or a particular elevation (*top right*) creates a discrete best auditory area in space for this neuron (*top middle*), shown as the colored ellipse on a plot of spatial locations with respect to a point straight in front of the owl. The neuron also responds to visual cues from the same area (the box labeled **V**). The photo illustrates the neuron's best area in space with respect to the position of the head (the intersection of the vertical and horizontal dotted lines indicates where the owl's head is pointing). The recording site for this neuron is also shown. (Adapted, with permission, from Cohen and Knudsen 1999. Copyright © 1999 Elsevier Science.)

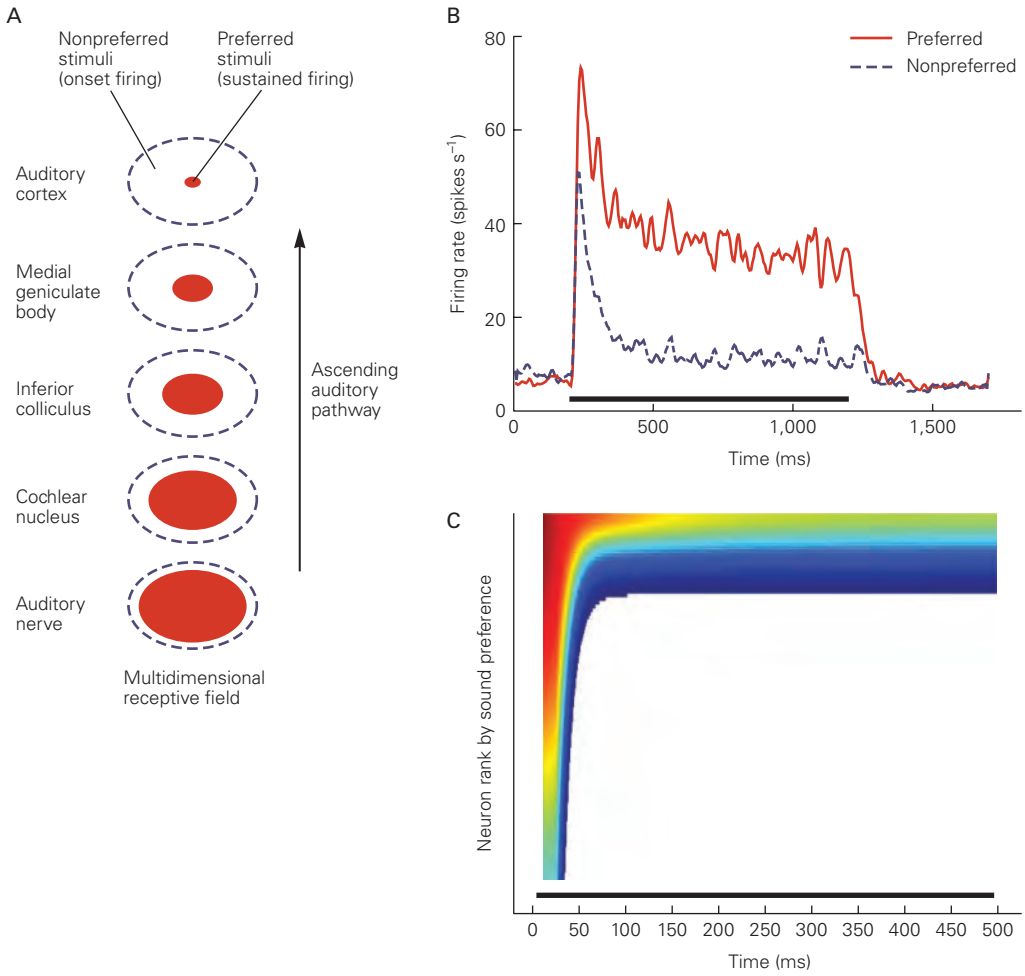

Figure 28–9 Stimulus selectivity increases along the ascending auditory pathway.

A. Stimulus selectivity and the relationship between sustained and onset firings along the ascending auditory pathway. Each open ellipse represents the multidimensional receptive field (RF) of a neuron illustrated on a two-dimensional plane. The filled ellipse represents the "sustained firing region" (corresponding to preferred stimuli) of a neuron's RF. The rest of the area within the RF is the "onset firing region" (corresponding to nonpreferred stimuli). A neuron exhibits sustained or onset firing depending on which region of the RF is stimulated. The neuron does not fire if stimuli fall outside the RF. (Adapted, with permission, from Wang 2018.)

B. Population-averaged firing rate in response to each neuron's preferred and nonpreferred stimuli from primary auditory cortex (A1). Extracellular recordings were made in awake marmoset monkeys. **Thick bar** = stimulus duration. (Adapted, with permission, from Wang et al. 2005. Copyright © 2005 Springer Nature.)

C. Distribution of activity among A1 neurons in response to a sound burst. On the *y*-axis, all A1 neurons are ranked according to their preference for a particular stimulus. The **blue-to-red color gradient** represents increasing firing rate. The neuron with the highest firing rate is located at the top end of the *y*-axis. **Black bar** = stimulus duration. Most neurons show a brief phasic response to the onset of the sound, but only those particularly tuned to the sound maintain their response until the end of the sound. (Adapted, with permission, from Middlebrooks 2005. Copyright © 2005 Springer Nature.)

The discovery of how sustained firing is evoked in the auditory cortex is important because it provides a direct link between neural firing and the perception of a continuous acoustic event. Such sustained firing by auditory cortex neurons has been observed only in awake animals. In contrast, an auditory nerve fiber typically shows sustains firing in response to a wide range of acoustic signals as long as the spectral energy of the stimulus falls within the neuron's receptive field, under either anesthetized or awake conditions. When David Hubel and his colleagues ventured into the auditory cortex more than half a century ago, they

were puzzled by how difficult it was to drive neurons in the auditory cortex of awake cats. Now we know it was because they were probably recording from highly selective neurons and using nonpreferred stimuli. The availability of digital technology since then has made it possible to create and test a large battery of acoustic stimuli in search of the preferred stimulus of a highly selective neuron in auditory cortex. The overall picture elucidated by experimenters is that when a sound is heard, the auditory cortex first responds with transient discharges (encoding the onset of a sound) across a relatively large population of neurons. As the time passes, the activation becomes restricted to a smaller population of neurons that are preferentially driven by the sound (Figure 28–9C), which results in a selective representation of the sound within the neuronal population and over time. Because each neuron has its own preferred stimulus that differs from preferred stimuli of other neurons, neurons in the auditory cortex collectively cover the entire acoustic space with their sustained firing regions. Therefore, any particular sound can evoke sustained firing throughout its duration in a particular population of neurons in the auditory cortex. In other words, the region of auditory cortex activated by acoustic stimulation in whole-brain imaging (eg, functional magnetic resonance imaging [fMRI], positron emission tomography [PET]) comprises neurons that are preferentially driven by the acoustic stimulus.

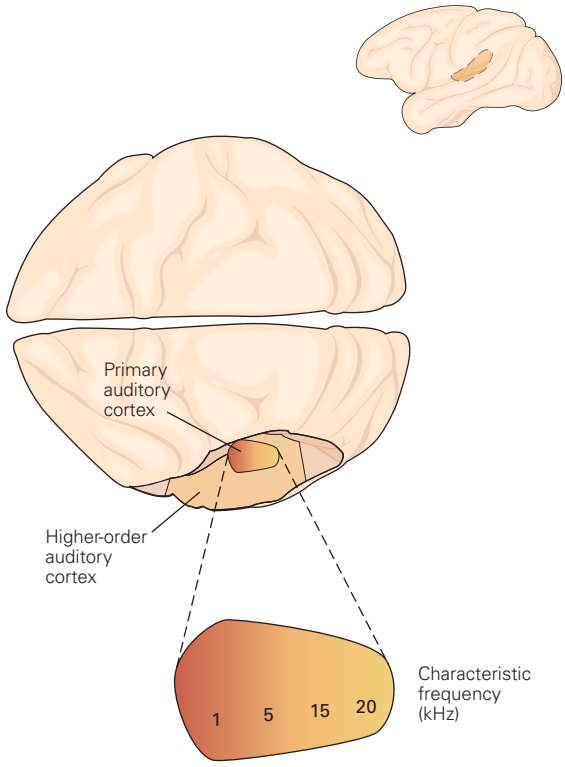

Figure 28–10 The auditory cortex of primates has multiple primary and secondary areas. The expanded figure of the primary auditory cortex shows its tonotopic organization. The primary areas are surrounded by higher-order areas (see Figure 28–11).

The Auditory Cortex Maps Numerous Aspects of Sound

The auditory cortex includes multiple distinct functional areas on the dorsal surface of the temporal lobe. The most prominent projection is from the ventral division of the medial geniculate nucleus to the primary auditory cortex (A1, or Brodmann's area 41). As in the subcortical structures, the neurons in this cytoarchitectonically distinct region are arranged tonotopically. In monkeys, neurons tuned to low frequencies are found at the rostral end of A1, while those responsive to high frequencies are in the caudal region (Figure 28–10). Thus, like the visual and somatosensory cortices, A1 contains a map reflecting the sensory periphery.

Because the cochlea encodes discrete frequencies at different points along the basilar membrane, however, a one-dimensional frequency map from the periphery is spread across the two-dimensional surface of the cortex, with a smooth frequency gradient in one direction and isofrequency contours along the other direction. In many species, subregions of the auditory cortex that represent biologically significant frequencies are larger than others because of extensive inputs, similar to the large area in the primary visual cortex devoted to inputs from the fovea.

In addition to frequency, other features of auditory stimuli are mapped in the primary auditory cortex, although the overall organization is less clear and precise than for vision. Auditory neurons in A1 are excited either by input from both ears (EE neurons), with the contralateral input usually stronger than the ipsilateral contribution, or by a unilateral input (EI). The EI neurons are inhibited by stimulation of the opposite ear.

Certain neurons in A1 also seem to be organized according to bandwidth, that is, according to their responsiveness to a narrow or broad range of frequencies. Neurons near the center of the isofrequency contours are tuned more narrowly to bandwidth or frequency than those located away from the center. Distinct subregions of A1 form clusters of cells with narrow or broadband tuning within individual isofrequency contours. Within intracortical circuits, neurons receive input primarily from neurons with similar bandwidths and characteristic frequencies.

This modular organization of bandwidth selectivity may allow redundant processing of incoming signals through neuronal filters of varying bandwidths as well as center frequencies, which could be useful for the analysis of spectrally complex sounds such as species-specific vocalizations, including speech.

Several other parameters are represented in A1. These include neuronal response latency, loudness, modulation of loudness, and the rate and direction of frequency modulation. Although it remains to be seen how these various maps intersect, this array of parameters clearly endows each neuron and each location in A1 with the ability to represent many independent variables of sound and thus allows for a great diversity of neuronal selectivity.

As is true for visual and somatosensory areas of the cortex, sensory representation in A1 can change in response to alterations in input pathways. After peripheral hearing loss, tonotopic mapping in A1 can be altered so that neurons that were previously responsive to sounds within the lost range of hearing will begin to respond to adjacent frequencies. The work of Michael Merzenich and others has shown that behavioral training of adult animals can also result in large-scale reorganization of the auditory cortex, so that the most behaviorally relevant frequencies—those specifically associated with attention or reinforcement—come to be overrepresented.

The auditory areas of young animals are particularly plastic. In rodents, the frequency organization of A1 emerges gradually during development from an early, crude frequency map. Raising animals in acoustic environments in which they are exposed to repeated tone pulses of a particular frequency results in a persistent expansion of cortical areas devoted to that frequency, accompanied by a general deterioration and broadening of the tonotopic map. This result not only suggests that the development of A1 is experience-dependent but also raises the possibility that early exposure to abnormal sound environments can create long-term disruptions of high-level sensory processing. A greater understanding of how this happens and whether it is also true for human fetuses and infants may provide insights into the origin and remediation of disorders in which central auditory processing is impaired, such as many forms of dyslexia. Moreover, the ability to induce plasticity in the auditory cortex of adults by engaging attention or reward raises new hopes for brain repair even in adulthood.

The primary auditory area of mammals is surrounded by multiple distinct regions, some of which are tonotopic. Adjacent tonotopic fields have mirror-image tonotopy: The direction of tonotopy reverses at the boundary between fields. In monkeys, as many as 7 to 10 secondary (belt) areas surround the three or four primary or primary-like (core) areas (see Figure 28–11). The secondary areas receive input from the core areas of the auditory cortex and, in some cases, from thalamic nuclei. Electrophysiological and imaging studies have confirmed that A1 in humans lies on Heschl's gyrus, in the temporal lobe, medial to the Sylvian fissure. In addition, recent fMRI studies have revealed that in humans, just as in monkeys, pure tones activate primarily core areas, whereas the neurons of belt areas prefer complex sounds such as narrowband noise bursts.

A Second Sound-Localization Pathway From the Inferior Colliculus Involves the Cerebral Cortex in Gaze Control

Many neurons in the auditory cortex have broad spatial tuning, but neurons with narrow spatial tuning are also found when studied in awake animals. In monkeys, auditory cortex neurons are tuned to both frontal space and rear space (outside the coverage of vision), as well as the space above and below the horizontal plane. In contrast to the auditory midbrain, however, there is yet no evidence for a spatially organized map of sound in any of the cortical areas sensitive to sound location.

The sound-localization pathways in the cortex originate in the central nucleus of the inferior colliculus and ascend through the auditory thalamus and the primary and secondary cortical areas, eventually reaching the frontal eye fields involved in gaze control. Eye or head movements can be elicited by stimulating the frontal eye fields, which connect directly to brain stem tegmentum premotor nuclei that mediate gaze changes as well as to the superior colliculus. But why should there be this second sound-localization pathway connected to gaze control circuitry when the midbrain pathway from location-sensitive neurons in the inferior colliculus to the superior colliculus to gaze control circuitry directly controls orientation movements of the head, eyes, and ears?

Behavioral experiments shed light on this question. Although lesions of A1 can result in profound sound-localization deficits, no deficiency is seen when the task is simply to indicate the side of the sound source by pushing a lever. The deficit becomes apparent only when the animal must approach the location of a brief sound source; that is, when the task is the more complex one of forming an image of the source, remembering it, and moving toward it.

Experiments in barn owls have produced particularly compelling evidence. The ability of owls to orient to sounds in space is unaffected by inactivation of the avian equivalent of the frontal eye fields. Similarly, when the midbrain sound localization pathway is disrupted by pharmacological inactivation of the superior colliculus, the probability of an accurate head turn is decreased, but animals still respond correctly more than half of the time. In contrast, when both structures are inactivated, animals are completely unable to orient accurately to acoustic stimuli on the contralateral side. Thus, cortical and subcortical sound-localization pathways have parallel access to gaze control centers, perhaps providing some redundancy. Moreover, when only the frontal eye fields are inactivated, birds lose their ability to orient their gaze toward a target that has been extinguished and must be remembered, just as is seen with mammalian A1 lesions. Thus, in both mammals and birds, cortical pathways are required for more complex sound-localization tasks.

This appears to be a general difference between cortical and subcortical pathways. Subcortical circuits are important for rapid and reliable performance of behaviors that are critical to survival. Cortical circuitry allows for working memory, complex recognition tasks, and selection of stimuli and evaluation of their significance, resulting in slower but more differentiated performance. Examples of this also exist in auditory pathways not involved in localization. Conditioned fear responses to simple auditory stimuli are mediated by direct rapid pathways from the auditory thalamus to the amygdala; they can still be elicited after cortical inactivation. However, fear responses that require more complex discrimination of auditory stimuli require pathways through the cortex and are accordingly slower but more specific.

Auditory Circuits in the Cerebral Cortex Are Segregated Into Separate Processing Streams

In the visual system, the output from the primary visual cortex is segregated into separate dorsal and ventral streams concerned respectively with object location in space and object identification. A similar division of labor is thought to exist in the somatosensory cortex, and recent evidence suggests that the auditory cortex also follows this plan.

Anatomical tracing studies of the three most accessible belt areas in monkeys show that the more rostral and ventral areas connect primarily to the more rostral and ventral areas of the temporal lobe, whereas the more caudal area projects to the dorsal and caudal temporal lobe. In addition, these belt areas and their temporal lobe targets both project to largely different areas of the frontal lobes (Figure 28–11).

The frontal areas receiving anterior auditory projections are generally implicated in nonspatial functions, whereas those that are targets of posterior auditory areas are implicated in spatial processing. Electrophysiological and imaging studies provide support for this. Caudal and parietal areas are more active when a stimulus must be localized or moves, and ventral areas are more active during identification of the same stimulus or analysis of its pitch. Thus anterior-ventral pathways may identify auditory objects by analyzing spectral and temporal characteristics of sounds, whereas the more dorsal-posterior pathways may specialize in sound-source location, detection of sound-source motion, and spatial segregation of sources.

Although the idea that all sensory areas of the cerebral cortex initially segregate object identification and location is attractive, it is likely an oversimplification. It is clear that the medial-belt areas of the auditory cortex project to both dorsal and ventral frontal cortices, and neurons with broad spatial responsiveness are distributed throughout caudal and anterior areas. Nonetheless, although the details may differ between systems, the basic concept holds that sensory systems deconstruct stimuli into features and analyze each type in discrete pathways.

The Cerebral Cortex Modulates Sensory Processing in Subcortical Auditory Areas

An intriguing feature of all mammalian cortical areas, and one shared by the auditory system, is the massive projection from the cortex back to lower areas. There are almost 10 times as many corticofugal fibers entering the sensory thalamus as there are axons projecting from the thalamus to the cortex. Projections from the auditory cortex also innervate the inferior colliculus, olivocochlear neurons, some basal ganglionic structures, and even the dorsal cochlear nucleus.

Insights into possible functions of this feedback have come from the bat's auditory system. Silencing of frequency-specific cortical areas leads to decreased responses in thalamus and inferior colliculus in the corresponding frequency-specific areas, whereas activation of cortical projections increases and sharpens the responses of some neurons. The auditory cortex can therefore actively adjust and improve auditory signal processing in subcortical structures. A variety of evidence suggests that cortical feedback also occurs in other mammals. This challenges the view of ascending

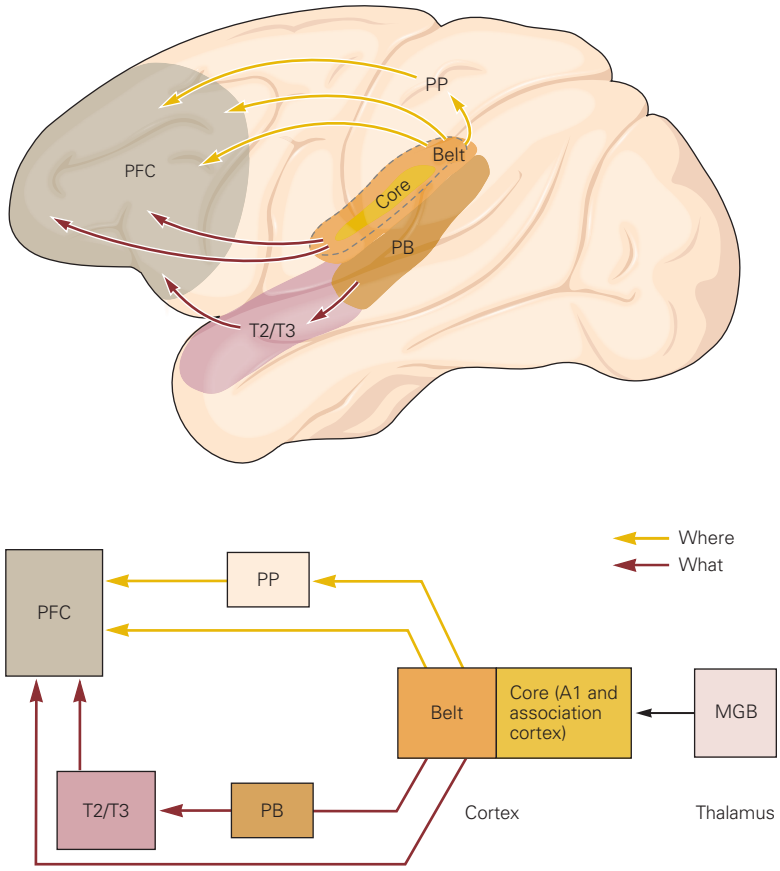

Figure 28–11 The "what" and "where" streams in the auditory cortical system of primates. The ventral "what" stream and dorsal "where" stream originate in different parts of primary and belt cortex and ultimately project to distinct regions of prefrontal cortex through independent paths. (**MGB**, medial geniculate body of the thalamus; **PB**, parabelt cortex; **PFC**, prefrontal cortex; **PP**, posterior parietal cortex; **T2/T3**, areas of temporal cortex.) sensory pathways as purely feedforward circuits and suggests that we should regard the thalamus and cortex as reciprocally and highly interconnected circuits in which the cortex exercises some top-down control of perception.

The Cerebral Cortex Forms Complex Sound Representations

The Auditory Cortex Uses Temporal and Rate Codes to Represent Time-Varying Sounds

An important function of the auditory system is to represent time-varying sounds across multiple time scales, from a few milliseconds to tens and hundreds of milliseconds or even longer. In the auditory nerve, firing patterns largely mirror the temporal structure of sounds, firing in phase with sounds to the limit of the phase-locking. The precision of this temporally based neural representation gradually decreases as information ascends toward the auditory cortex due to synaptic integration at the soma and dendrites.

The upper limit of the phase-locking to periodic sounds progressively decreases along the ascending auditory pathway from approximately 3,000 Hz in the auditory nerve to less than approximately 300 Hz in the medial geniculate body in the thalamus and less than 100 Hz in A1. The upper limit of the phase-locking in A1 is similar to that found in the primary visual and somatosensory areas of cortex. In the auditory cortex, the temporal firing pattern alone is inadequate to represent the entire range of time-varying sounds that are perceived by humans and animals.

Cortical neurons use an alternative method to represent time-varying sounds that change more rapidly than the upper limit of the phase-locking in A1. When an animal listens to a sequence of periodic clicks, two types of neural responses are observed in A1. One population of neurons displays phase-locked periodic firing in response to click trains with long intervals between clicks or slowly varying sounds, but not to click trains with short intervals between clicks or rapidly varying sounds (Figure 28–12A). The second population of neurons does not respond to click trains

at long interclick intervals, but instead fires increasingly rapidly as the interclick interval becomes shorter (Figure 28–12B). These two populations of A1 neurons, referred to as *synchronized* and *nonsynchronized*, respectively, have complementary response properties. Neurons of the synchronized population *explicitly* represent slowly occurring sound events by synchronized neural firing (a temporal code), whereas neurons of the nonsynchronized population *implicitly* represent rapidly changing sound events by changes in average firing rates (a rate code).

The nonsynchronized neurons have been observed in the auditory cortex of awake primates and rodents. In A1, neural representation changes from a temporal code to a rate code at the interclick interval of about 25 ms, corresponding to a repetition rate of approximately 40 Hz (Figure 28–12A,B). This is near the boundary where our perception of a periodic click train changes from being "discrete" to "continuous."

The combination of temporal and rate codes to represent the whole range of time-varying sounds is the consequence of a progressive transformation beginning in the auditory nerve, where only a temporal code (phase-locking) is available. The progressive reduction in the upper limit of the phase-locking along the ascending auditory pathway is accompanied by the emergence of firing-rate-based representations. In the medial geniculate body of the thalamus, the intersection between temporal and rate codes is at a shorter interclick interval than in A1 (Figure 28–12C). This indicates that neurons in the medial geniculate body can phase-lock to more rapidly time-varying sounds than A1 neurons, but still utilize a rate code to represent rapidly changing sounds beyond their phase-locking limit.

The prevalence of rate-coding neurons in A1 has important functional implications. It shows that a considerable transition from temporal to rate coding has taken place by the time auditory signals reach the auditory cortex. The importance of the nonsynchronized neural responses is that they represent transformed instead of preserved temporal information. It suggests that cortical processing of sound streams operates on a segment-by-segment basis rather than on a moment-by-moment basis, as found in the auditory nerve. This is necessary for complex integration because higher-level processing tasks require temporal integration over a time window. The reduction in A1 of the upper limit of phase-locking is a prerequisite for multisensory integration in the cerebral cortex. Auditory information is encoded at the periphery at a much faster temporal modulation rate than visual or tactile information, but phase-locking is similar across

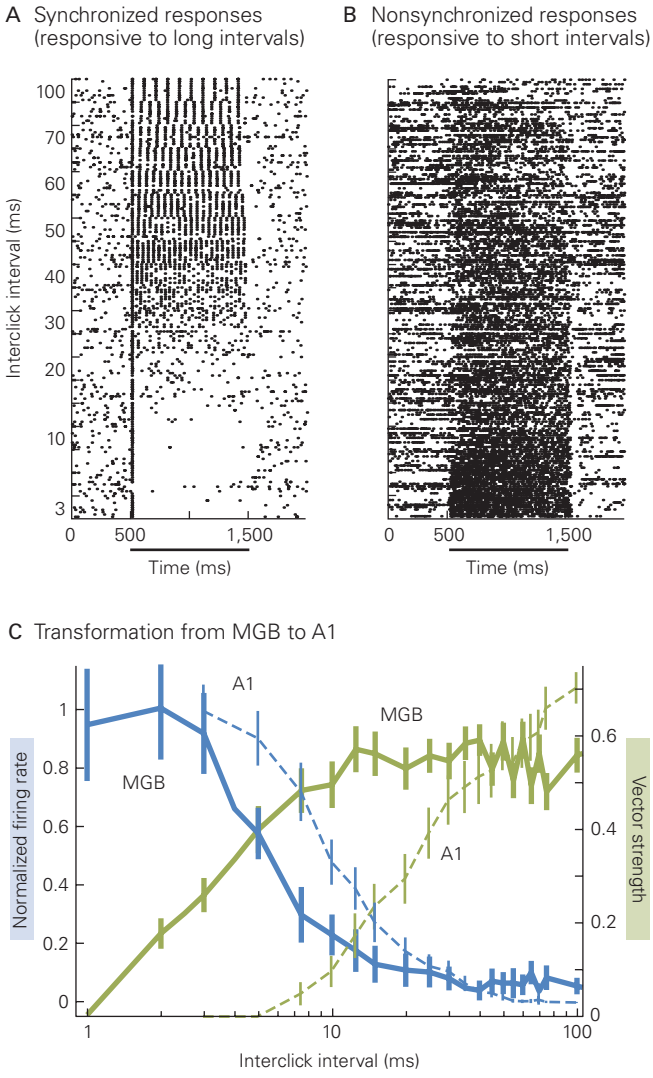

Figure 28–12 Temporal and rate coding of time-varying sounds.

A. Stimulus-synchronized responses of a neuron to periodic click trains recorded from A1 of an awake marmoset. The horizontal bar below the *x*-axis indicates the duration of the stimulus. (Adapted, with permission, from Lu, Liang, and Wang 2001. Copyright © 2001 Springer Nature.)

B. Nonsynchronized responses of a neuron to periodic click trains recorded from A1 in an awake marmoset. (Adapted, with permission, from Lu, Liang, and Wang 2001. Copyright © 2001 Springer Nature.)

C. Comparison of temporal response properties between primary auditory cortex (**A1**) and medial geniculate body of the thalamus (**MGB**). Stimulus-synchronized responses are quantified by vector strength, a measure of the strength of phase-locking. Nonsynchronized responses are quantified by the normalized firing rate (data curves identified as A1 rate and MGB rate). Error bars represent standard error of the mean. (Adapted, with permission, from Bartlett and Wang 2007.)

primary sensory areas of the cortex. The slowing of the phase-locking limit along the ascending auditory pathway and accompanying transition from a temporal code to a rate code are necessary for auditory information to be integrated in the cerebral cortex with information from other sensory modalities that are intrinsically slower.

Primates Have Specialized Cortical Neurons That Encode Pitch and Harmonics

Pitch perception is crucial for perceiving speech and music and for recognizing auditory objects in a complex acoustic environment. Pitch is the percept that allows harmonically structured periodic sounds to be perceived and ordered on a musical scale. Pitch carries crucial linguistic information in tonal languages such as Chinese and prosodic information in European languages. We use pitch to identify a particular voice from a noisy background in a cocktail party. When listening to an orchestra, we hear the melody of the soloist over the background of accompanying instruments.

An important phenomenon for understanding pitch is the perception of "missing fundamental," also referred to as the residue pitch. When the harmonics of a fundamental frequency are played together, the pitch is perceived as the fundamental frequency even if the fundamental frequency is missing. For example, the harmonics of the fundamental frequency of 200 Hz are at 400, 600, 800 Hz, and so on. Playing the frequencies 400, 600, and 800 Hz together will generate a pitch perception of 200 Hz, even though a distinct frequency component of 200 Hz is not physically present in the sound. We encounter this phenomenon routinely when we listen to music over speakers that are too small to generate sounds at low frequencies.

Many combinations of frequencies can give rise to a common fundamental frequency or pitch, making it a particularly valuable auditory cue. This is especially useful when pitch conveys behaviorally important information, as in the case of human speech or animal vocalizations. Sounds propagated through the environment can become spectrally degraded, losing high or low frequencies. While such spectral filtering distorts spectral information, the perception of the missing fundamental is robust despite the loss of some harmonic components.

The ability to perceive pitch is not unique to humans; birds, cats, and monkeys can also pick out pitch. Monkeys are capable of spectral pitch discrimination, melody recognition, and octave generalization, each of which requires the perception of pitch. Marmoset monkeys (*Callithrix jacchus*), a highly vocal New World primate species whose hearing range is similar to that of humans, exhibit human-like pitch perception. Marmosets are able to discriminate a missing fundamental in harmonic sounds with a precision as small as one semitone for the periodicity above 440 Hz.

Given that both humans and some animals experience a pitch that generalizes across a variety of sounds with the same periodicity (including harmonic sounds with a missing fundamental), it is reasonable to expect that some neurons extract pitch from complex sounds. Xiaoqin Wang and his colleagues discovered a decade ago that a small region in the auditory cortex of marmoset monkeys contains "pitch-selective neurons." These neurons are tuned to pure tones with a best frequency and respond to harmonic complexes with a fundamental frequency near its best frequency even when the harmonics lay outside the neuron's excitatory-frequency response area (Figure 28–13A).

A pitch-selective neuron responds to pitch-evoking sounds (eg, harmonic sounds, click trains) when the pitch is near the neuron's preferred best frequency. Pitch-selective neurons increase their firing rates as the behavioral salience of pitch increases and prefer sounds with periodicity over aperiodic sounds. It is important to note that the pitch-selective neurons in marmoset monkeys, which extract and code for pitch embedded in harmonic sounds (a highly nonlinear computation), are distinctly different from neurons in subcortical areas or A1 that merely "reflect" information on pitch in their firing patterns.

The region containing the pitch-selective neurons in marmoset monkeys is confined to the low-frequency border of A1, the rostral auditory cortex (area R), and lateral belt areas (Figure 28–13B). Human imaging studies have identified a restricted region at the lateral end of Heschl's gyrus anterolateral to A1 that extracts pitch of harmonic complex sounds and is sensitive to changes in pitch salience. The location of this region mirrors the location of the pitch center in marmoset monkeys (Figure 28–13B).

The core regions of auditory cortex in marmosets also contain a class of harmonic template neurons that respond weakly or not at all to pure tones or two-tone combinations but respond strongly to particular combinations of multiple harmonics. The harmonic template neurons show stronger responses to harmonic sounds than inharmonic sounds and selectivity for particular harmonic structures. In contrast to the pitch-selective neurons that are localized within a small cortical region lateral to the low-frequency border between A1 and R and have best frequencies

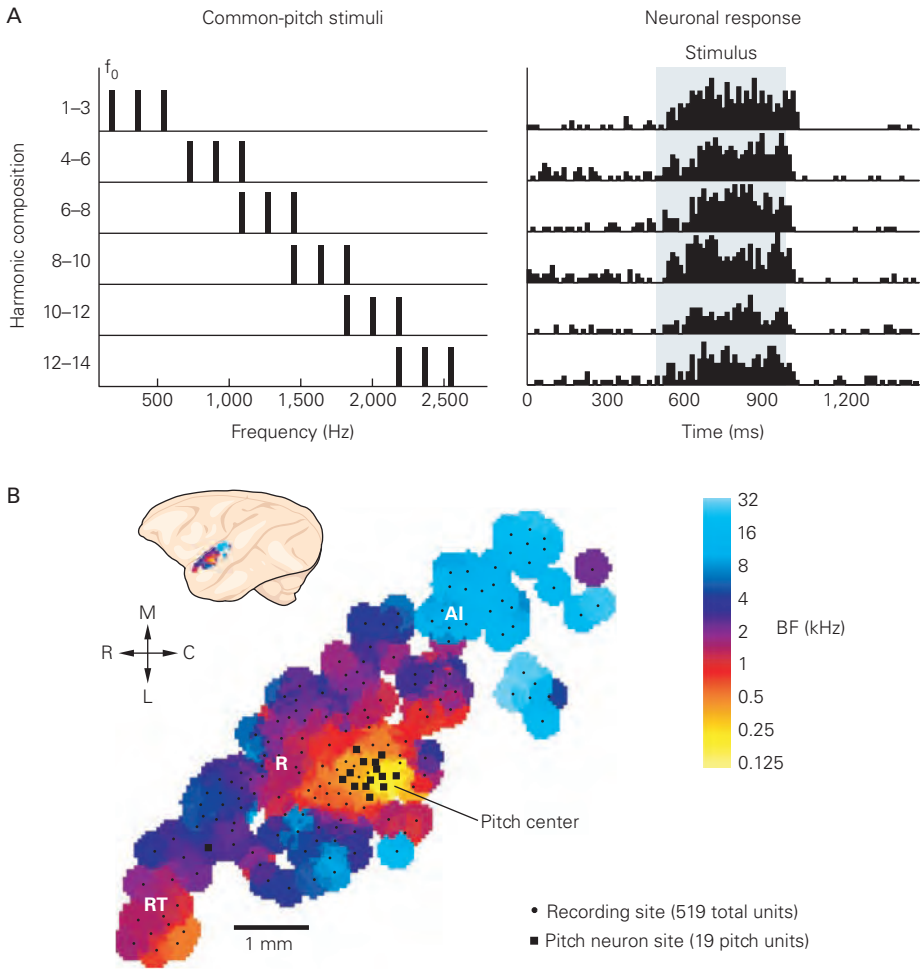

Figure 28–13 Pitch is encoded by specialized neurons in primate auditory cortex.

A. An example of a pitch-selective neuron recorded from marmoset auditory cortex. *Left*: Frequency spectra of a series of harmonic stimuli that share the same fundamental frequency (f_0). *Right*: Peristimulus time histogram of the neuron's response to the stimuli (stimulus duration indicated by the shaded region). B. Anatomical organization of the marmoset auditory cortex and the location of a pitch center. **Top:** Side view of the marmoset brain. **Bottom:** Tonotopic map of the left auditory cortex characterized in one marmoset. Pitch-selective neurons (**black squares**) are clustered near the low-frequency border between A1 and area **R** (rostral auditory cortex). Frequency reversals indicate the borders between A1/R and **R/RT** (rostrotemporal auditory cortex). (**BF**: best frequency.) (Adapted from Bendor and Wang 2005. Copyright © 2005 Springer Nature.)

less than 1,000 Hz, the harmonic template neurons are distributed across A1 and R and have best frequencies ranging from approximately 1 kHz to approximately 32 kHz, a range that covers the entire hearing range of marmosets.

Whereas in the periphery single auditory nerve fibers encode individual components of harmonic sounds, the properties of the harmonic template neurons reveal harmonically structured receptive fields for extracting harmonic patterns. The change in neural representation of harmonic sounds from auditory nerve fibers to the auditory cortex reflects a principle of neural coding in sensory systems. Neurons in sensory pathways transform the representation of physical features, such as the frequency of sounds in hearing or luminance of images in vision, into a representation of perceptual features, such as pitch in hearing or curvature in vision. Such features lead to the formation of auditory or visual percepts. The harmonic template neurons in the auditory cortex are key to processing sounds with harmonic structures such as animal vocalizations, human speech, and music.

Insectivorous Bats Have Cortical Areas Specialized for Behaviorally Relevant Features of Sound

Although it is generally assumed that upstream auditory areas perform increasingly specialized functions related to hearing, much less is known about the functions of serial relays in the auditory system compared to the visual system. In humans, one of the most important aspects of audition is its role in processing language, but we know relatively little about how speech sounds are analyzed by neural circuits. New techniques for imaging the human brain are gradually providing insights into the functional specialization of cortical areas associated with language (Chapter 55).

Evidence for specialized analysis of complex auditory signals in the cerebral cortex comes from studies of insectivorous bats. These animals find their prey almost entirely through *echolocation*, emitting ultrasonic pulses of sound that are reflected by flying insects. Bats analyze the timing and structure of the echoes to help locate and identify the targets, and discrete auditory areas are devoted to processing different aspects of the echoes.

Many bats, such as the mustached bat studied by Nobuo Suga and his collaborators, emit echolocating pulses with two components. An initial *constant-frequency* (CF) component consists of several harmonically related sounds. These harmonics are emitted stably for tens to hundreds of milliseconds, akin to human vowel sounds. The constant-frequency component is followed by a sound that decreases steeply in frequency, the *frequency-modulated* (FM) component, which resembles the rapidly changing frequency of human consonants (Figure 28–14A).

The FM sounds are used to determine the distance to the target. The bat measures the interval between the emitted sound and the returning echo, which corresponds to a particular distance, based on the relatively constant speed of sound. Neurons in the FM-FM area of auditory cortex (Figure 28–14B) respond preferentially to pulse-echo pairs separated by a specific delay. Moreover, these neurons respond better to particular combinations of sounds than to the individual sounds in isolation; such neurons are called *feature detectors* (Figure 28–14C). The FM-FM area contains an array of such detectors, with preferred delays systematically ranging from 0.4 to 18 ms, corresponding to target ranges of 7 to 280 cm (Figure 28–14B). These neurons are organized in columns, each of which is responsive to a particular combination of stimulus frequency and delay. In this way, the bat, like the barn owl in its inferior colliculus, is able to represent an acoustic feature that is not directly represented by sensory receptors.

The CF components of bat calls are used to determine both the speed of the target relative to the bat and the acoustic image of the target. When an echolocating bat is flying toward an insect, the sounds reflected from the insect are Doppler-shifted to a higher frequency at the bat's ear, for the bat is moving toward the returning sound waves from the target, causing a relative speeding up of these waves at its ear. Similarly, a receding insect yields reflections of lowered frequency at the bat's ear. Neurons in the CF-CF area (Figure 28–14B) are sharply tuned to a combination of frequencies close to the emitted frequency or its harmonics. Each neuron responds best to a combination of a pulse of a particular fundamental frequency with an echo corresponding to the first or second harmonic of the pulse, Doppler-shifted to a specific extent. As in the FM-FM area, neurons do not respond to the pulse or echo alone, but rather to the combination of the two CF signals.

CF-CF neurons are arranged in columns, each encoding a particular combination of frequencies. These columns are arranged regularly along the cortical surface, with the fundamental frequency along one axis and the echo harmonics along a perpendicular axis. This dual-frequency coordinate system creates a map wherein a specific location corresponds to a particular Doppler shift and thus a particular target velocity, ranging systematically from –2 m/s to 9 m/s.

The CF components of returning echoes are also used for detailed frequency analysis of the acoustic image, presumably important in its identification. The Doppler-shifted constant-frequency area (DSCF) of the mustached bat is a dramatic expansion of the primary auditory cortex's representation of frequencies between 60 kHz and 62 kHz, corresponding well to the set of returning echoes from the major CF component of the bat's call (Figure 28–14B). Within the DSCF area, individual neurons are extremely sharply tuned to frequency, so that the tiny changes in frequency created by fluttering moth wings are easily detected.

Transient inactivation of some of these specialized cortical areas while the bat performs a discrimination task strikingly supports the importance of their functional specialization in behavior. Silencing of the DSCF selectively impairs fine frequency discrimination while leaving time perception intact. Conversely, inactivation of the FM-FM area impairs the bat's ability to detect small differences in the time of arrival of two echoes, while leaving frequency perception unchanged.

Investigation of this auditory system was greatly facilitated by knowledge of the stimuli relevant to bats. It remains to be seen whether these cortical areas are functionally or anatomically analogous to particular

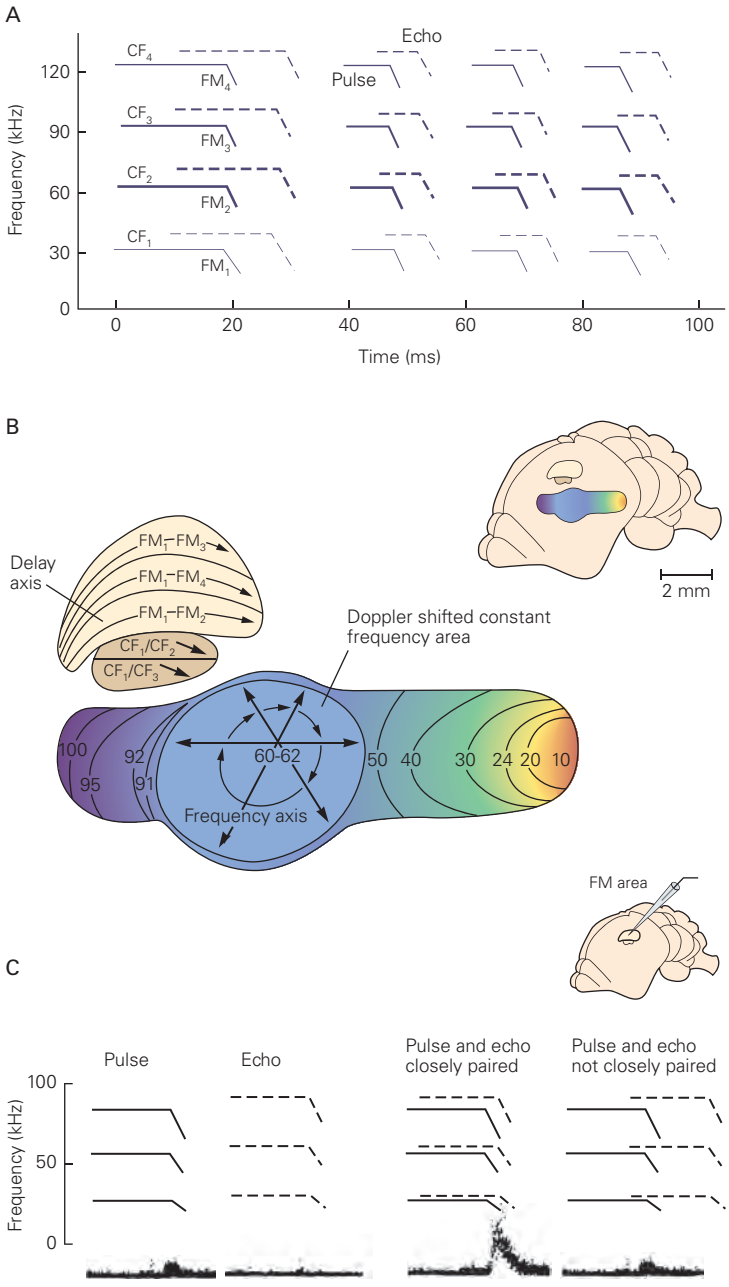

Figure 28–14 The auditory system of the bat has specialized areas for locating sounds.

A. A sonogram of an animal's calls (**solid lines**) and the resultant echoes (**dashed lines**) illustrates the two components of the call: the protracted, harmonically related constant-frequency (**CF**) signal and the briefer frequency-modulated (**FM**) signal. The duration of the calls declines as the animal approaches its target. (Adapted, with permission, from Suga 1984.)

B. A view of the cerebral hemisphere of the mustached bat shows three of the functional areas within the auditory cortex. The FM area is where the distance from the target is computed; the CF area is where the velocity of the target is computed; and the Doppler-shifted CF area is specialized for the identification of small fluttering objects. The expanded cortical representation of Doppler-shifted CF signals near the second harmonic of the call frequency (60–62 kHz) forms the acoustic "fovea." (Adapted, with permission, from Suga 1984.)

C. The FM-FM combination-sensitive neuron shown does not respond significantly to either pulses or echoes alone, but responds very strongly to a closely paired pulse-echo. However, the neuron is also sensitive to the time difference between the pulse and echo, as seen in the record on the right, where the neuron fails to respond to a pulse-echo combination that is not closely paired. (Adapted, with permission, from Suga et al. 1983.)

fields in cats, monkeys, and humans. Regardless, the choice of appropriate stimuli is likely to be as important in studying these other species as it has been in studies of bats.

The Auditory Cortex Is Involved in Processing Vocal Feedback During Speaking

Vocal communication involves both speaking and hearing, often taking place concurrently. When we speak, the sound of our voice is delivered not only to the intended listener but also back to our own ears. Such feedback to our auditory system during vocal production is conducted not only through the air but also through bone and can be loud as a result of the proximity of the mouth and the ears.

The auditory system must distinguish an auditory percept as being self-generated or externally generated. To monitor external sounds from the acoustic environment during speaking, self-generated sounds have to be masked. At the same time, the auditory system must also monitor our own voice in order to detect errors in vocal production. An accurate representation of one's own voice through vocal feedback is crucial to maintaining desired vocal production and to the learning of a new language. In humans and animals, perturbations of the vocal feedback can lead to alterations in vocal production, and interruptions or blockages of the vocal feedback can result in degradation in vocal learning.

The evidence for the involvement of the auditory cortex in processing vocal feedback comes from both human and animal studies. Responses in the auditory cortex of human subjects to their own voice while speaking are smaller than the responses to the playback of the same sounds. This reduction can be observed in electrocorticographical (ECoG) recordings (Figure 28–15A) or with a variety of imaging methods (eg, fMRI, PET, magnetoencephalography [MEG]).

Single-neuron recordings from the auditory cortex of vocalizing monkeys have shown that self-initiated vocalizations result in suppression of cortical responses to monkeys' own vocalizations, of external sounds heard during vocalization, and also spontaneous activity (Figure 28–15B). Because in many instances firing rates are suppressed to below spontaneous activity, the suppression is likely caused by inhibition. Neurons suppressed by self-initiated vocalizations show frequency and intensity tuning, as is typical of auditory cortical neurons, and respond to the playback of vocalizations.

The vocalization-induced suppression begins several hundred milliseconds prior to the onset of vocalization (Figure 28–15B), suggesting that these neurons receive modulatory signals originating in vocal production circuits. In humans, vocal production is carried out by cortical areas in the frontal lobe, from Broca's area to premotor and motor cortex. In humans and monkeys, axons from the premotor cortex to auditory regions of the superior temporal gyrus have been described, and presumably, they mediate the vocalization-induced suppression. This modulatory connection is not active when humans or monkeys simply listen to vocal sounds played to them.

Why do we suppress our auditory cortex when we speak? A simple answer is that this suppression helps reduce the masking effect of our own voice, which can be very loud. A more interesting answer is that this suppression results from a vocal feedback-monitoring network in auditory cortex. In humans, there is less or no suppression of auditory cortex if vocal feedback is experimentally altered through earphones, for example, when the pitch of the voice is shifted (Figure 28–15A). In marmoset monkeys, neurons suppressed by self-initiated vocalizations may become less suppressed or even excited when the animal hears its own frequency-shifted vocalizations (Figure 28–15C). This sensitivity to feedback perturbations suggests that neurons exhibiting vocalization-induced suppression are part of a network responsible for monitoring vocal feedback signals. The presence of vocal feedback-related neural activity in the auditory cortex of both humans and monkeys suggests that the auditory cortex combines both internal modulation and vocal feedback responses, rather than merely responding to sensory signals coming through the ears.

Not all neurons in the auditory cortex are suppressed by speaking or vocalizing. A smaller proportion (~30%) of neurons in marmoset A1 increase their responses during self-initiated vocalizations, consistent with their auditory response characteristics. In contrast to vocalization-induced suppression, vocalization-related excitation begins after the onset of vocalization and is likely the result of feedback through the ascending auditory pathway. The vocalization-related excitation may help maintain the sensitivity of the auditory cortex to the external acoustic environment during speaking or vocalizing.

Vocalization-induced suppression of auditory responses has been observed in several mammalian subcortical structures, including the brain stem and inferior colliculus. Such suppression begins a few milliseconds before or is synchronized with vocal production. In contrast, cortical suppression begins several hundred milliseconds before the vocal onset. It is possible that subcortical suppression of auditory responses during speaking or vocalizing is initiated by cortical commands.

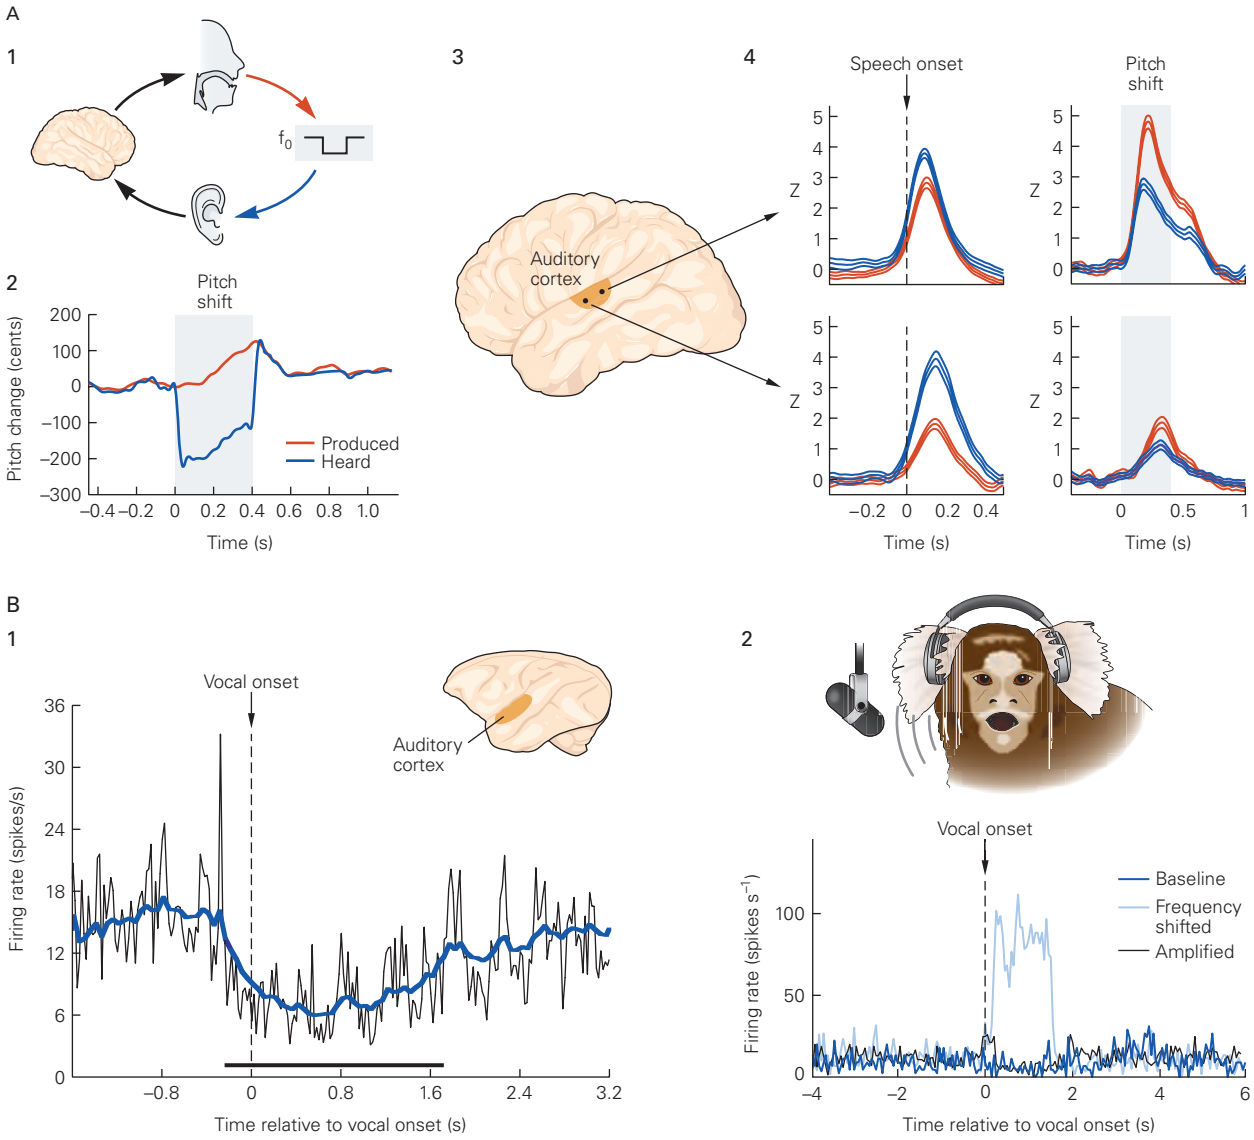

Figure 28–15 Vocal feedback processing in auditory cortex.

A. Examples of vocalization-induced suppression and sensitivity to pitch perturbation in human cerebral cortex. **1.** A subject's vocalizations (**red arrow**) went through a digital signal processor that shifted pitch and delivered the distorted auditory feedback (**blue arrow**) to the subject's earphones. **2.** Pitch track of an example trial shows the pitch recorded by the microphone (produced) and the pitch delivered to the earphones (heard). Shaded region indicates the time interval when the signal processor shifted the pitch by –200 cents (1 cent = 1/1200 octave). **3.** The locations of electrodes that recorded from two sites in the auditory cortex on the surface of the superior temporal gyrus. **4.** The Z variable represents the power in the 50 to 150 Hz (high-γ) range of cortical activity, which has been shown to correlate well with neuronal spiking activity. It was extracted from the signals recorded at each electrode in the speaking (**red**) and listening (**blue**) conditions. Vertical lines in the left column of plots indicate vocalization onset, and shaded regions in the right column of plots indicate the onset and offset of perturbation. The response of a subject's auditory cortex to his or her own self-produced vocalization is generally smaller than the response seen when the subject passively listens to playback of the same vocalization (*left column).* The response of auditory cortex to the perturbation during active phonation (speaking) is enhanced (*right column*). (Adapted, with permission, from Houde and Chang, 2015.)

B. 1. Vocalization-induced suppression of neural activity in marmoset monkey auditory cortex. Population-averaged firing rate of all vocalization-suppressed responses are aligned by vocal onset (a "Phee" call). The **blue line** is a moving average (100 ms window) and shows that suppression begins prior to vocalization (indicated by **arrow**). The **thick bar** indicates the period over which suppression is continuously significant (P <0.05). (Adapted, with permission, from Eliades and Wang 2003.)

2. Neurons subject to vocalization-induced suppression are sensitive to vocal feedback perturbations. **Top:** Self-produced vocalizations with or without feedback alterations were delivered to the marmoset through a customized headphone. **Bottom:** This auditory cortical neuron was suppressed during normal vocalization (**dark blue**) but showed a large increase in firing rate when the auditory feedback of the vocalization was shifted in the frequency domain (**light blue**). Amplifying auditory feedback alone did not generate firing rate changes (**black**). (Adapted, with permission, from Eliades and Wang 2008; Crapse and Sommer 2008.)

Highlights

1. Sound impinging on two ears carries information that the brain uses to compute where sounds arise and what they mean. Sounds are characterized by the amount of energy at one or more frequencies. To determine where sounds arise in the horizontal plane, many mammals compute differences in the time of arrival at the two ears for sounds less than approximately 3,000 Hz. To determine where sounds arise in the vertical dimension and whether they arise from the front or the back, mammals use spectral filtering of sounds greater than approximately 6,000 Hz by the head, shoulders, and external ears.
2. Acoustic information is brought to the brain from the cochlea by auditory nerve fibers, each sharply tuned to a narrow range of frequencies and together representing the entire hearing range of the animal. Auditory nerve fibers terminate in the ventral and dorsal cochlear nuclei, distributing acoustic information to four major groups of principal cells that form parallel ascending pathways through the brain stem. The topographic organization of the auditory nerve inputs imparts a tonotopic organization to the ipsilateral cochlear nuclei that is preserved all along the auditory pathway, including auditory cortex.
3. A marked feature of auditory neurons at processing stations along the ascending pathway is their progressively increasing stimulus selectivity.
4. The ventral cochlear nucleus extracts three features of sounds: (a) The monaural pathways through octopus cells of the ventral cochlear nucleus, the superior paraolivary nucleus, and ventral nucleus of the lateral lemniscus detect coincident firing of auditory nerve fibers that is useful for detecting onsets and gaps in sounds. (b) Stellate cells detect and sharpen the encoding of spectral peaks and valleys and convey that spectral information to the dorsal cochlear nucleus, olivocochlear neurons in the ventral nucleus of the lateral lemniscus, ventral nucleus of the lateral lemniscus, inferior colliculus, and thalamus. Spectral information is used for understanding the meaning of sounds and for localizing their sources. (c) Bushy cells sharpen and convey information about the fine structure of sounds, which is used in the binaural pathways through the medial and lateral superior olivary nuclei to make the interaural comparisons of timing and intensity of sounds at the two ears, which are used to localize sound sources along the azimuth.
5. The dorsal cochlear nucleus integrates acoustic signals with somatosensory information in its principal cells. Somatosensory information helps distinguish the spectral cues generated by an animal's own movements, which are biologically uninteresting, from those that arise from the environment.
6. Auditory brainstem pathways converge in the inferior colliculus. The inferior colliculus feeds acoustic information through the medial geniculate body of the thalamus to auditory cortex.
7. A projection from the inferior colliculus carries information about the location of sounds to the superior colliculus, a part of the brain that controls reflexive orienting movements of the head and eyes.
8. Within auditory cortex, auditory neurons continue to become more selective to the stimuli to which they respond. Subregions of the auditory cortex represent different biologically significant features such as pitch of tones that form harmonic complexes. Auditory cortex also transforms rapidly varying features of sounds into firing-rate-based representations, while representing slowly varying sounds using spike timing.
9. Auditory circuits in the cerebral cortex are segregated into separate processing streams, with dorsal and ventral streams concerned respectively with sound location in space and sound identification.
10. The cerebral cortex modulates processing in subcortical auditory areas. Projections from the auditory cortex innervate the thalamus, inferior colliculus, olivocochlear neurons, some basal ganglionic structures, and even the dorsal cochlear nucleus.
11. Auditory cortex is involved in processing vocal feedback signals during speaking. Speaking induces suppression of neural activity in auditory cortex that begins several hundred milliseconds prior to the vocal onset. This suppression results from a vocal feedback-monitoring network that functions to guide vocal production and learning.

Smell and Taste: The Chemical Senses

Through the senses of smell and taste, we are able to perceive a staggering number and variety of chemicals in the external world. These chemical senses inform us about the availability of foods and their potential pleasure or danger. Smell and taste also initiate physiological changes required for the digestion and utilization of food. In many animals, the olfactory system also serves an important social function by detecting pheromones that elicit innate behavioral or physiological responses.

Although the discriminatory ability of humans is somewhat limited compared with that of many other animals, odor chemists estimate that the human olfactory system may be capable of detecting more than 10,000 different volatile chemicals. Perfumers who are highly trained to discriminate odorants can distinguish as many as 5,000 different types of odorants, and wine tasters can discern more than 100 different components of taste based on combinations of flavor and aroma.

In this chapter, we consider how odor and taste stimuli are detected and how they are encoded in patterns of neural signals transmitted to the brain. In recent years, much has been learned about the mechanisms underlying chemosensation in a variety of animal species. Certain features of chemosensation have

been conserved through evolution, whereas others are specialized adaptations of individual species.

A Large Family of Olfactory Receptors Initiate the Sense of Smell

Odorants—volatile chemicals that are perceived as odors—are detected by olfactory sensory neurons in the nose. The sensory neurons are embedded in a specialized olfactory epithelium that lines part of the nasal cavity, approximately 5 cm^2 in area in humans (Figure 29–1), and are interspersed with glia-like supporting cells (Figure 29–2). They are relatively short lived, with a life span of only 30 to 60 days, and are continuously replaced from a layer of basal stem cells in the epithelium.

The olfactory sensory neuron is a bipolar nerve cell. A single dendrite extends from the apical end to the epithelial surface, where it gives rise to numerous

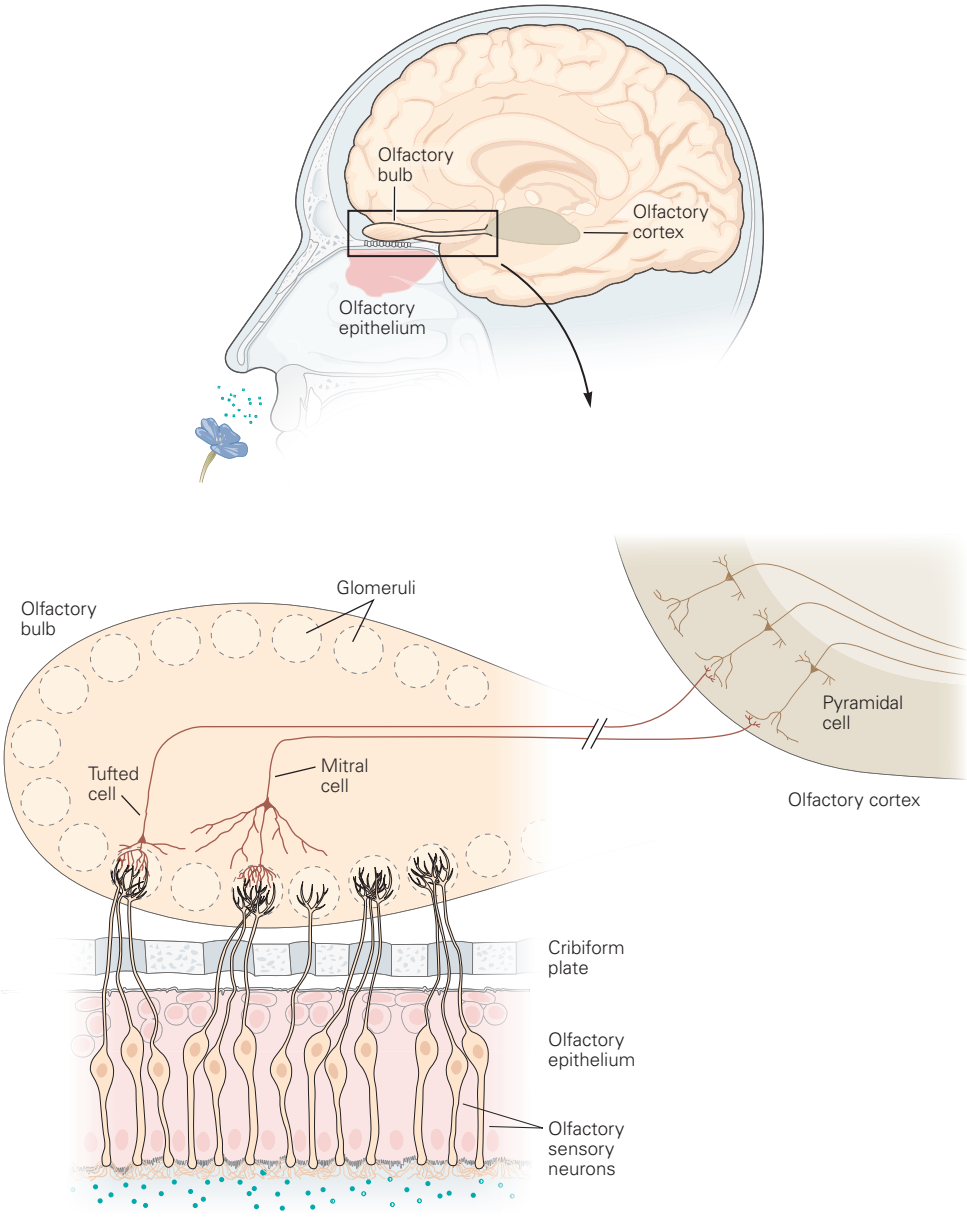

Figure 29–1 The olfactory system. Odorants are detected by olfactory sensory neurons in the olfactory epithelium, which lines part of the nasal cavity. The axons of these neurons project to the olfactory bulb, where they terminate on the dendrites of mitral and tufted cell relay neurons within glomeruli. In turn, the axons of the relay neurons project to the olfactory cortex, where they terminate on the dendrites of pyramidal neurons whose axons project to other brain areas.

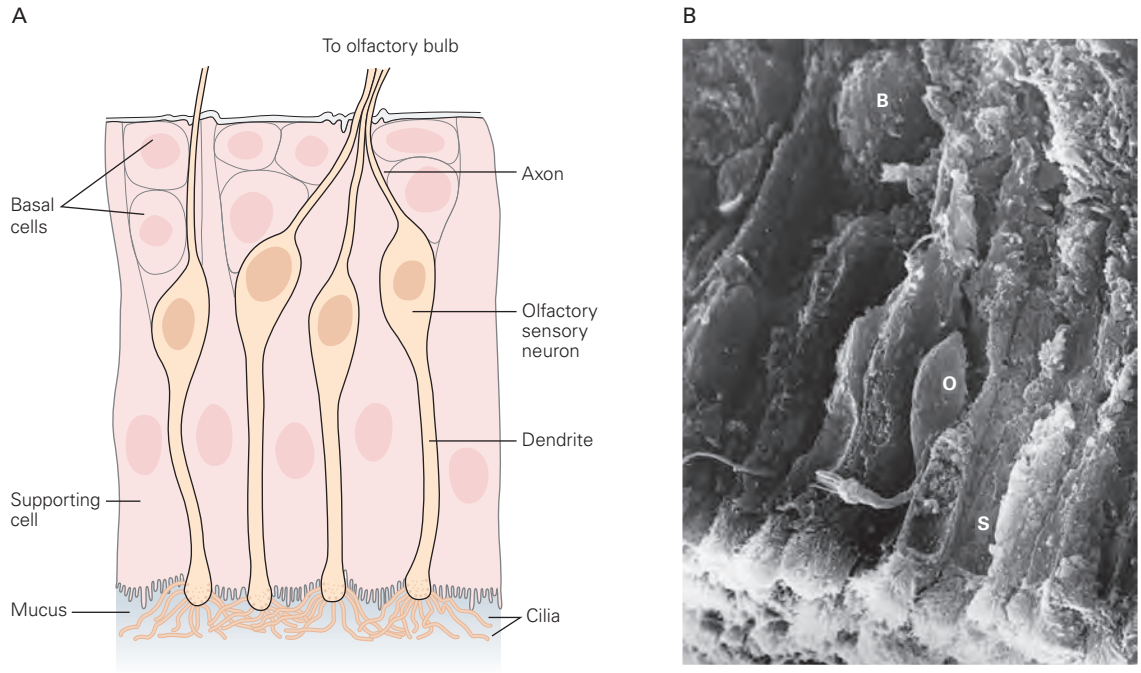

Figure 29–2 The olfactory epithelium.

A. The olfactory epithelium contains sensory neurons interspersed with supporting cells as well as a basal layer of stem cells. A single dendrite extends from the apical end of each neuron; sensory cilia sprout from the end of the dendrite into the mucus lining the nasal cavity. An axon extends from the basal end of each neuron to the olfactory bulb.

B. A scanning electron micrograph of the olfactory epithelium shows the dense mat of sensory cilia at the epithelial surface. Supporting cells (**S**) are columnar cells that extend the full depth of the epithelium and have apical microvilli. Interspersed among the supporting cells is an olfactory sensory neuron (**O**) with its dendrite and cilia, and a basal stem cell (**B**). (Reproduced, with permission, from Morrison and Costanzo 1990. Copyright © 1990 Wiley-Liss, Inc.)

thin cilia that protrude into the mucus that coats the nasal cavity (Figure 29–2). The cilia contain the odorant receptors as well as the transduction machinery needed to amplify sensory signals from the receptors and transform them into electrical signals in the neuron's axon, which projects from the basal pole of the neuron to the brain. The axons of olfactory sensory neurons pass through the cribriform plate, a perforated region in the skull above the nasal cavity, and then terminate in the olfactory bulb (see Figure 29–1).

Mammals Share a Large Family of Odorant Receptors

Odorant receptors are proteins encoded by a multigene family that is evolutionarily conserved and found in all vertebrate species. Humans have approximately 350 different odorant receptors, whereas mice have approximately 1,000. Although odorant receptors belong to the G protein–coupled receptor superfamily, they share sequence motifs not seen in other superfamily members. Significantly, the odorant receptors vary considerably in amino acid sequence (Figure 29–3A).

Like other G protein–coupled receptors, odorant receptors have seven hydrophobic regions that are likely to serve as transmembrane domains (Figure 29–3A). Detailed studies of other G protein–coupled receptors, such as the β-adrenergic receptor, suggest that odorant binding occurs in a pocket in the transmembrane region formed by a combination of the transmembrane domains. The amino acid sequences of odorant receptors are especially variable in several transmembrane domains, providing a possible basis for variability in the odorant binding pocket that could account for the ability of different receptors to recognize structurally diverse ligands.

A second, smaller family of chemosensory receptors is also expressed in the olfactory epithelium. These receptors, called trace amine-associated receptors (TAARs), are G protein–coupled, but their protein sequence is unrelated to that of odorant receptors. They are encoded by a small family of genes present in humans and mice as well as fish. Studies in mice, which have 14 different olfactory TAARs, indicate that TAARs recognize volatile amines, one of which is present in high concentrations in the urine of male

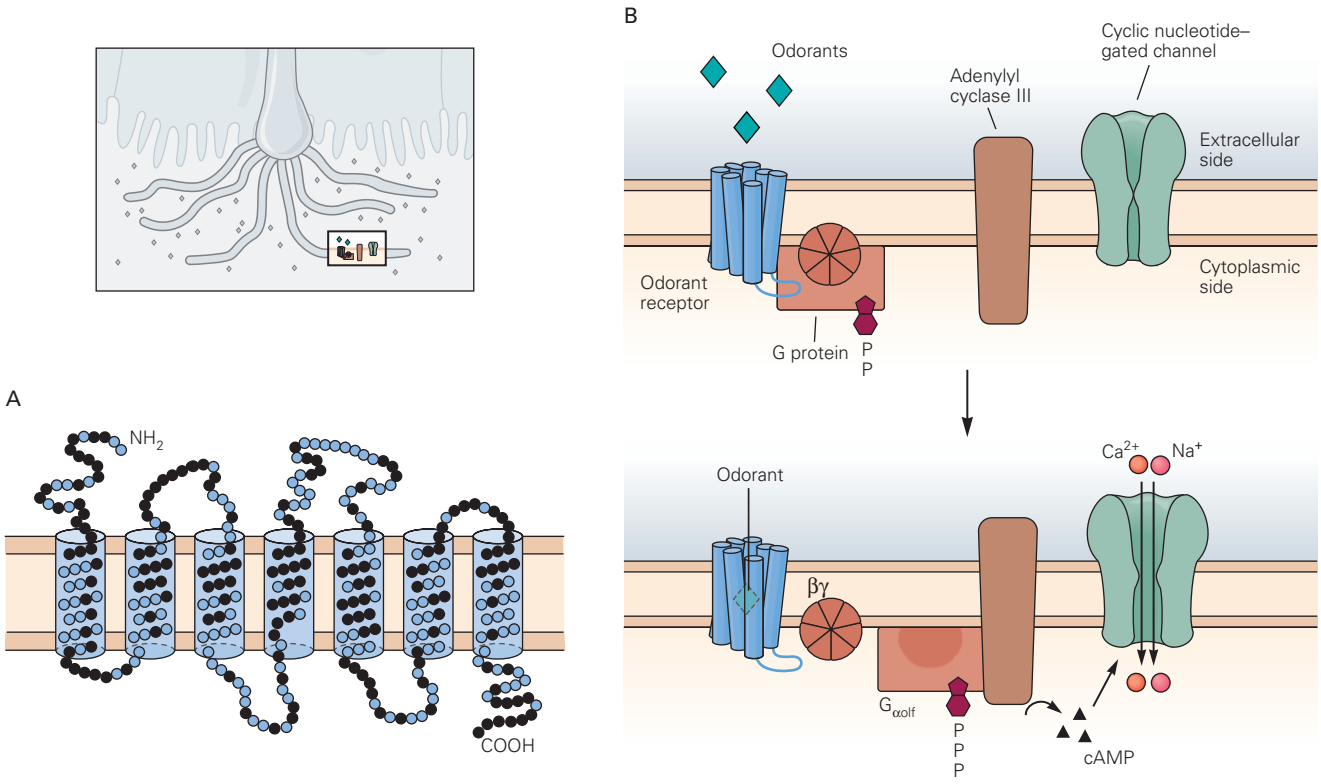

Figure 29–3 Odorant receptors.

A. Odorant receptors have the seven transmembrane domains characteristic of G protein–coupled receptors. They are related to one another but vary in amino acid sequence (positions of highest variability are shown here as **black balls**). (Reproduced, with permission, from Buck and Axel 1991.)

B. Binding of an odorant causes the odorant receptor to interact with $G\alpha_{olf}$, the α-subunit of a heterotrimeric G protein. This causes the release of a guanosine triphosphate (GTP)-coupled $G\alpha_{olf}$, which stimulates adenylyl cyclase III, leading to an increase in cyclic adenosine monophosphate (**cAMP**). The elevated cAMP in turn induces the opening of cyclic nucleotide–gated cation channels, causing cation influx and a change in membrane potential in the ciliary membrane.

mice and another in the urine of some predators. It is possible that this small receptor family has a function distinct from that of the odorant receptor family, perhaps one associated with the detection of animal cues. Another family of 12 receptors, called MS4Rs, is also found in mice, where it may be involved in the detection of pheromones and certain food odors.

The binding of an odorant to its receptor induces a cascade of intracellular signaling events that depolarize the olfactory sensory neuron (Figure 29–3B). The depolarization spreads passively to the cell body and then the axon, where action potentials are generated that are actively conducted to the olfactory bulb.

Humans and other animals rapidly accommodate to odors, as seen for example in the weakening of detection of an unpleasant odor that is continuously present. The ability to sense an odorant rapidly recovers when the odorant is temporarily removed. The adaptation to odorants is caused in part by modulation of a cyclic nucleotide–gated ion channel in olfactory cilia, but the mechanism by which sensitivity is speedily restored is not yet understood.

Different Combinations of Receptors Encode Different Odorants

To be distinguished perceptually, different odorants must cause different signals to be transmitted from the nose to the brain. This is accomplished in two ways. First, each olfactory sensory neuron expresses only one odorant receptor gene and therefore one type of receptor. Second, each receptor recognizes multiple odorants, and conversely, each odorant is detected by multiple different receptors (Figure 29–4). Importantly, however, each odorant is detected, and thereby encoded, by a unique combination of receptors and thus causes a distinctive pattern of signals to be transmitted to the brain.

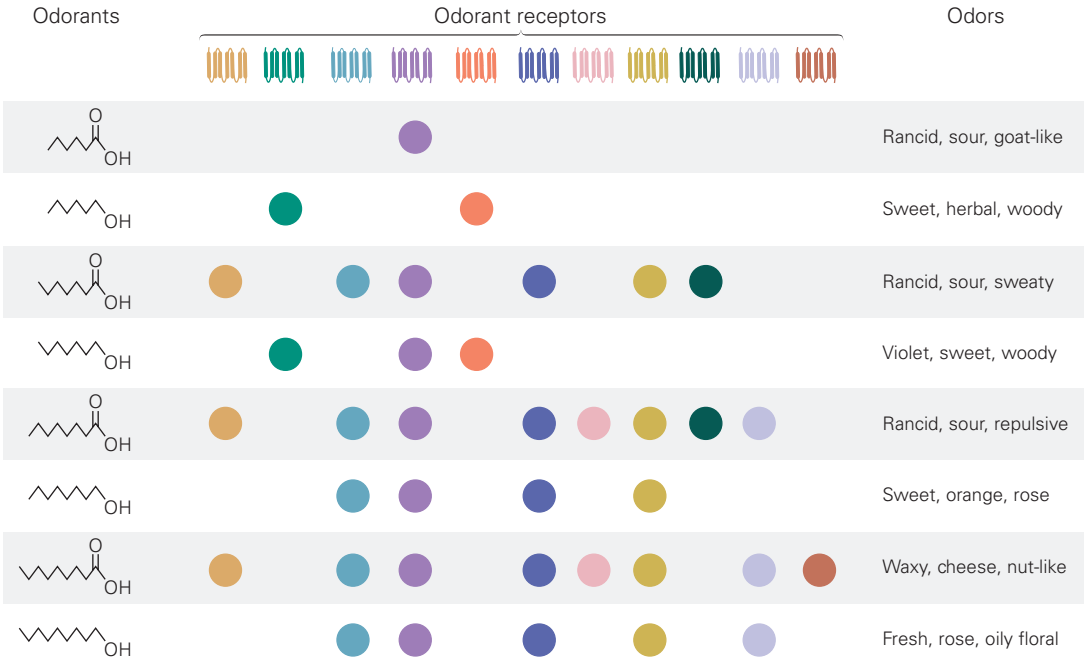

Figure 29–4 Each odorant is recognized by a unique combination of receptors. A single odorant receptor can recognize multiple odorants, but different odorants are detected, and thus encoded, by different combinations of receptors. This combinatorial coding explains how mammals can distinguish odorants with similar chemical structures as having different scents. The data in the figure were obtained by testing mouse olfactory sensory neurons with different odorants and then determining the odorant receptor gene expressed by each responsive neuron. The perceived qualities of these odorants in humans shown on the right illustrate how highly related odorants can have different scents. (Adapted, with permission, from Malnic et al. 1999.)

The combinatorial coding of odorants greatly expands the discriminatory power of the olfactory system. If each odorant were detected by only three different receptors, this strategy could in theory generate millions of different combinatorial receptor codes—and an equivalently vast number of different signaling patterns sent from the nose to the brain. Interestingly, even odorants with nearly identical structures are recognized by different combinations of receptors (Figure 29–4). The fact that highly related odorants have different combinatorial receptor codes explains why a slight change in the chemical structure of an odorant can alter its perceived odor. In some cases, the result is dramatic, for example, changing the perception of a chemical from rose to sour.

A change in concentration of an odorant can also change the perceived odor. For example, a low concentration of thioterpineol smells like tropical fruit, whereas a higher concentration smells like grapefruit and an even higher concentration smells putrid. As the concentration of an odorant is increased, additional receptors with lower affinity for the odorant are recruited into the response and thus change the combinatorial receptor code, providing an explanation for the effects of odorant concentration on perception.

Olfactory Information Is Transformed Along the Pathway to the Brain

Odorants Are Encoded in the Nose by Dispersed Neurons

How are signals from a large array of different odorant receptors organized in the nervous system to generate diverse odor perceptions? This question has been investigated in rodents. Studies in mice have revealed that olfactory information undergoes a series of transformations as it travels from the olfactory epithelium to the olfactory bulb and then to the olfactory cortex.

The olfactory epithelium has a series of spatial zones that express different olfactory receptors. Each receptor type is expressed in approximately 5,000 neurons that are confined to one zone (Figure 29–5). (Recall that each neuron expresses only one odorant receptor gene.) Neurons with the same receptor are randomly scattered within a zone so neurons with different receptors are interspersed. All zones contain a variety of receptors, and a specific odorant may be recognized by receptors in different zones. Thus, despite a rough organization of odorant receptors into spatial

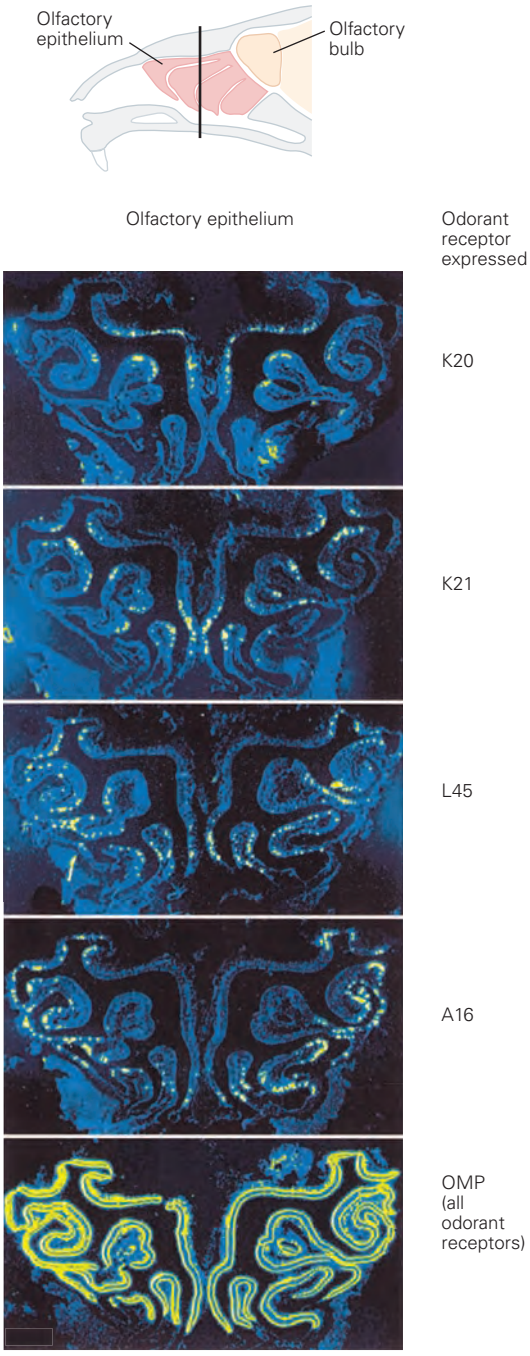

Figure 29–5 Organization of sensory inputs in the olfactory epithelium. The olfactory epithelium has different spatial zones that express different sets of odorant receptor genes. Each sensory neuron expresses only one receptor gene and thus one type of receptor. Neurons with the same receptor are confined to one zone but randomly scattered within that zone, such that neurons with different receptors are interspersed. The micrographs show the distribution of neurons labeled by four different receptor probes in sections through the mouse nose. An olfactory marker protein (**OMP**) probe labels all neurons expressing odorant receptors. (Adapted, with permission, from Ressler, Sullivan, and Buck 1993; Sullivan et al. 1996.)

zones, information provided by the odorant receptor family is highly distributed in the epithelium.

Because each odorant is detected by an ensemble of neurons widely dispersed across the epithelial sheet, receptors in one part of the epithelium will be able to detect a particular odorant even when those in another part are impaired by respiratory infection.

Sensory Inputs in the Olfactory Bulb Are Arranged by Receptor Type

The axons of olfactory sensory neurons project to the ipsilateral olfactory bulb, whose rostral end lies just above the olfactory epithelium. The axons of olfactory sensory neurons terminate on the dendrites of olfactory bulb neurons within bundles of neuropil called glomeruli that are arrayed over the bulb's surface (Figure 29–1). In each glomerulus, the sensory axons make synaptic connections with three types of neurons: mitral and tufted projection (relay) neurons, which project axons to the olfactory cortex, and periglomerular interneurons, which encircle the glomerulus (Figure 29–6).

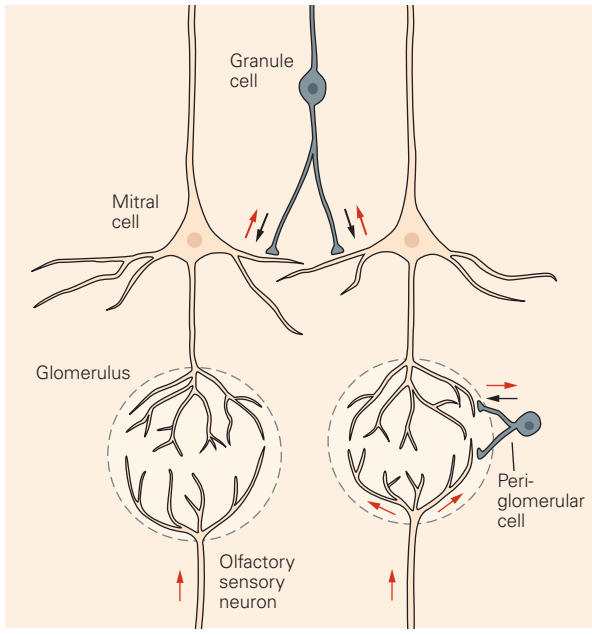

Figure 29–6 Olfactory bulb interneurons. In addition to excitatory mitral and tufted relay neurons, the olfactory bulb contains inhibitory interneurons. Within each glomerulus, the dendrites of GABAergic periglomerular cells receive excitatory input from olfactory sensory neurons and have reciprocal synapses with the primary dendrites of mitral and tufted relay neurons, suggesting a possible role in signal modification. The dendrites of GABAergic granule cells deeper in the bulb have reciprocal excitatory-inhibitory synapses with the secondary dendrites of the relay neurons and are thought to provide negative feedback to relay neurons that shapes the odor response. (Adapted from Shepherd and Greer 1998.)

The axon of an olfactory sensory neuron as well as the primary dendrite of each mitral and tufted relay neuron terminate in a single glomerulus. In each glomerulus, the axons of several thousand sensory neurons converge on the dendrites of approximately 40 to 50 relay neurons. This convergence results in approximately a 100-fold decrease in the number of neurons transmitting olfactory signals.

The organization of sensory information in the olfactory bulb is dramatically different from that of the epithelium. Whereas olfactory sensory neurons with the same odorant receptor are randomly scattered in one epithelial zone, their axons typically converge in two glomeruli at specific locations, one on either side of the olfactory bulb (Figure 29–7C). Each glomerulus, and each mitral and tufted relay neuron connected to it, receives input from just one type of odorant receptor. The result is a precise arrangement of sensory inputs from different odorant receptors, one that is similar between individuals.

Because each odorant is recognized by a unique combination of receptor types, each also activates a particular combination of glomeruli in the olfactory bulb (Figure 29–7B). At the same time, just as one odorant receptor recognizes multiple odorants, a single glomerulus—or a given mitral or tufted cell—is activated by more than one odorant. Owing to the nearly stereotyped pattern of receptor inputs in the olfactory bulb, the patterns of glomerular activation elicited by individual odorants are similar in all individuals and are bilaterally symmetrical in the two adjacent bulbs.

This organization of sensory information in the olfactory bulb is likely to be advantageous in two respects. First, signals from thousands of sensory neurons with the same odorant receptor type always converge on the same few glomeruli, and relay neurons in the olfactory bulb may optimize the detection of odorants present at low concentrations. Second, although olfactory sensory neurons with the same receptor type are dispersed and are continually replaced, the arrangement of inputs in the olfactory bulb remains unaltered. As a result, the neural code for an odorant in the brain is maintained over time, assuring that an odorant encountered previously can be recognized years later.

One mystery that remains unsolved is how all the axons of olfactory sensory neurons with the same type of receptor are directed to the same glomeruli. Studies using transgenic mice indicate that the odorant receptor itself somehow determines the target of the axon, but how it does so is not yet understood.

Sensory information is processed and possibly refined in the olfactory bulb before it is forwarded to the olfactory cortex. Each glomerulus is encircled by periglomerular interneurons that receive excitatory input from sensory axons and form inhibitory dendrodendritic synapses with mitral and tufted cell dendrites in that glomerulus and perhaps adjacent glomeruli. The periglomerular interneurons may therefore have a role in signal modulation. In addition, granule cell interneurons deep in the bulb provide negative feedback onto mitral and tufted cells. The granule cell interneurons are excited by the basal dendrites of mitral and tufted cells and in turn inhibit those relay neurons and others with which they are connected. The lateral inhibition afforded by these connections is thought to dampen signals from glomeruli and relay neurons that respond to an odorant only weakly, thereby sharpening the contrast between important and irrelevant sensory information before its transmission to the cortex.

Other potential sources of signal refinement are the retrograde projections to the olfactory bulb from the olfactory cortex, basal forebrain (horizontal limb of the diagonal band), and midbrain (locus ceruleus and raphe nuclei). These connections may modulate olfactory bulb output according to the physiological or behavioral state of an animal. When the animal is hungry, for example, some centrifugal projections might heighten the perception of the aroma of foods.

The Olfactory Bulb Transmits Information to the Olfactory Cortex

The axons of the mitral and tufted relay neurons of the olfactory bulb project through the lateral olfactory tract to the olfactory cortex (Figure 29–8 and see Figure 29–1). The olfactory cortex, defined roughly as that portion of the cortex that receives a direct projection from the olfactory bulb, comprises multiple anatomically distinct areas. The six major areas are the anterior olfactory nucleus, which connects the two olfactory bulbs through a portion of the anterior commissure; the anterior and posterior-lateral cortical nuclei of the amygdala; the olfactory tubercle; part of the entorhinal cortex; and the piriform cortex, the largest and considered the major olfactory cortical area.

The functions of the different olfactory cortical areas are largely unknown. However, the piriform cortex is thought to be important for odor learning. Recent studies indicate that the posterior-lateral cortical amygdala may have a role in innate attraction and fear behaviors, and the amygdalo-piriform transition area, a minor olfactory cortical area, a role in stress hormone responses to predator odors detected in the nose.

In the piriform cortex, the axons of olfactory bulb mitral and tufted cells leave the lateral olfactory tract

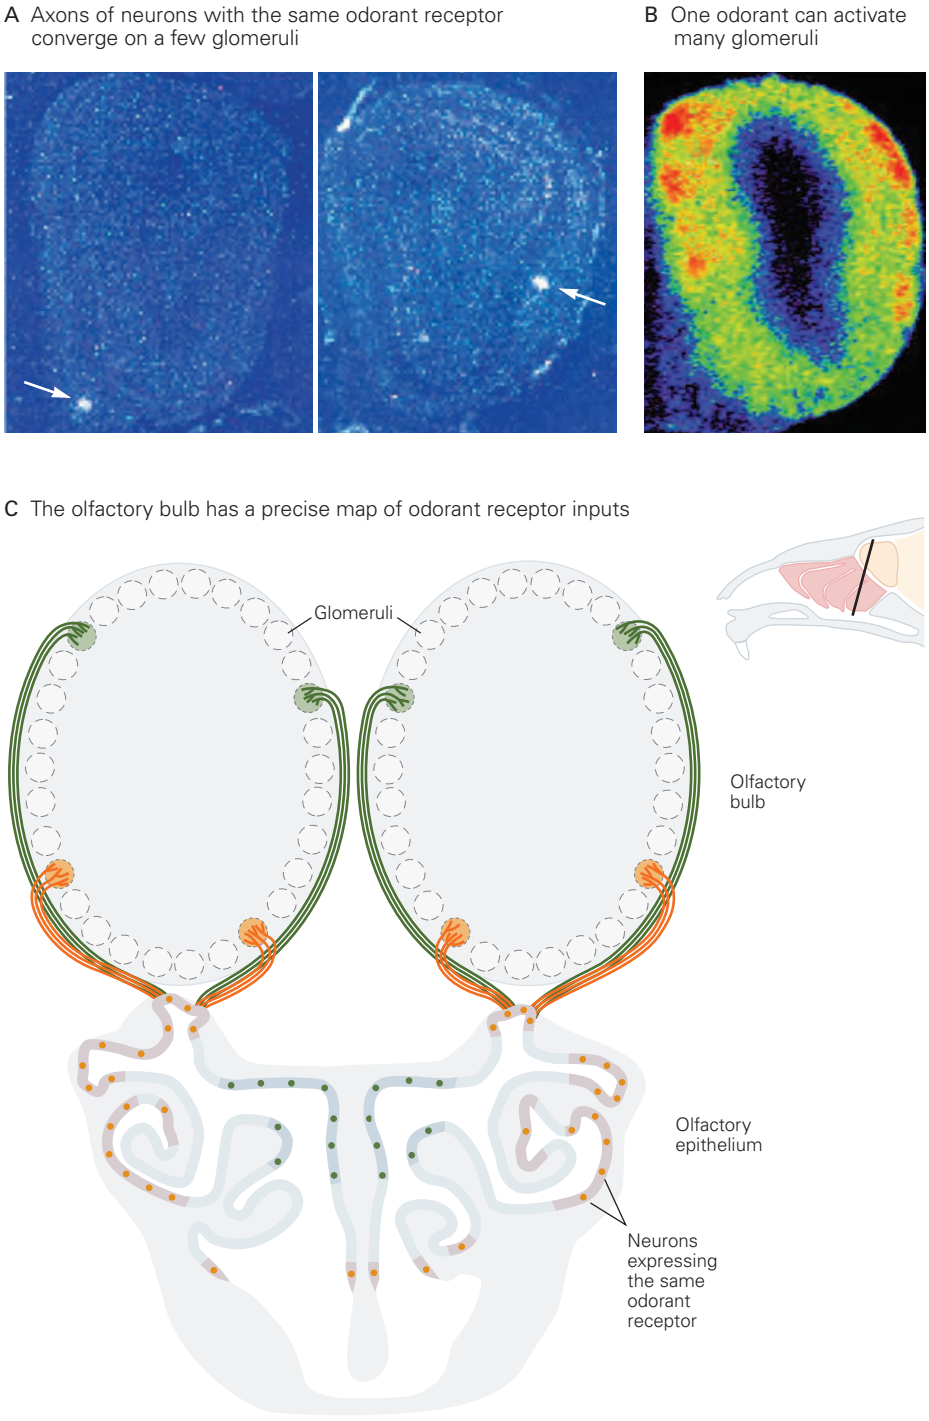

Figure 29–7 Odor responses in the olfactory bulb.

A. The axons of sensory neurons with the same odorant receptor type usually converge in only two glomeruli, one on each side of the olfactory bulb. Here, a probe specific for one odorant receptor gene labeled a glomerulus on the medial side (*left*) and lateral side (*right*) of a mouse olfactory bulb. The probe hybridized to receptor messenger RNAs present in sensory axons in these coronal sections. (Adapted, with permission, from Ressler, Sullivan, and Buck 1994.)

B. A single odorant often activates multiple glomeruli with input from different receptors. This section of a rat olfactory bulb shows the uptake of radiolabeled 2-deoxglucose at multiple foci (**red**) following exposure of the animal to the odorant methyl benzoate. The labeled foci correspond to numerous glomeruli at different locations in the olfactory bulb. (Reproduced, with permission, from Johnson, Farahbod, and Leon 2005. Copyright © 2005 Wiley-Liss, Inc.)

C. The olfactory bulb has a precise map of odorant receptor inputs because each glomerulus is dedicated to only one type of receptor. The maps in the two olfactory bulbs are bilaterally symmetrical and are nearly identical across individuals. The maps on the medial and lateral sides of each bulb are similar, but slightly displaced along the dorsal-ventral and anterior-posterior axes.

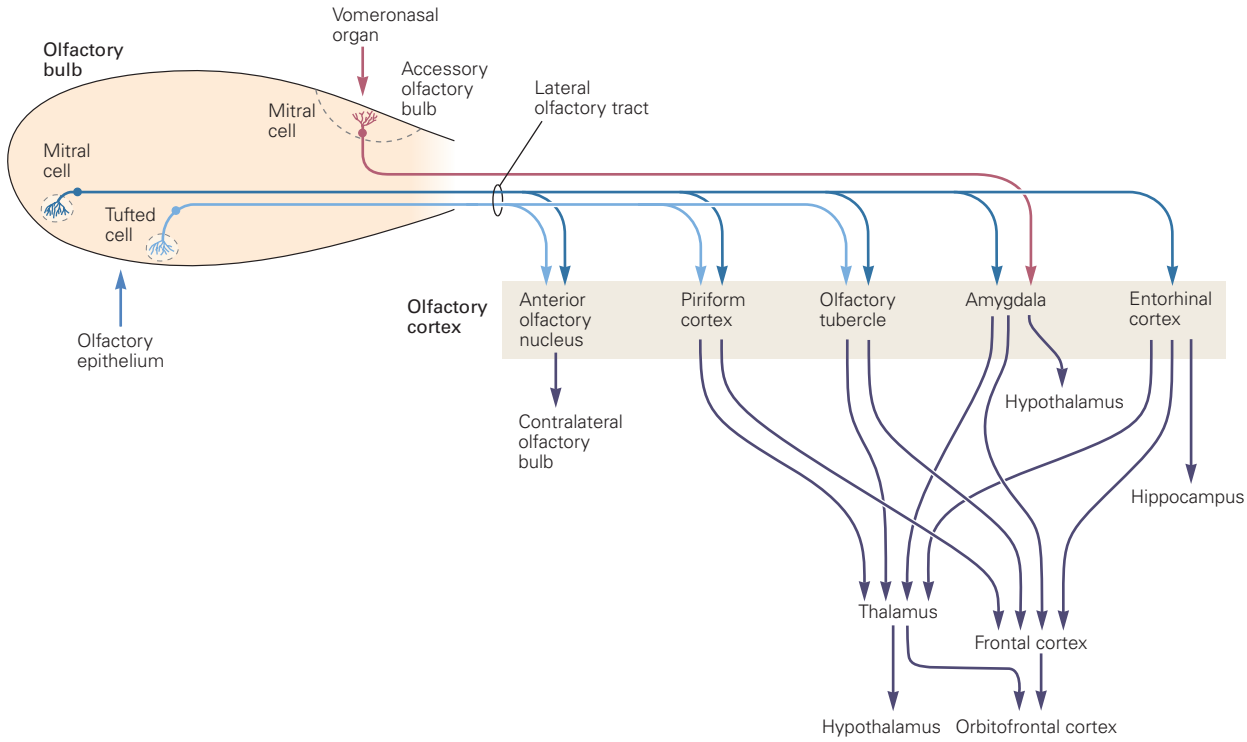

Figure 29–8 Afferent pathways to olfactory cortex. The axons of mitral and tufted relay neurons of the olfactory bulb project through the lateral olfactory tract to the olfactory cortex. The olfactory cortex consists of a number of distinct areas, the largest of which is the piriform cortex. From these areas, olfactory information is transmitted to other brain areas directly as well as indirectly via the thalamus. Targets include frontal and orbitofrontal areas of the neocortex, which are thought to be important for odor discrimination, and the amygdala and hypothalamus, which may be involved in emotional and physiological responses to odors. Mitral cells in the accessory olfactory bulb project to specific areas of the amygdala that transmit signals to the hypothalamus.

to form excitatory glutamatergic synapses with pyramidal neurons, the projection neurons of the cortex. Pyramidal neuron activity appears to be modulated by inhibitory inputs from local GABAergic interneurons as well as by excitatory inputs from other pyramidal neurons in the same and other olfactory cortical areas and the contralateral piriform cortex. The piriform cortex also receives centrifugal inputs from modulatory brain areas, suggesting that its activity may be adjusted according to physiological or behavioral state. Finally, the olfactory cortex projects to the olfactory bulb, providing yet another possible means of signal modulation.

As with the olfactory bulb relay neurons, individual pyramidal neurons can be activated by more than one odorant. However, the pyramidal neurons activated by a particular odorant are scattered across the piriform cortex, an arrangement different from that of the olfactory bulb. Mitral cells in different parts of the olfactory bulb can project axons to the same subregion of the piriform cortex, further indicating that the highly organized map of odorant receptor inputs in the olfactory bulb is not recapitulated in the cortex.

Output From the Olfactory Cortex Reaches Higher Cortical and Limbic Areas

Pyramidal neurons in the olfactory cortex transmit information indirectly to the orbitofrontal cortex through the thalamus and directly to the frontal cortex. These pathways to higher cortical areas are thought to be important in odor discrimination. In fact, people with lesions of the orbitofrontal cortex are unable to discriminate odors. Interestingly, recordings in the orbitofrontal cortex suggest that some individual neurons in that area receive multimodal input, responding, for example, to the smell, sight, or taste of a banana.

Many areas of the olfactory cortex also relay information to nonolfactory areas of the amygdala, which is linked to emotions, and to the hypothalamus, which controls basic drives, such as appetite, as well as a number of innate behaviors. These limbic areas are thought to play a role in the emotional and motivational aspects of smell as well as many of the behavioral and physiological effects of odorants. In animals, they may be important in the generation of

stereotyped behavioral and physiological responses to odors of predators or to pheromones that are detected in the olfactory epithelium.

Olfactory Acuity Varies in Humans

Olfactory acuity can vary as much as 1,000-fold among humans, even among people with no obvious abnormality. The most common olfactory aberration is *specific anosmia*. An individual with a specific anosmia has lowered sensitivity to a specific odorant even though sensitivity to other odorants appears normal. Specific anosmias to some odorants are common, with a few occurring in 1% to 20% of people. For example, 12% of individuals tested in one study exhibited a specific anosmia for musk. Recent studies indicate that specific anosmias can be caused by mutations in particular odorant receptor genes.

Far rarer abnormalities of olfaction, such as *general anosmia* (complete lack of olfactory sensation) or *hyposmia* (diminished sense of smell), are often transient and can derive from respiratory infections. Chronic anosmia or hyposmia can result from damage to the olfactory epithelium caused by infections; from particular diseases, such as Parkinson disease; or from head trauma that severs the olfactory nerves passing through holes in the cribriform plate, which then become blocked by scar tissue. Olfactory hallucinations of repugnant smells (*cacosmia*) can occur as a consequence of epileptic seizures.

Odors Elicit Characteristic Innate Behaviors

Pheromones Are Detected in Two Olfactory Structures

In many animals, the olfactory system detects not only odors but also pheromones, chemicals that are released from animals and influence the behavior or physiology of members of the same species. Pheromones play important roles in a variety of mammals, although they have not been demonstrated in humans. Often contained in urine or glandular secretions, some pheromones modulate the levels of reproductive hormones or stimulate sexual behavior or aggression. Pheromones are detected by two separate structures: the nasal olfactory epithelium, where odorants are detected, and the vomeronasal organ, an accessory olfactory organ thought to be specialized for the detection of pheromones and other animal cues.

The vomeronasal organ is present in many mammals, although not in humans. It is a tubular structure in the nasal septum that has a duct opening into the nasal cavity and one inner wall lined by a sensory epithelium. Signals generated by sensory neurons in the epithelium of the vomeronasal organ follow a distinct pathway. They travel through the accessory olfactory bulb primarily to the medial amygdala and posterior-medial cortical amygdala and from there to the hypothalamus.

Sensory detection in the vomeronasal organ differs from that in the olfactory epithelium. The vomeronasal organ has two different families of chemosensory receptors, the V1R and V2R families. In the mouse, each family has more than 100 members. Variation in amino acid sequence between members of each receptor family suggests that each family may recognize a variety of different ligands. Like odorant receptors, V1R and V2R receptors have the seven transmembrane domains typical of G protein–coupled receptors. The V2R receptor differs from both V1R and odorant receptors in having a large extracellular domain at the N-terminal end (Figure 29–9A). By analogy with receptors with similar structures, ligands may bind V1R receptors in a membrane pocket formed by a combination of transmembrane domains, whereas binding to V2R receptors may occur in the large extracellular domain. Although the V1R receptors are thought to recognize volatile chemicals, at least some V2Rs are thought to recognize proteins. These include a protein pheromone present in tears, mouse urinary proteins that stimulate aggression, and predator proteins from cats and rats that stimulate fear in mice.

The V1R and V2R families are expressed in different spatial zones in the vomeronasal organ that express different G proteins (Figure 29–9B,C). Each *V1R* or *V2R* gene is expressed in a small percentage of neurons scattered throughout one zone, an arrangement similar to that of odorant receptors in the olfactory epithelium. Similar to the main olfactory bulb, vomeronasal neurons with the same receptor type project to the same glomeruli in the accessory olfactory bulb, although the glomeruli for each receptor type are more numerous and their distribution less stereotyped than in the main olfactory bulb. In addition to V1R and V2R receptors, the vomeronasal organ has a family of five formyl peptide-related receptors (FPRs). These receptors are related to immune system FPRs that detect bacterial proteins, raising speculation that they might play a role in detecting diseased animals of the same species.

Invertebrate Olfactory Systems Can Be Used to Study Odor Coding and Behavior

Because invertebrates have simple nervous systems and often respond to olfactory stimuli with stereotyped

behaviors, they are useful for understanding the relationship between the neural representation of odor and behavior.

Certain features of chemosensory systems are highly conserved in evolution. First, all metazoan animals can detect a variety of organic molecules using specialized chemosensory neurons with cilia or microvilli that contact the external environment. Second, the initial events of odor detection are mediated by families of transmembrane receptors with specific expression patterns in peripheral sensory neurons. Other features of the olfactory system differ between species, reflecting selection pressures and evolutionary histories of the animals.

The primary sensory organs of insects are the antennae and appendages known as maxillary palps near the mouth (Figure 29–10A). Whereas mammals have millions of olfactory neurons, insects have a much smaller number. There are approximately 2,600 olfactory neurons in the fruit fly *Drosophila* and approximately 60,000 in the honeybee.

The insect odorant receptors were discovered by finding multigene receptor families in the *Drosophila* genome, and these genes have now been examined in other insect genomes as well. Remarkably, they have little similarity to mammalian odorant receptors save for the presence of many transmembrane domains. Indeed, insect receptors appear to have an independent evolutionary origin from mammalian receptors and may not even be G protein–coupled receptors—an extreme example of the fast evolutionary change observed across all olfactory receptor systems. In *Drosophila*, the main odorant receptor family has only 60 genes, rather than the hundreds characteristic of vertebrates. The malaria mosquito *Anopheles gambiae* and the honeybee have similar numbers (85–95 genes), whereas leaf-cutter ants have more than 350 odorant

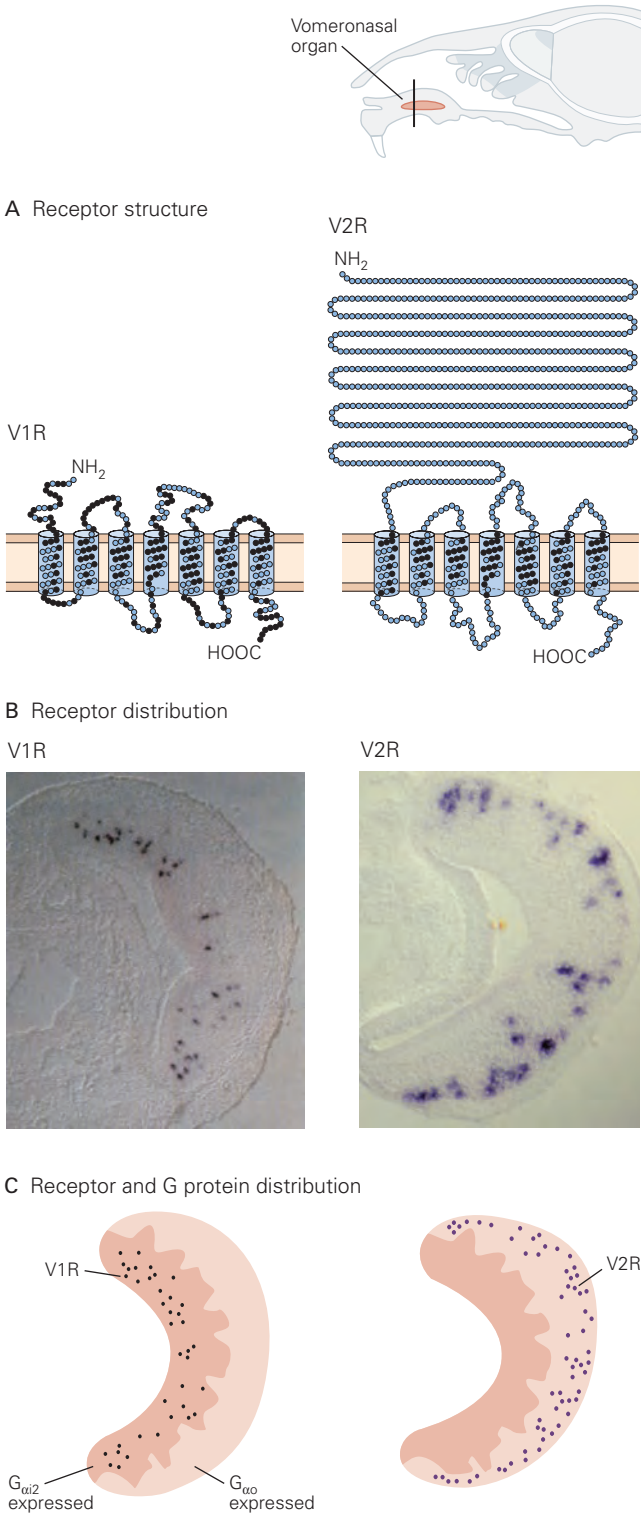

Figure 29–9 (Right) Candidate pheromone receptors in the vomeronasal organ.

A. The V1R and V2R families of receptors are expressed in the vomeronasal organ. In the mouse, each family has more than 100 members, which vary in protein sequence. Members of both families have the seven transmembrane domains of G protein–coupled receptors, but V2R receptors also have a large extracellular domain at the N-terminal end that may be the site of ligand binding.

B. Sections through the vomeronasal organ show individual V1R and V2R probes hybridized to subsets of neurons in two distinct zones. (Reproduced, with permission, from Dulac and Axel 1995; Matsunami and Buck 1997.)

C. The two zones express high levels of different G proteins, $G\alpha_{\alpha i2}$ and $G\alpha_{\alpha o}$.

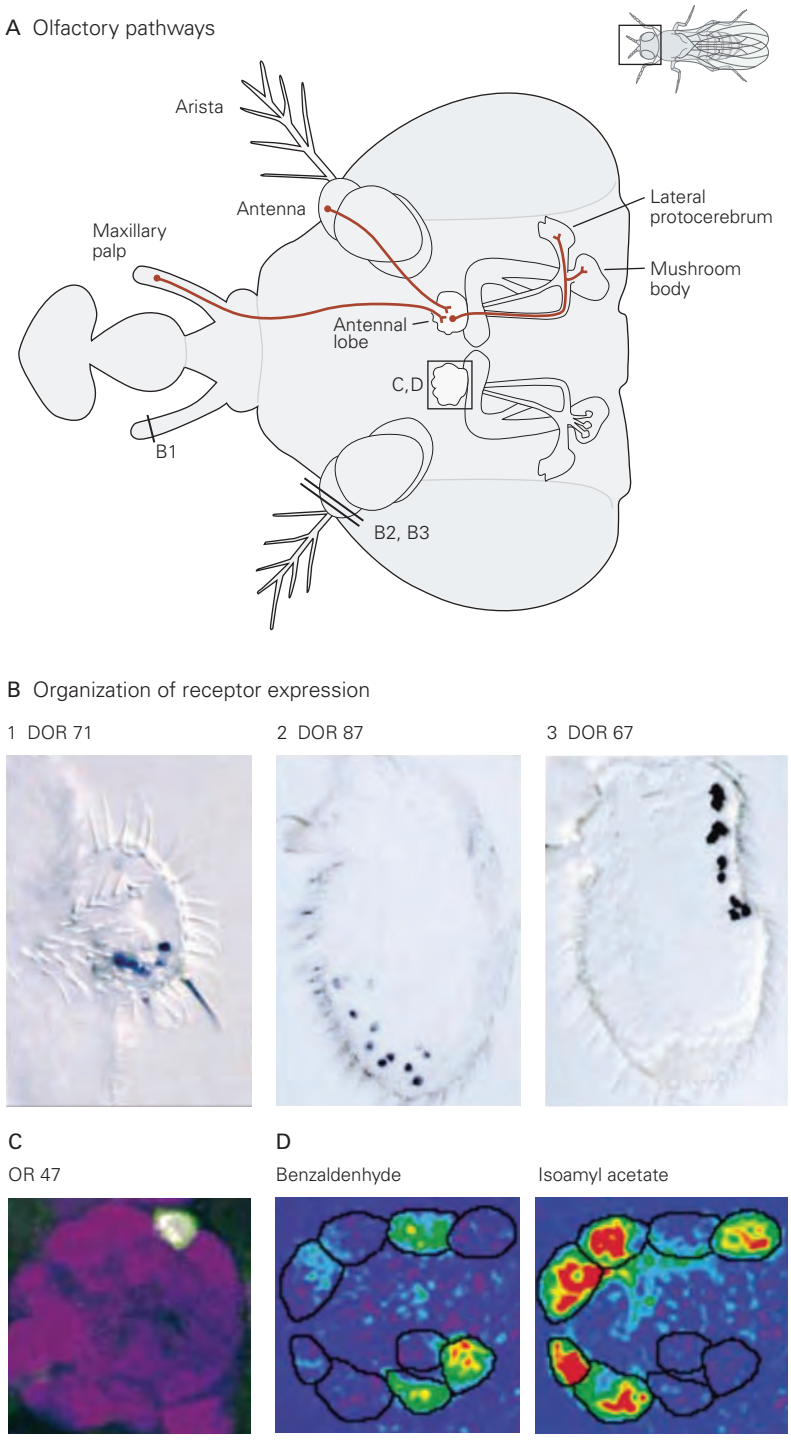

Figure 29–10 Olfactory pathways from the antenna to the brain in *Drosophila*.

A. The axons of olfactory neurons with cell bodies and dendrites in the antenna and maxillary palp project axons to the antennal lobe. Projection neurons in the antennal lobe then project to two regions of the fly brain, the mushroom body and lateral protocerebrum. (Reproduced, with permission, from Takaki Komiyama and Liqun Luo.)

B. The neurons that express one type of olfactory receptor gene, detected by RNA in situ hybridization, are scattered in the maxillary palp (**1**) or antenna (**2**, **3**).

C. All neurons that express the olfactory receptor gene *OR47* converge on a glomerulus in the antennal lobe. (Reproduced, with permission, from Vosshall et al. 1999; Vosshall, Wong, and Axel 2000.)

D. Each odorant elicits a physiological response from a subset of glomeruli in the antennal lobe. Two-photon calcium imaging was used to detect odor-evoked signals. (Reproduced, with permission, from Wang et al. 2003. Copyright © 2003 Elsevier.)

receptor genes, suggesting a wide variation in receptor number in insects.

Despite molecular differences in receptors, the anatomical organization of the fly's olfactory system is quite similar to that of vertebrates. Each olfactory neuron expresses one or sometimes two functional odorant receptor genes. The neurons expressing a particular gene are loosely localized to a region of the antenna but interspersed with neurons expressing other genes (Figure 29–10B). This scattered distribution is

not the case at the next level of organization, the antennal lobe. Axons from sensory neurons that express one type of receptor converge on two invariant glomeruli in the antennal lobe, one each on the left and right sides of the animal (Figure 29–10C). This organization is strikingly similar to that of the first sensory relay in the vertebrate olfactory bulb and is also found in the moth, honeybee, and other insects.

Because there are only a few dozen receptor genes in *Drosophila*, it is possible to characterize the entire repertory of odorant-receptor interactions, a goal that is not yet attainable in mammals. Sophisticated genetic methods can be used to label and record from a *Drosophila* neuron expressing a single known odorant receptor gene. By repeating this experiment with many receptors and odors, the receptive fields of the odorant receptors have been defined and shown to be quite diverse.

In insects, individual odorant receptors can detect large numbers of odorants, including odorants with very different chemical structures. This broad recognition of odorants by "generalist" receptors is necessary if only a small number of receptors is available to detect all biologically significant odorants. A single insect receptor protein that detects many odors can be stimulated by some odors and inhibited by others, often with distinct temporal patterns. A subset of insect odorant receptors that convey information about pheromones or other unusual odors like carbon dioxide are more selective. Thus, the coding potential of each olfactory neuron can be broad or narrow and arises from a combination of stimulatory and inhibitory signals delivered to its receptors.

Information from the olfactory neurons is relayed to the antennal lobe where sensory neurons expressing the same odorant receptor converge onto a small number of projection neurons in one glomerulus (Figure 29–10A). Because *Drosophila* glomeruli are stereotyped in position and have one type of odorant receptor input, the transformation of information across the synapse can be described. Convergence of many olfactory sensory axons onto a few projection neurons leads to a great increase in the signal-to-noise ratio of olfactory signals, so projection neurons are much more sensitive to odor than individual olfactory neurons. Within the antennal lobe, excitatory interneurons distribute signals to projection neurons at distal locations, and inhibitory interneurons feed back onto the olfactory sensory neurons to dampen their input. Thus, while activity of an individual olfactory neuron is conveyed to one glomerulus. its activity is also distributed across the entire antennal lobe, as it is processed by excitatory and inhibitory local interneurons that connect many glomeruli.

The projection neurons from the antennal lobe extend to higher brain centers called mushroom bodies and lateral protocerebrum (Figure 29–10A). These structures may represent insect equivalents of the olfactory cortex. The mushroom bodies are sites of olfactory associative learning and multimodal associative learning; the lateral protocerebrum is important for innate olfactory responses. At this stage, projection neurons form complex connections with a large number of downstream neurons. Neurons in higher brain centers in *Drosophila* have the potential to integrate information from many receptors.

Olfactory Cues Elicit Stereotyped Behaviors and Physiological Responses in the Nematode

The nematode roundworm *Caenorhabditis elegans* has one of the simplest nervous systems in the animal kingdom, with only 302 neurons in the entire animal. Of these, 32 are ciliated chemosensory neurons. Because *C. elegans* has strong behavioral responses to a wide variety of chemicals, it has been a useful experimental animal for relating olfactory signals to behavior. Each chemosensory neuron detects a specific set of chemicals, and activation of the neuron is required for the behavioral responses to those substances. The neuron for a particular response, such as attraction to a specific odor, occurs in the same position in all individuals.

The molecular mechanisms of olfaction in *C. elegans* were elucidated through genetic screens for mutant worms lacking the ability to detect odors (anosmia). The G protein–coupled receptor for the volatile odorant diacetyl emerged from these screens (Figure 29–11). This receptor is one of approximately 1,700 predicted G protein–coupled chemoreceptor genes in *C. elegans*, the largest number of chemoreceptors among known genomes. Other kinds of chemosensory receptors are also present; for example, *C. elegans* senses external oxygen levels indirectly by detecting soluble guanylate cyclases that bind directly to oxygen. With so many chemoreceptors, nematodes are able to recognize a large variety of odors with great sensitivity. Some chemosensory neurons use G proteins to regulate cyclic guanosine 3′,5′-monophosphate (cGMP) and a cGMP-gated channel, a signal transduction pathway like that of vertebrate photoreceptors. Other chemosensory neurons signal through a transient receptor potential vanilloid (TRPV) channel, like vertebrate nociceptive neurons.

The "one neuron, one receptor" principle observed in vertebrates and insects does not operate in nematodes because the number of neurons is much smaller

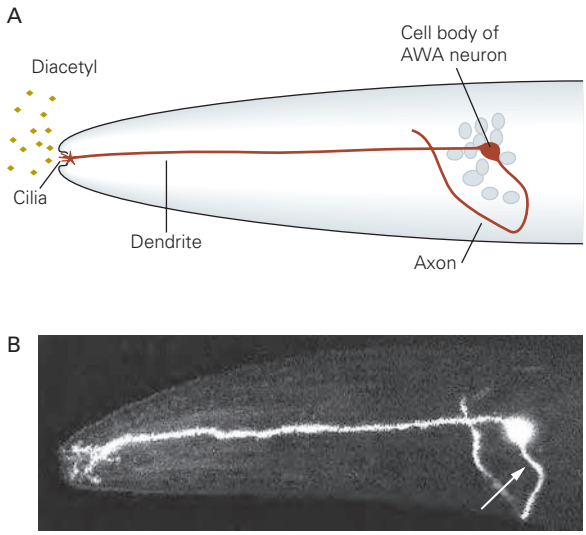

Figure 29–11 The receptor for diacetyl in the *Caenorhabditis elegans* worm.

A. A lateral view of the worm's anterior end shows the cell body and processes of the AWA chemosensory neuron. A dendrite terminates in cilia that are exposed to environmental chemicals. The neuron detects the volatile chemical diacetyl; animals with a mutation in the *odr-10* gene are unable to sense diacetyl.

B. The *odr-10* gene is active only in the AWA neurons. The micrograph here shows the gene product marked with fusion to a fluorescent reporter protein; the **arrow** indicates the neuron's axon. (Reproduced, with permission, from Sarafi-Reinach and Sengupta 2000.)

than the number of receptors. Each chemoreceptor gene is typically expressed in only one pair of chemosensory neurons, but each neuron expresses many receptor genes. The small size of the *C. elegans* nervous system limits olfactory computations. For example, a single neuron responds to many odors, but odors can be distinguished efficiently only if they are sensed by different primary sensory neurons.

The relationship between odor detection and behavior has been explored in *C. elegans* through genetic manipulations. For example, diacetyl is normally attractive to worms, but when the diacetyl receptor is experimentally expressed in an olfactory neuron that normally senses repellents, the animals are instead repelled by diacetyl. This observation indicates that specific sensory neurons encode the hardwired behavioral responses of attraction or repulsion and that a "labeled line" connects specific odors to specific behaviors. Similar ideas have emerged from genetic manipulations of taste systems in mice and flies, where sweet and bitter preference pathways are encoded by different sets of sensory cells.

Olfactory cues are linked to physiological responses as well as behavioral responses in nematodes. Food and pheromone cues that regulate development are detected by specific sensory neurons through G protein–coupled receptors. With low pheromone levels and plentiful food, animals rapidly develop to adulthood, whereas with high pheromone levels and scarce food, animals arrest in a long-lived larval stage called *dauer larvae* (Figure 29–12). Activation of these sensory neurons ultimately regulates the activity of an insulin signaling pathway that controls physiology and growth as well as the life span of the nematode. It is an open question whether the chemosensory systems and physiological systems of other animals are as entangled as they are in nematodes.

Strategies for Olfaction Have Evolved Rapidly

Why have independent families of odorant receptors evolved in mammals, nematodes, and insects? And why have the families changed so rapidly compared to genes involved in other important biological processes? The answer lies in a fundamental difference between olfaction and other senses such as vision, touch, and hearing.

Most senses are designed to detect physical entities with reliable physical properties: photons, pressure, or sound waves. By contrast, olfactory systems are designed to detect organic molecules that are infinitely variable and do not fit into a simple continuum of properties. Moreover, the organic molecules that are detected are produced by other living organisms, which evolve far more rapidly than the world of light, pressure, and sound.

An ancient olfactory system was present in the common ancestor of all animals that exist today. That ancestor lived in the ocean, where it gave rise to different lineages for mammals, insects, and nematodes. Those three phyla of animals came onto land hundreds of millions of years after the phyla diverged. Each phylum independently modified its olfactory system to detect airborne odors, leading to diversification of the receptors.

A consideration of the natural history of dipteran and hymenopteran insects, which have evolved in the last 200 million years, helps explain the rapid diversification of the odorant receptors. These insects include honeybees that pollinate flowers, fruit flies that feed on rotting fruit, flesh flies that arrive within minutes of death, and mosquitoes that prey on living animals. The odorants important for the survival of these insects are radically different, and receptor genes tuned to those odorants have evolved accordingly.

Figure 29–12 Chemosensory cues regulate the development of *C. elegans*. When exposed to different chemosensory cues, two larvae of the same age follow different development paths. A dauer larva, which forms under stressful conditions of low food and high population density, develops into a small slender adult (*left*). It is a nonfeeding, nonreproducing, stress-resistant form of the worm. In contrast, a larva in a rich environment favoring reproductive growth develops into a normal adult (*right*). The Gustatory System Controls the Sense of Taste

Taste Has Five Submodalities That Reflect Essential Dietary Requirements

The gustatory system is a specialized chemosensory system dedicated to evaluating potential food sources. It is the only sensory system that detects sugars and harmful compounds present in foods, and it serves as a main driver of feeding decisions. Unlike the olfactory system, which distinguishes millions of odors, the gustatory system recognizes just a few taste categories.

Humans and other mammals can distinguish five basic taste qualities: sweet, bitter, salty, sour, and umami, a Japanese word meaning delicious and associated with the "savory" taste of amino acids. This limited palate detects all essential dietary requirements of animals: A sweet taste invites consumption of energy-rich foods; bitter taste warns against the ingestion of toxic, noxious chemicals; salty taste promotes a diet that maintains proper electrolyte balance; sour taste signals acidic, unripened, or fermented foods; and umami indicates protein-rich foods.

Consistent with the nutritional importance of carbohydrates and proteins, both sweet and umami tastants elicit innately pleasurable sensations in humans and are attractants for animals in general. In contrast, bitter and sour tastants elicit innately aversive responses in humans and animals.

Taste is often thought to be synonymous with flavor. However, taste refers strictly to the five qualities encoded in the gustatory system, whereas flavor, with its rich and varied qualities, stems from the multisensory integration of inputs from the gustatory, olfactory, and somatosensory systems (eg, texture and temperature).

Tastant Detection Occurs in Taste Buds

Tastants are detected by taste receptor cells clustered in taste buds. Although the majority of taste buds in

humans are located on the tongue surface, some can also be found on the palate, pharynx, epiglottis, and upper third of the esophagus.

Taste buds on the tongue occur in structures called papillae, of which there are three types based on morphology and location. *Fungiform papillae*, located on the anterior two-thirds of the tongue, are peg-like structures that are topped with taste buds. Both the *foliate papillae*, situated on the posterior edge of the tongue, and the *circumvallate papillae*, of which there are only a few in the posterior area of the tongue, are structures surrounded by grooves lined with taste buds (Figure 29–13A). In humans, each fungiform papilla contains one to five taste buds, whereas each foliate and circumvallate papilla may contain hundreds to thousands of taste buds, respectively.

The taste bud is a garlic-shaped structure embedded in the epithelium. A small opening at the epithelial surface, the taste pore, is the point of contact with tastants (Figure 29–13B). Each taste bud contains approximately 100 taste receptor cells (taste cells), elongated cells that stretch from the taste pore to the basal area of the bud. The taste bud also contains other elongated cells that are thought to serve a supporting function, as well as a small number of round cells at the base, which are thought to serve as stem cells. Each taste cell extends microvilli into the taste pore, allowing the cell to contact chemicals dissolved in saliva at the epithelial surface.

At its basal end, the taste cell contacts the afferent fibers of gustatory sensory neurons, whose cell bodies reside in specific sensory ganglia (see Figure 29–17). Although taste cells are nonneural, their contacts with the gustatory sensory neurons have the morphological characteristics of chemical synapses, including clustered presynaptic vesicles. Taste cells also resemble neurons in that they are electrically excitable; they have voltage-gated Na^+, K^+, and Ca^{2+} channels and are capable of generating action potentials. Taste cells are very short-lived (days to weeks) and are continually replaced from the stem cell population. This turnover requires that newborn taste cells differentiate to detect one of the five taste qualities and connect to the terminals of appropriate gustatory sensory neurons, such that a sweet taste cell connects to sweet sensory neurons and a bitter taste cell to bitter sensory neurons.

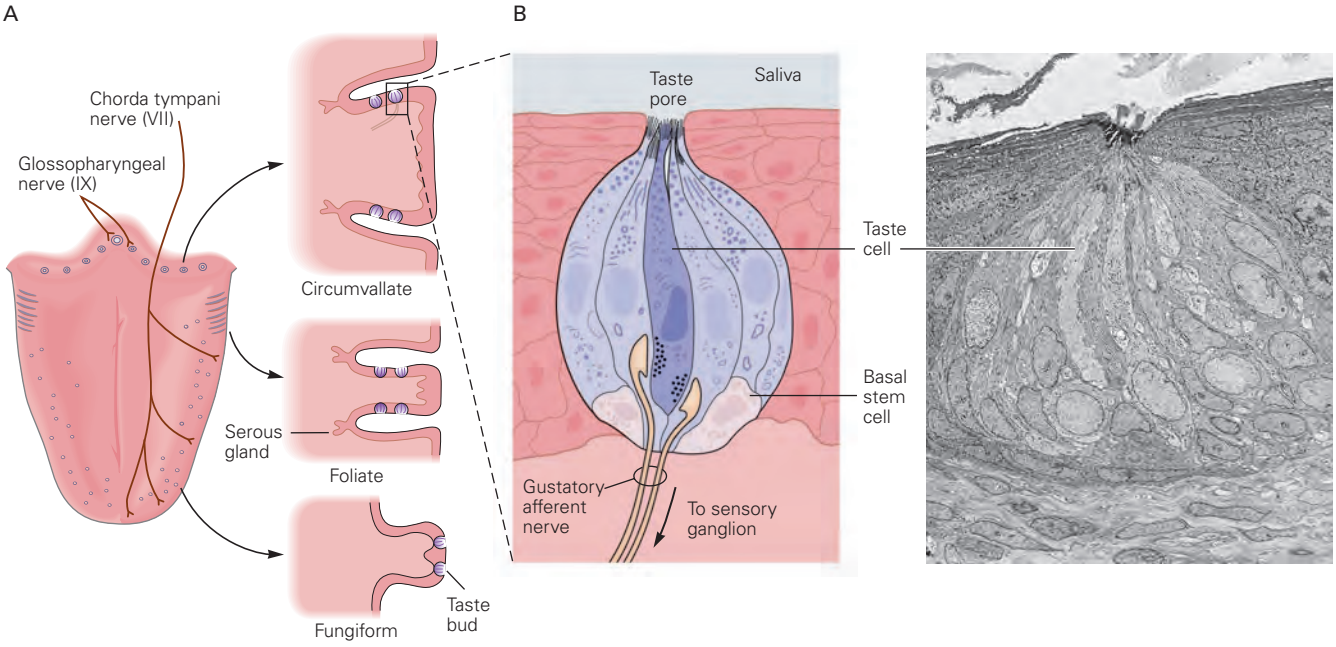

Figure 29–13 Taste buds are clustered in papillae on the tongue.

A. The three types of papillae—circumvallate, foliate, and fungiform—differ in morphology and location on the tongue and are differentially innervated by the chorda tympani and glossopharyngeal nerves.

B. Each taste bud contains 50 to 150 elongated taste receptor cells, as well as supporting cells and a small population of basal stem cells. The taste cell extends microvilli into the taste pore, allowing it to detect tastants dissolved in saliva. At its basal end, the taste cell contacts gustatory sensory neurons that transmit stimulus signals to the brain. The scanning electron micrograph shows a taste bud in a foliate papilla in a rabbit. Each Taste Modality Is Detected by Distinct Sensory Receptors and Cells

The five taste qualities are detected by sensory receptors in the microvilli of different taste cells. There are two general types of receptors: Bitter, sweet, and umami tastants interact with G protein–coupled receptors, whereas salty and sour tastants interact directly with specific ion channels (Figure 29–14). These interactions depolarize the taste cell, leading to the generation of action potentials in the afferent gustatory fibers.

Sweet Taste Receptor

Compounds that humans perceive as sweet include sugars, artificial sweeteners such as saccharin and aspartame, a few proteins such as monellin and thaumatin, and several D-amino acids. All of these sweet-tasting compounds are detected by a heteromeric receptor composed of two members of the T1R taste receptor family, T1R2 and T1R3 (Figure 29–15). The T1R receptors are a small family of three related G protein–coupled receptors that participate in sweet and umami detection.

Receptors of the TIR family have a large N-terminal extracellular domain (Figure 29–14) that serves as the main ligand-binding domain, similar to the V2R receptor of vomeronasal neurons. This domain recognizes many different sugars with low-affinity binding in the millimolar range. This ensures that only high sugar concentrations of nutritive value are detected. Changing a single amino acid in this domain in mice can alter an animal's sensitivity to sweet compounds. Indeed, T1R3 was initially discovered by examining genes at the mouse saccharin preference (Sac) locus, a chromosomal region that governs sensitivity to saccharin, sucrose, and other sweet compounds.

In mice, taste cells with T1R2 receptors are found mostly in palate, foliate, and circumvallate papillae; almost invariably, those cells also possess T1R3 receptors (Figure 29–16A). Gene knockout experiments in mice indicate that the T1R2/T1R3 complex mediates

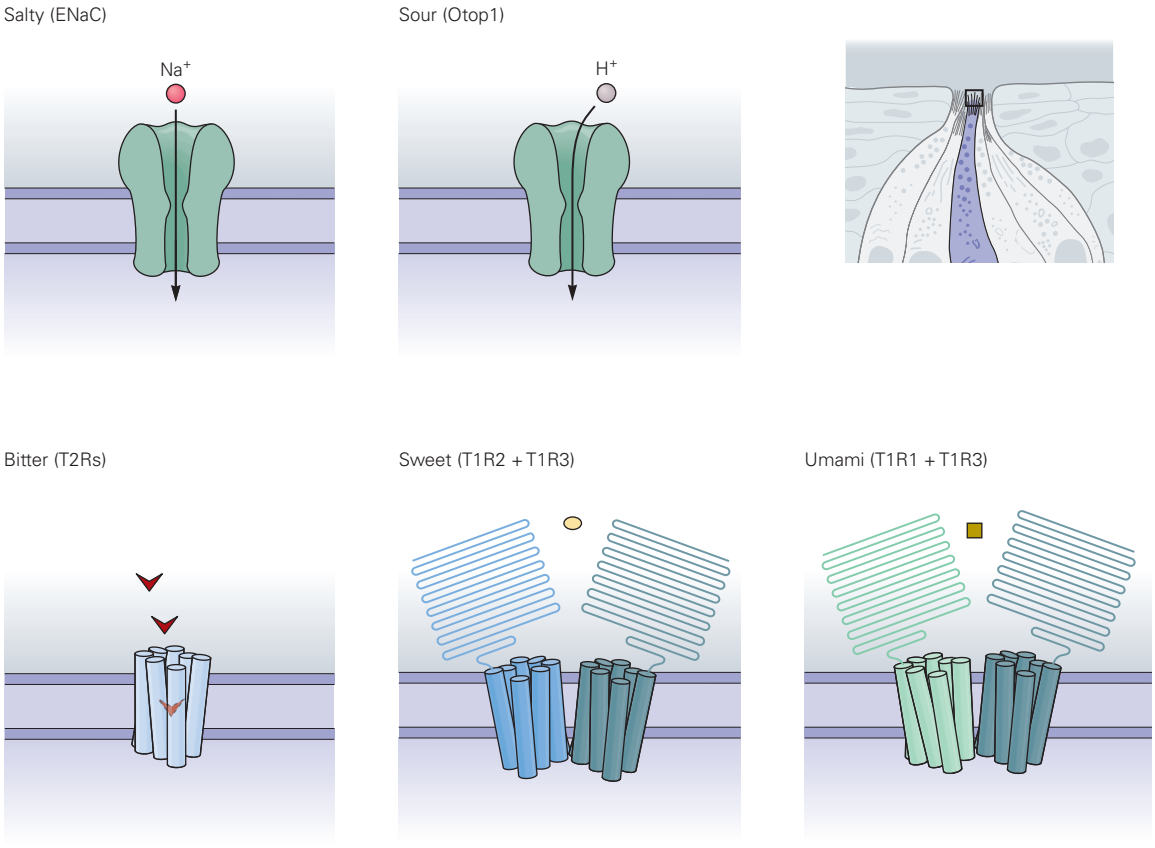

Figure 29–14 Sensory transduction in taste cells. Different taste qualities involve different detection mechanisms in the apical microvilli of taste cells (see Figure 29–13B). Salty and sour tastants directly activate ion channels, whereas tastants perceived as bitter, sweet, or umami activate G protein–coupled receptors. Bitter tastants are detected by T2R receptors, whereas sweet tastants are detected by a combination of T1R2 and T1R3, and umami tastants by a combination of T1R1 and T1R3.

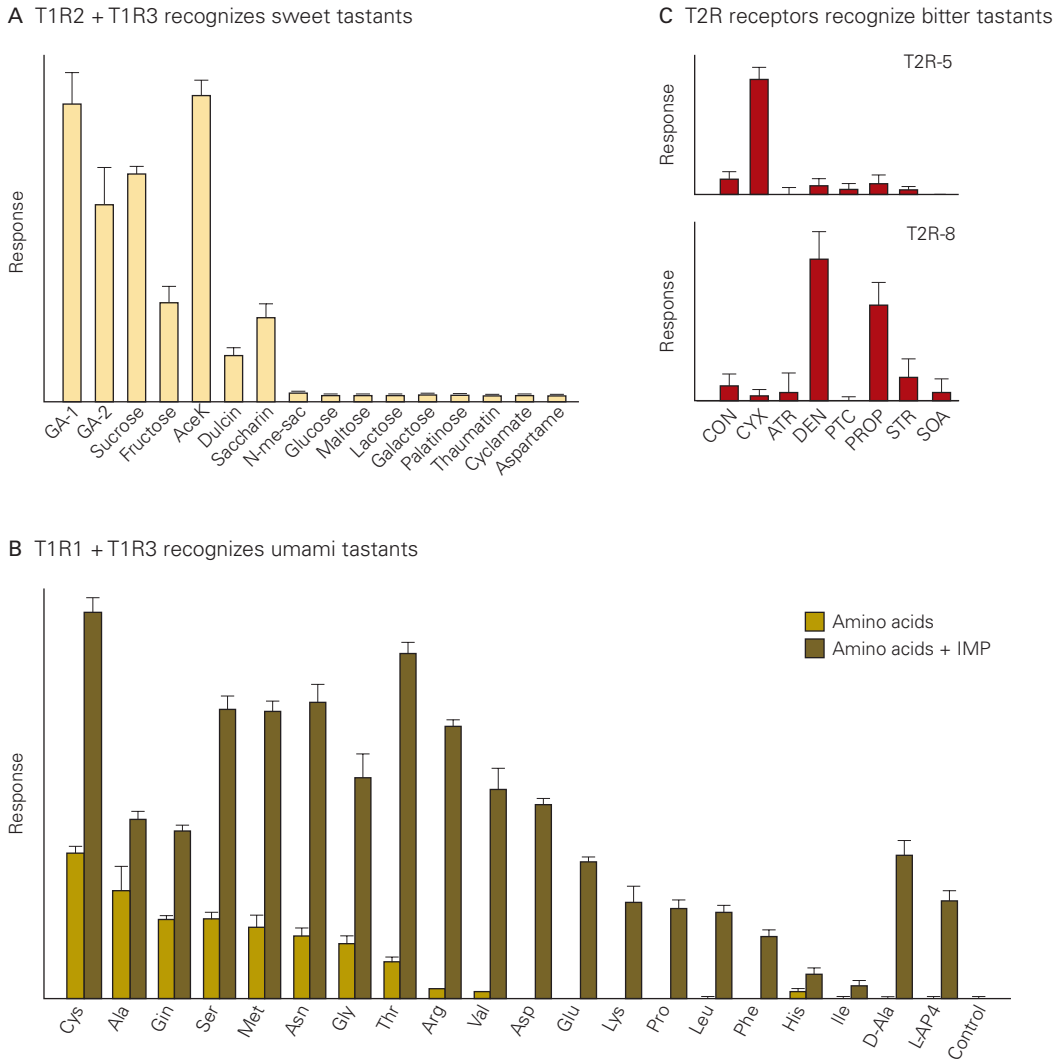

Figure 29–15 Tastants recognized by T1R and T2R receptors. A calcium-sensitive dye was used to test whether T1R and T2R receptors expressed in a tissue culture cell line could detect tastants.

A. Cells expressing both rat T1R2 and rat T1R3 responded to a number of sweet compounds. (Reproduced, with permission, from Nelson et al. 2001.)

B. Cells expressing mouse T1R1 and mouse T1R3 responded to numerous L-amino acids (umami taste). Responses were potentiated by inosine monophosphate (**IMP**). (Reproduced, with permission, from Nelson et al. 2002. Copyright © 2002 Springer Nature.)

C. Cells expressing different T2R receptors responded selectively to different bitter compounds. Cells expressing mouse T2R5 responded most vigorously to cycloheximide (**CYX**), whereas cells expressing mouse T2R8 responded preferentially to denatonium (**DEN**) and 6-n-propyl-2-thiouracil (**PROP**). (**ATR**, atropine; **CON**, control; **PTC**, phenyl thiocarbamide; **SOA**, sucrose octaacetate; **STR**, strychnine.) (Reproduced, with permission, from Chandrashekar et al. 2000.)

the detection of all sweet compounds except for high concentrations of sugars, which may also be detected by T1R3 alone.

Umami Taste Receptor

Umami is the name given to the savory taste of monosodium glutamate, an amino acid widely used as a flavor enhancer. It is believed that the pleasurable sensation associated with umami taste encourages the ingestion of proteins and is thus evolutionarily important for nutrition.

The receptor for umami taste is a complex of two T1R receptor subunits: T1R1, specific to the umami receptor, and T1R3, present in both sugar and umami receptors (Figure 29–14). In mice, the T1R1/T1R3

complex can interact with all L-amino acids (Figure 29–15B), but in humans it is preferentially activated by glutamate. Purine nucleotides, such as inosine 5′-monophosphate (IMP), are often added to monosodium glutamate to enhance its pleasurable umami taste. Interestingly, in vitro studies demonstrated that IMP potentiates the responsiveness of T1R1/T1R3 to L-amino acids, acting as a strong positive allosteric modulator of the receptor (Figure 29–15B).

Taste cells with both T1R1 and T1R3 are concentrated in fungiform papillae (Figure 29–16A). Studies in genetically engineered mice in which individual T1R genes have been deleted indicate that the T1R1/T1R3 complex is solely responsible for umami taste, whereas T1R2/T1R3 is solely responsible for sweet taste. As expected, a genetic knockout of T1R1 selectively abolishes umami taste, a knockout of T1R2 specifically abolishes sweet taste, while a knockout of T1R3 eliminates both sweet and umami taste (exactly as predicted, given that it is a common subunit of both the umami and sweet taste receptors).

Sweet and umami receptors differ significantly among different species. Most interestingly, different T1R subunits have been lost in some species, likely reflecting their evolutionary niche and diet. For example, the giant panda, which feeds almost exclusively on a bamboo diet, lacks a functional umami receptor. On the other hand, domestic cats, tigers, and cheetahs do not have a functional sweet receptor, whereas vampire bats that feed on a blood diet have mutations that have eliminated both sweet and umami functional receptors.

Bitter Taste Receptor

Bitter taste is thought to have evolved as an aversive signal of toxic molecules. Bitter taste sensation is elicited by a variety of compounds, including caffeine, nicotine, alkaloids, and denatonium, the most bitter-tasting chemical known (this compound is sometimes added to toxic products that are odorless and tasteless to prevent their ingestion).

Bitter tastants are detected by a family of approximately 30 G protein–coupled receptors called

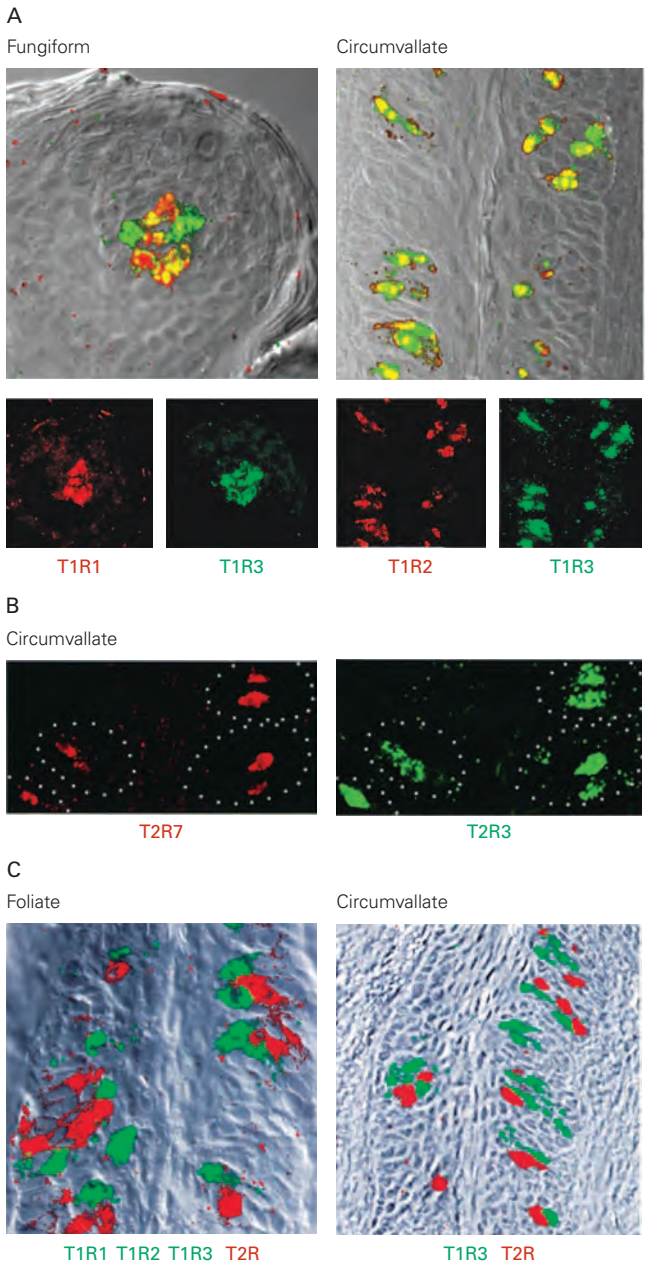

Figure 29–16 (Right) Expression of T1R and T2R receptors on the tongue. Sections of mouse or rat tongue were hybridized to probes that label T1R or T2R mRNAs to detect their sites of expression in taste cells.

A. The T1R3 receptor is expressed in taste cells of all three types of papillae. However, T1R1 is found mostly in fungiform papillae, whereas T1R2 is located predominantly in circumvallate (and foliate) papillae. Overlap between sites of expression appears as yellow cells in the micrographs at the top. The T1R1-T1R3 umami receptor is more frequently found in fungiform papillae, whereas the T1R2-T1R3 sweet receptor is more frequently found in circumvallate and foliate papillae. (Reproduced, with permission, from Nelson et al. 2001.)

B. A taste cell that detects bitter tastants can express several variants of T2R receptors. Here, probes for T2R3 and T2R7 labeled the same taste cells in circumvallate papillae. (Reproduced, with permission, from Adler et al. 2000.)

C. The T1R and T2R receptors are expressed in different taste cells. Taste cells labeled by a T1R3 probe or mixed T1R probes (**green**) did not overlap with cells labeled by a mixture of T2R probes (**red**). (Reproduced, with permission, from Nelson et al. 2001.)

T2Rs (Figure 29–14). However, different animal species contain different numbers of bitter receptors (varying from just a handful in the chicken genome to over 50 in the western clawed frog; humans have 28 T2R genes). These receptors recognize bitter compounds that have diverse chemical structures, with each T2R tuned to detect a small number of bitter compounds (Figure 29–15C). The T2R receptors recognize chemicals with high-affinity binding in the micromolar range, allowing detection of minute quantities of harmful compounds. A single taste cell expresses many, probably most, types of T2R receptors (Figure 29–16B). This arrangement implies that information about different bitter tastants is integrated in individual taste cells. Because different bitter compounds are detected by the same cells, all these compounds elicit the same perceptual bitter taste quality. The degree of bitterness might be caused by a compound's effectiveness in activating bitter taste cells.

Interestingly, genetic differences in the ability to perceive specific bitter compounds have been identified in both humans and mice. For example, humans are either super-tasters, tasters, or taste-blind to the bitter chemical 6-n-propylthiouracil. It was by mapping variation in this trait to specific chromosomal loci, and then by searching for novel G protein–coupled receptor genes within that chromosomal interval, that the T2R receptors were first identified. In the case of 6-n-propylthiouracil detection, the gene responsible for the genetic difference has proven to be a particular T2R gene. Thus, some bitter compounds may be recognized predominantly by only one of the approximately 30 T2R receptor types.

Taste cells expressing T2R receptors are found in both foliate and circumvallate papillae in mice (Figure 29–16C). A given taste cell expresses either T2R or T1R receptors (ie, one taste cell–one receptor class), but a single taste bud can contain taste cells of all types (eg, sweet, umami, bitter). Such mixing of cells accords with the observation that a single taste bud can be activated by more than one class of tastant; for example, sweet as well as bitter.

Salty Taste Receptor

Salt intake is critical to maintaining electrolyte balance. Perhaps because electrolytes must be maintained within a stringent range, the behavioral response to salt is concentration dependent: Low salt concentrations are appetitive, whereas high salt concentrations are aversive. How does the response to salt change based on concentration? It turns out that multiple taste cells detect salt. The essential salt taste receptor cell uses the epithelial sodium channel ENaC (see Figure 29–14). These specialized salt taste receptors are distinct from sweet, bitter, or umami receptors. At much higher salt concentrations, some bitter and sour taste cells also respond to salt, although the molecular details of detection have not been determined. Therefore, appetitive concentrations of salt drive responses via the ENaC salt taste receptor in the salt-sensing cells, whereas high salt concentrations activate the bitter and sour cells and thus trigger behavioral aversion.

Sour Taste Receptor

Sour taste is associated with acidic or fermented foods or drink. As with bitter compounds, animals are innately averse to sour substances, suggesting that the adaptive advantage of sour taste is avoidance of spoiled foods. Sour, like the other 4 taste qualities, is also detected by its own type of taste receptor cells (Figure 29–14). The ion channel Otopetrin-1 (Otop1), a proton-selective channel normally involved in the sensation of gravity in the vestibular system, is the sour-sensing ion channel in the taste system. As expected, a knockout of Otop1 in mice eliminated acid responses from sour taste receptor cells. Furthermore, mice engineered to express Otop1 in sweet taste receptor cells now have sweet cells that also respond to sour stimuli, demonstrating that this channel is sufficient to confer acid sensing.

Molecular-genetic studies have demonstrated that the different taste modalities are detected by distinct subsets of taste cells. As we have seen, a combination of T1R1 and T1R3 is responsible for all umami taste, and a combination of T1R2 and T1R3 is needed for all sweet taste detection except for the detection of high concentrations of sugars, which can be mediated by T1R3 alone. The T1R1 and T1R2 receptors are expressed by separate subsets of taste cells, indicating that the detection of sweet and umami tastants is segregated. Similarly, receptors and molecular markers uniquely define bitter, low salt, and sour taste cells.

A dramatic demonstration that each taste quality is detected by a different category of taste cells comes from studies of mice lacking a specific taste receptor gene or cell type. These studies showed that the loss of one taste modality did not affect the others. For example, mice in which sweet cells have been genetically ablated do not detect sugars but still detect amino acids, bitter compounds, salts, and sour compounds. Similarly, mice engineered to lack specific taste receptors cannot detect the corresponding tastants. For instance, mice lacking selective bitter receptors are not responsive to the corresponding bitter tastants,

and mice lacking ENaC cannot detect the taste of salt. These types of studies have shown that different tastes are detected by different receptors expressed in different classes of taste cells that drive specific behaviors.

Studies in mice further indicate that it is the taste cells rather than the receptors that determine the animal's response to a tastant. The human bitter receptor T2R16 recognizes a bitter tastant that mice cannot detect. When this receptor was expressed in mouse taste cells that normally express T2R bitter receptors, the ligand caused strong taste aversion. However, when that receptor was expressed in cells that express the T1R2/T1R3 sweet complex (ie, sweet cells), the bitter ligand elicited strong taste acceptance. These findings showed that innate responses of mice to different tastants (sweet and bitter in this example) operate via labeled lines that link the activation of different subsets of taste cells to different behavioral outcomes.

Gustatory Information Is Relayed From the Periphery to the Gustatory Cortex

Each taste cell is innervated at its base by the peripheral branches of the axons of primary sensory neurons (Figure 29–13). Each sensory fiber branches many times, innervating several taste cells within taste buds. The release of neurotransmitter from taste cells onto the sensory fibers induces action potentials in the fibers and the transmission of signals to the sensory cell body.

The cell bodies of gustatory sensory neurons lie in the geniculate, petrosal, and nodose ganglia. The peripheral branches of these neurons travel in cranial nerves VII, IX, and X, while the central branches enter the brain stem, where they terminate on neurons in the gustatory area of the nucleus of the solitary tract (Figure 29–17). In most mammals, neurons in this nucleus transmit signals to the parabrachial nucleus of the pons, which in turn sends gustatory information to the ventroposterior medial nucleus of the thalamus. In primates, however, these neurons transmit gustatory information directly to the taste area of the thalamus.

From the thalamus, taste information is transmitted to the gustatory cortex, a region of the cerebral cortex located along the border between the anterior insula and the frontal operculum (Figure 29–17). The gustatory cortex is believed to mediate the conscious perception and discrimination of taste stimuli. The taste areas of the thalamus and cortex also transmit information both directly and indirectly to the hypothalamus, which controls feeding behavior and autonomic responses.

Large-scale calcium imaging revealed that some neurons in the gustatory cortex respond preferentially to one taste modality, such as bitter or sweet. These neurons are localized in segregated cortical fields or hot spots. Interestingly, using a light-activated ion channel to activate neurons in the sweet hot spot elicits innately attractive responses. In contrast, activation of the bitter hot spot evokes suppression of licking and strong aversive orofacial responses, mimicking what is often seen in response to bitter tastants. These experiments showed that direct control of primary taste cortex can evoke specific, reliable, and robust behaviors that mimic responses to natural tastants. They also illustrated that the gustatory pathway can activate innate, immediate responses to sweet and bitter chemicals. To demonstrate that these cortically triggered behaviors are innate (ie, independent of learning or experience), similar stimulation experiments were performed in mutant mice that had never tasted sweet or bitter chemicals (the mutation abolished all sweet and bitter signal transduction). Even in these animals, activation of the corresponding cortical fields triggered the expected behavioral response, thus substantiating the predetermined nature of the sense of taste.

Perception of Flavor Depends on Gustatory, Olfactory, and Somatosensory Inputs

Much of what we think of as the flavor of foods derives from information provided by the integration of the taste and olfactory systems. Volatile molecules released from foods or beverages in the mouth are pumped into the back of the nasal cavity ("retronasal passage") by the tongue, cheek, and throat movements that accompany chewing and swallowing. Although the olfactory epithelium of the nose clearly makes a major contribution to sensations of flavor, such sensations are localized in the mouth rather than in the nose.

The somatosensory system is also thought to be involved in this localization of flavors. The coincidence between taste, somatosensory stimulation of the tongue, and the retronasal passage of odorants into the nose is assumed to cause odorants to be perceived as flavors in the mouth. Sensations of flavor also frequently have a somatosensory component that includes the texture of food as well as sensations evoked by spicy or minty foods and by carbonation.

Insects Have Modality-Specific Taste Cells That Drive Innate Behaviors

Insects have a specialized gustatory system that evaluates potential nutrients and toxins in food. Taste neurons are found on the proboscis, internal mouthparts, legs, wings, and ovipositor, allowing insects to sample

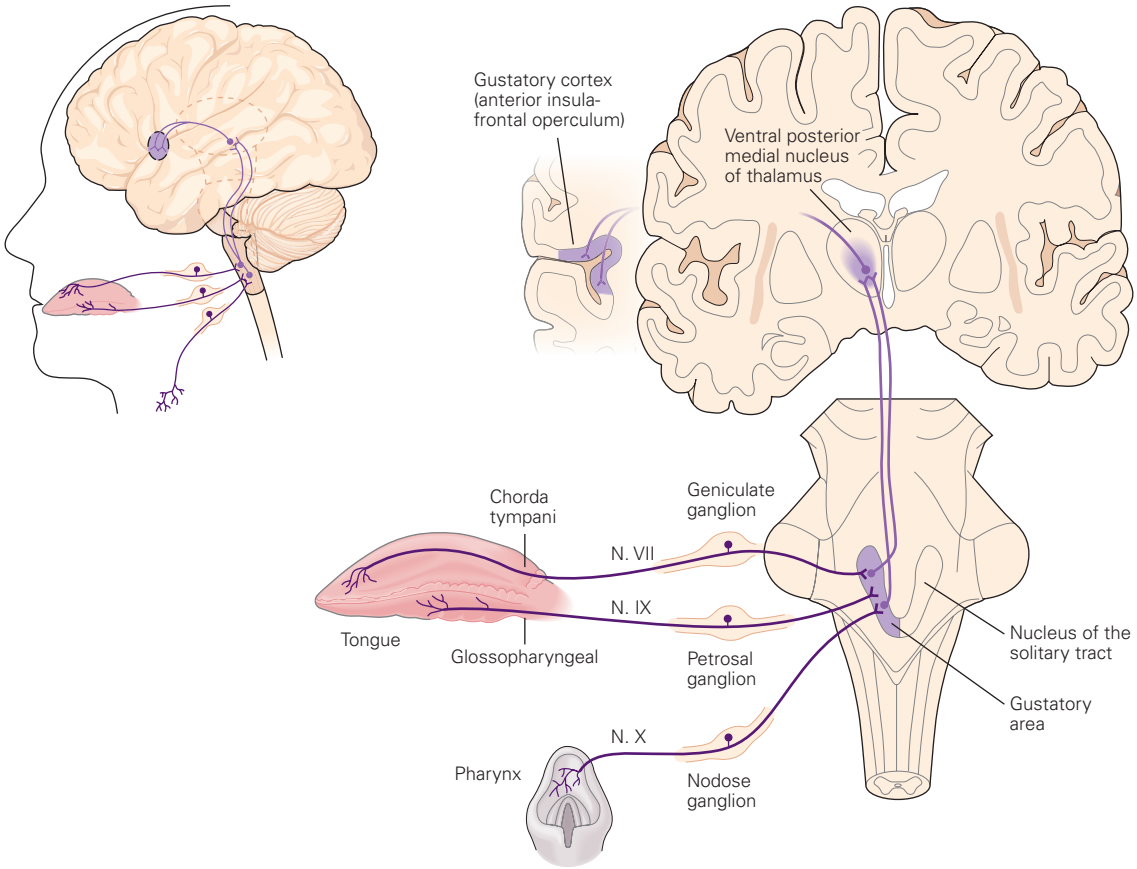

Figure 29–17 The gustatory system. Tastants are detected in taste buds in the oral cavity. Taste buds on the tongue and pharynx are innervated by the peripheral fibers of gustatory sensory neurons, which travel in the glossopharyngeal, chorda tympani and vagus nerves and terminate in the nucleus of the solitary tract in the brain stem. From there, taste information is relayed through the thalamus to the gustatory cortex as well as to the hypothalamus.

the local chemical environment prior to ingestion. As in mammals, only a few different types of taste cells detect different tastes. In the *Drosophila* fly, the different taste cell classes include those that sense sugars, bitter compounds, water, and pheromones. As in mammals, activation of these different taste cells drives different innate behaviors; for example, activation of sugar cells drives food acceptance behavior, whereas activation of bitter cells drives food rejection. Thus, the basic organization of taste detection is remarkably similar in insects and mammals, despite divergent evolutionary histories.

The taste receptors in insects are not related to vertebrate receptors. Members of the gustatory receptor (GR) gene family participate in the detection of sugars and bitter compounds. The GRs are membrane-spanning receptors that are distantly related to the odorant receptors of the fly. The fly has approximately 70 GR genes, a surprisingly large number considering it has approximately 60 olfactory receptor genes. Different GRs are found in sugar cells versus bitter cells, with many GRs present in a single neuron. In addition to GRs, other gene families participate in insect taste, including variants of ionotropic glutamate receptors and other ion channel classes. Similar to olfactory detection, the gene families involved in taste recognition differ across phyla, demonstrating that the gene families for chemical recognition have evolved independently.

Highlights

1. Odor detection in the nose is mediated by a large family of odorant receptors that number approximately 350 in humans and 1,000 in mice. These receptors vary in protein sequence, consistent with an ability to detect structurally diverse odorants.

2. Individual odorant receptors can detect multiple odorants, and different odorants activate different combinations of receptors. This combinatorial strategy explains how we can discriminate a multitude of odorants and how nearly identical odorants can have different scents.
3. Each olfactory sensory neuron in the nose expresses a single type of receptor. Thousands of neurons with the same receptor are dispersed in the olfactory epithelium and intermingled with neurons expressing other receptors.
4. In the olfactory bulb, the axons of the sensory neurons expressing the same receptor converge in a few receptor-specific glomeruli, generating a map of odorant receptor inputs that is similar among individuals.
5. The axons of olfactory bulb projection neurons project broadly to multiple areas of the olfactory cortex, generating a highly distributed organization of cortical neurons responsive to individual odorants. The olfactory cortex transmits information to many other brain areas.
6. In mice, pheromones can be detected in the nose or in the vomeronasal organ, a structure absent in humans. Signals from the nose and vomeronasal organ travel through different neural pathways in the brain.
7. The olfactory system of the fruit fly *Drosophila melanogaster* resembles that of mammals in many aspects. It uses a large number of diverse olfactory receptors, with one or a few olfactory receptors expressed by each olfactory sensory neuron. Moreover, neurons with the same receptor synapse in a few specific glomeruli in the antennal lobe of the brain. From there, olfactory signals are transmitted to two major brain areas involved in innate versus learned odor responses. The ease of using genetic approaches in fruit flies has enabled rapid study of mechanisms underlying odor coding and behavior.
8. The gustatory system detects five basic tastes: sweet, sour, bitter, salty, and umami (amino acids). Tastants that activate these taste qualities are detected by taste receptor cells located primarily in taste buds on the tongue and palate epithelium. The detection of the five different taste modalities is mediated by different taste receptor cells, each dedicated to one modality.
9. Sweet tastants are detected by a single type of receptor, which is composed of two subunits, T1R2 and T1R3. Umami receptors are related but comprise a combination of T1R1 and T1R3 subunits.
10. Bitter taste receptors constitute a family of approximately 30 related but diverse receptors that vary in ligand specificity. Individual taste receptor cells express many or all bitter receptors.
11. In contrast to sweet, umami, and bitter receptors, which are all G protein–coupled receptors, salty and sour tastes are detected by ion channels: ENaC for salt taste and Otopetrin-1 for sour taste.
12. Taste signals travel from taste buds through cranial nerves from gustatory sensory neurons in the geniculate, petrosal, and nodose ganglia via labeled lines (sweet taste receptor cells to sweet neurons, bitter taste cells to bitter neurons, etc.). They then travel to the gustatory area of the nucleus of the solitary tract and parabrachial nucleus, and from there to the taste area of the thalamus and then the gustatory cortex. The gustatory cortex, in turn, projects to many brain areas, including those involved in motor control, feeding, hedonic value, learning, and memory.
13. The gustatory cortex contains hot spots for sweet and bitter taste, which, when directly stimulated, can elicit behavioral responses similar to those obtained with tastants applied to the tongue.
14. The fruit fly *Drosophila* also has a specialized gustatory system that evaluates potential nutrients and toxins in food. Different classes of taste cells sense sugars, bitter compounds, pheromones, or water. Activation of these different peripheral sensors drives different innate behaviors, such as food acceptance or rejection.

Fresco of dancing Peucetian women from the Tomb of the Dancers in the Corso Cotugno necropolis of Ruvo di Puglia, 4th–5th century BC. The tomb has a semichamber design. Its six painted panels depict 30 dancing women, moving from left to right with arms interlocked as though they were dancing in a circle around the interior of the tomb. The skeletal remains of the deceased in the tomb clearly belonged to a distinguished male warrior. The tomb is named after the dancing women that appear on the frescoes in the tomb. The panels with the frescoes are now exhibited in the Naples National Archaeological Museum, inv. 9353. (Source: https://en.wikipedia.org/wiki/Tomb_of_the_Dancers.)

V Movement

The capacity for movement, as many dictionaries remind us, is a defining feature of animal life. As Sherrington, who pioneered the study of the motor system pointed out, "to move things is all that mankind can do, for such the sole executant is muscle, whether in whispering a syllable or in felling a forest."*

The immense repertoire of motions that humans are capable of stems from the activity of some 640 skeletal muscles—all under the control of the central nervous system. After processing sensory information about the body and its surroundings, the motor centers of the brain and spinal cord issue neural commands that effect coordinated, purposeful movements.

The task of the motor systems is the reverse of the task of the sensory systems. Sensory processing generates an internal representation in the brain of the outside world or of the state of the body. Motor processing begins with an internal representation: the desired purpose of movement. Critically, however, this internal representation needs to be continuously updated by internally generated information (efference copy) and external sensory information to maintain accuracy as the movement unfolds.

Just as psychophysical analysis of sensory processing tells us about the capabilities and limitations of the sensory systems, psychophysical analyses of motor performance reveal the control rules used by the motor system.

Because many of the motor acts of daily life are unconscious, we are often unaware of their complexity. Simply standing upright, for example, requires continual adjustments of numerous postural muscles in response to the vestibular signals evoked by miniscule swaying. Walking, running, and other forms of locomotion involve the combined action of central pattern generators, gated sensory information, and descending commands, which together generate the complex patterns of alternating excitation and inhibition to the appropriate sets of muscles. Many actions, such as serving a tennis

*Sherrington CS. 1979. 1924 Linacre lecture. In: JC Eccles, WC Gibson (eds). *Sherrington: His Life and Thought*, p. 59. New York: Springer-Verlag.

ball or executing an arpeggio on a piano, occur far too quickly to be shaped by sensory feedback. Instead, centers, such as the cerebellum, make use of predictive models that simulate the consequences of the outgoing commands and allow very short latency corrections. Motor learning provides one of the most fruitful subjects for studies of neural plasticity.

Motor systems are organized in a functional hierarchy, with each level concerned with a different decision. The highest and most abstract level, likely requiring the prefrontal cortex, deals with the purpose of a movement or series of motor actions. The next level, which is concerned with the formation of a motor plan, involves interactions between the posterior parietal and premotor areas of the cerebral cortex. The premotor cortex specifies the spatiotemporal characteristics of a movement based on sensory information from the posterior parietal cortex about the environment and about the position of the body in space. The lowest level of the hierarchy coordinates the spatiotemporal details of the muscle contractions needed to execute the planned movement. This coordination is executed by the primary motor cortex, brain stem, and spinal cord. This serial view has heuristic value, but evidence suggests that many of these processes can occur in parallel.

Some functions of the motor systems and their disturbance by disease have now been described at the level of the biochemistry of specific transmitter systems. In fact, the discovery that neurons in the basal ganglia of parkinsonian patients are deficient in dopamine was the first important clue that neurological disorders in the central nervous system can result from altered chemical transmission. Neurophysiological studies have provided information as to how such transmitters play a critical role in action selection and the reinforcement of successful movements.

Understanding the functional properties of the motor system is not only fundamental in its own right, but it is of further importance in helping us to understand disorders of this system and explore the possibilities for treatment and recovery. As would be expected for such a complex apparatus, the motor system is subject to various malfunctions. Disruptions at different levels in the motor hierarchy produce distinctive symptoms, including the movement-slowing characteristic of disorders of the basal ganglia, such as Parkinson disease, the incoordination seen with cerebellar disease, and the spasticity and weakness typical of spinal cord damage. For this reason, the neurological examination of a patient inevitably includes tests of reflexes, gait, and dexterity, all of which provide information about the status of the nervous system. In addition to pharmacological therapies, the treatment of motor system disorders has been augmented by two new approaches. First, focal stimulation of the basal ganglia has been shown to restore motility to certain patients with Parkinson disease; such deep-brain stimulation is also being tested in the context of other neurological and psychiatric conditions. And

second, the motor systems have become a target for the application of neural prosthetics; neural signals are decoded and used to drive devices that aid patients with paralysis caused by spinal cord injury and stroke.

Principles of Sensorimotor Control

The preceding chapters in this book consider how the brain constructs internal representations of the world around us. These representations are behaviorally meaningful when used to guide movement. Thus, an important function of the sensory representations is to shape the actions of the motor systems. This chapter describes the principles that govern the neural control of movement using concepts derived from behavioral studies and computational models of the brain and musculoskeletal system.

We start by considering the challenges motor systems face in generating skillful actions. We then examine some of the neural mechanisms that have evolved to meet these challenges and produce smooth, accurate, and efficient movements. Finally, we see how motor learning improves our performance and allows us to adapt to new mechanical conditions, such as when using a tool, or to learn novel correspondences between sensory and motor events, such as when using a computer mouse to control a cursor. This chapter focuses on voluntary movement; reflexes and rhythmic movements are discussed in further detail in Chapters 32 and 33.

Voluntary movements are generated by neural circuits that span different levels of the sensory and motor hierarchies, including regions of the cerebral cortex, subcortical areas such as the basal ganglia and cerebellum, and the brain stem and spinal networks. These different structures have unique patterns of neural activity. Moreover, focal damage to different structures can cause distinct motor deficits. Although it is tempting to suggest that these individual structures have distinct functions, these brain and spinal areas normally work together as a network, such that damage to one component likely affects the function of all

others. Many of the principles discussed in this chapter cannot be easily attributed to a single brain or spinal area. Instead, distributed neural processing is likely to underlie the computational mechanisms that subserve sensorimotor control.

The Control of Movement Poses Challenges for the Nervous System

Motor systems produce neural commands that act on the muscles, causing them to contract and generate movement. The ease with which we move, from tying our shoelaces to returning a tennis serve, masks the complexity of the control processes involved. Many factors inherent in sensorimotor control are responsible for this complexity, which becomes clearly evident when we try to build machines to perform human-like movement (Chapter 39). Although computers can now beat the world's best players at chess and Go, no robot can manipulate a chess piece with the dexterity of a 6-year-old child.

The act of returning a tennis serve illustrates why the control of movement is challenging for the brain (Figure 30–1). First, motor systems have to contend with different forms of uncertainty, such as our incomplete knowledge with regard to the state of the world and the rewards we might gain. On the sensory side, although the player may see the serve, she cannot be certain where her opponent will aim or where the ball might strike the racket. On the motor side, there is uncertainty as to the likely success of different possible returns. Skilled performance requires reducing uncertainty by anticipating events we may encounter (the trajectory of an opponent's tennis serve) and by motor planning (adopting an appropriate stance to return the expected serve).

Second, even if the player can reliably estimate the ball's trajectory, she must determine from sensory signals which of the 600 muscles she will use in order to move her body and racket to intercept the ball. Controlling such a system can be challenging as it is hard to explore all possible actions effectively in a system with many degrees of freedom (eg, a large number of individual muscles), making learning difficult. We will see how the motor system reduces the degrees of freedom of the musculoskeletal system by controlling groups of muscles, termed synergies, to simplify control.

Third, unwanted disturbances, termed noise, corrupt many signals and are present at all stages of sensorimotor control, from sensory processing, through planning, to the outputs of the motor system. For example, in a tennis serve, such noise will cause the ball to land in different places even when the server is trying to hit the same location on the court. Both sensory feedback, reflecting the ball's location, and motor outputs are contaminated with noise. The variability inherent in such noise limits our ability to perceive accurately and act precisely. The amount of noise in our motor commands tends to increase with stronger commands (ie, more force). This limits our ability to move rapidly and accurately at the same time and thus

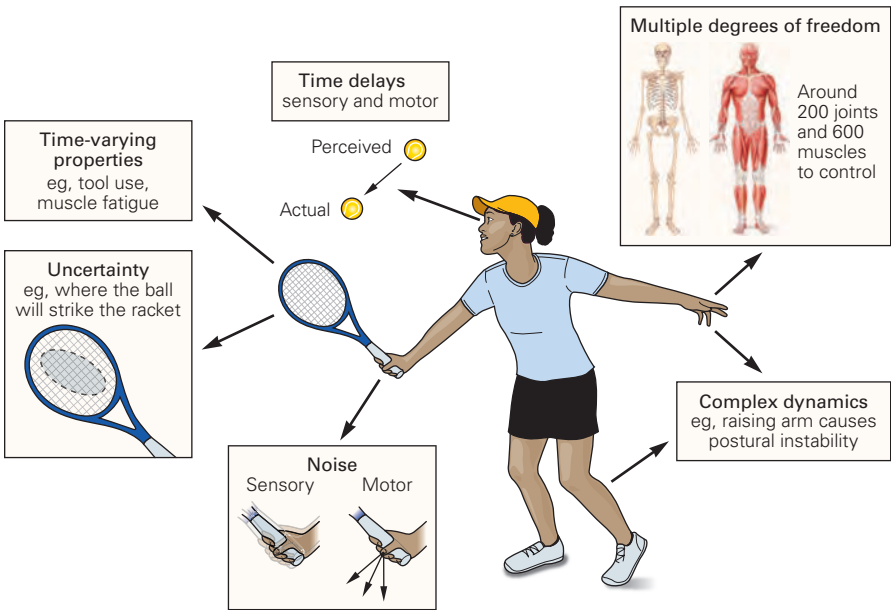

Figure 30–1 The challenges of sensorimotor control.

leads to a trade-off between speed and accuracy. We will see how efficient planning of movement can minimize the deleterious effects of noise on task success.

Fourth, time delays are present at all stages of the sensorimotor system, including the delays arising from receptor dynamics, conduction delays along nerve fibers and synapses, and delays in the contraction of muscles in response to motor commands. Together, these delays, which can be on the order of 100 ms, depend on the particular sensory modality (eg, longer for vision than proprioception) and complexity of processing (eg, longer for face recognition than motion perception). Therefore, we effectively live in the past, with the control system only having access to out-of-date information about the world and our own body. Such delays can result in instability when trying to make fast movements, as we try to correct for errors we perceive but that no longer exist. We will see how the brain makes predictions of the future states of the body and environment to reduce the negative consequences of such delays.

Fifth, the body and environment change both on a short and a long timescale. For example, within the relatively short period of a game, a player must correct for weakening muscles as she fatigues and changes in the court surface when it rains. On a longer timescale, the properties of our motor system change dramatically during growth as our limbs lengthen and increase in weight. As we will see, the ever-changing properties of the motor system place a premium on our ability to use motor learning to adapt control appropriately.

Finally, the relation between motor command and the ensuing action is highly complex. The motion of each body segment produces torques, and potentially motions, at all other body segments through mechanical interactions. For example, when a player raises the racket to hit the ball, she must anticipate destabilizing forces and counteract them to maintain balance. Indeed, when we raise our arms forward while standing, the first muscle to activate is an ankle flexor ensuring you remain upright. We will see how the sensorimotor system controls movement of different segments to maintain fine coordination of actions.

Actions Can Be Controlled Voluntarily, Rhythmically, or Reflexively

Although movements are often classified according to function—as eye movement, prehension (reach and grasp), posture, locomotion, breathing, and speech—many of these functions are subserved by overlapping groups of muscles. Moreover, the same groups of muscles can be controlled voluntarily, rhythmically, or reflexively. For example, the muscles that control respiration can be used to take a deep breath voluntarily before diving under water, to breathe automatically and rhythmically in a regular cycle of inspiration and expiration, or to act reflexively in response to a noxious stimulus in the throat, producing a cough.

Voluntary movements are those that are under conscious control. Rhythmic movements can also be controlled voluntarily but differ from voluntary movements in that their timing and spatial organization are to a larger extent controlled autonomously by spinal or brain stem circuitry. Reflexes are stereotyped responses to specific stimuli that are generated by neural circuits in the spinal cord or brain stem (although some reflexes involve pathways through cortex). These responses occur on a shorter timescale than voluntary responses.

Although we may consciously intend to perform a task or plan a certain sequence of actions, and at times are aware of deciding to move at a particular moment, movements generally seem to occur automatically. Conscious processes are not necessary for moment-to-moment control of movement. We carry out the most complicated movements without a thought to the actual joint motions or muscle contractions required. The tennis player does not consciously decide which muscles to use to return a serve with a backhand or which body parts must be moved to intercept the ball. In fact, thinking about each body movement before it takes place can disrupt the player's performance.

Motor Commands Arise Through a Hierarchy of Sensorimotor Processes

Although the final output to the musculoskeletal system is via motor neurons in the spinal cord, the motor control of muscles for a specific action occurs through a hierarchy of control centers. This arrangement can simplify control: Higher levels can plan more global goals, whereas lower levels are concerned with how these goals are implemented.

At the lowest level, muscles themselves have properties that can contribute to control even without any change in the motor command. Unlike the electric motors of a robot, muscles have substantial passive properties that depend on both the motor command acting on the muscle as well as the muscle's length and rate of change of length (Chapter 31). As a simple approximation, a muscle can be seen as acting like a spring (increasing tension as it is stretched and reducing tension as it is shortened) and damper

(increasing tension as the rate of stretch increases). For small perturbations, these properties tend to act to stabilize the length of a muscle and hence stabilize the joint on which the muscle acts. For example, if an external perturbation extends a joint, the flexor muscles will be stretched, increasing their tension, while the extensor muscles will be shortened, reducing their tension, and the imbalance in tension will tend to bring the joint back toward its original position. A particular advantage of such control is that, unlike higher levels in the motor hierarchy, such changes in force act with minimal delay as they are simply an effect of passive physical properties of the muscles.

In addition to the passive properties of muscles, sensory inputs can cause motor output directly without the intervention of higher brain centers. Sensorimotor responses, such as spinal reflexes, control for local disturbance or noxious stimuli. Reflexes are stereotyped responses to specific stimuli that are generated by simple neural circuits in the spinal cord or brain stem. For example, a spinal flexor withdrawal reflex can remove your hand from a hot stove without any descending input from the brain. The advantage of such reflexes is that they are fast; the disadvantage is they are less flexible than voluntary control systems (Chapter 32). Again, there is a hierarchy of reflex circuits. The fastest is the monosynaptic stretch reflex, which drives contraction of a stretched muscle. In this reflex circuit, sensory neurons that are activated by stretch receptors in the muscle (the muscle spindle) directly synapse onto motor neurons that cause the same muscle to contract. The time from the stimulus to the response is around 25 ms. This reflex can be tested clinically by striking the quadriceps muscle tendon just below the patella.

While this monosynaptic stretch reflex is not adaptable on short timescales, multisynaptic reflexes, which involve higher level structures such as motor cortex, can produce responses at around 70 ms. Unlike the monosynaptic reflex, multisynaptic reflexes are adaptable to changes in behavioral goals because the circuit connecting sensory and motor neurons can be modified by task-dependent properties. The strength of a reflex tends to increase with the tension in a muscle (called gain-scaling), and therefore, reflexes can be amplified by co-contracting the set of muscles around a joint so as to respond to perturbations with a greater force. In fact, we use such co-contraction when holding the hand of a rebellious child when crossing a road. Such a strategy can amplify the reflexes, thereby reducing deviations of the arm caused by random external forces.

Finally, voluntary movements are those that are under conscious control by the brain. Voluntary movements can be generated in the absence of a stimulus or used to compensate for a perturbation. The time to generate a voluntary movement in response to a physical perturbation depends both on the nature of the perturbation (modality and size) as well as whether the response can be specified before the perturbation occurs. For example, a voluntary correction to a small physical perturbation can occur with a latency of about 110 ms.

Although we have described clear distinctions between the different levels of the motor hierarchy, from reflexes through to voluntary control, in reality, such distinctions are blurred in a continuum of responses spanning different latencies. Increasing the response time permits additional neural circuitry to be involved in the sensorimotor loop and tends to increase the sophistication and adaptability of the response, leading to a trade-off between the speed of the response and the sophistication of processing as one ascends the motor hierarchy.

Motor Signals Are Subject to Feedforward and Feedback Control

In this section, we will first illustrate some principles of control that are important for dealing with the problem of sensory delays, sensory noise, and motor noise. For simplicity, we confine our discussion to relatively simple movements, such as moving the eyes in response to head movements or moving the hand from one location to another. We consider two broad classes of control, feedforward and feedback, which differ in their reliance on sensory feedback during the movement.

Feedforward Control Is Required for Rapid Movements

Some movements are executed without monitoring the sensory feedback that arises from the action. In such feedforward control situations, the motor command is generated without regard to the sensory consequences. Such commands are therefore also termed *open-loop*, reflecting the fact that the sensorimotor loop is not completed by sensory feedback (Figure 30–2A).

Open-loop control requires some information about the body so that the appropriate command can be generated. For example, it should include information about the dynamics of the motor system. Here, "dynamics" refers to the relation between the motor command (or the torques or forces) applied and the ensuing motion of the body, for example, joint rotations. For perfect open-loop control, one needs to

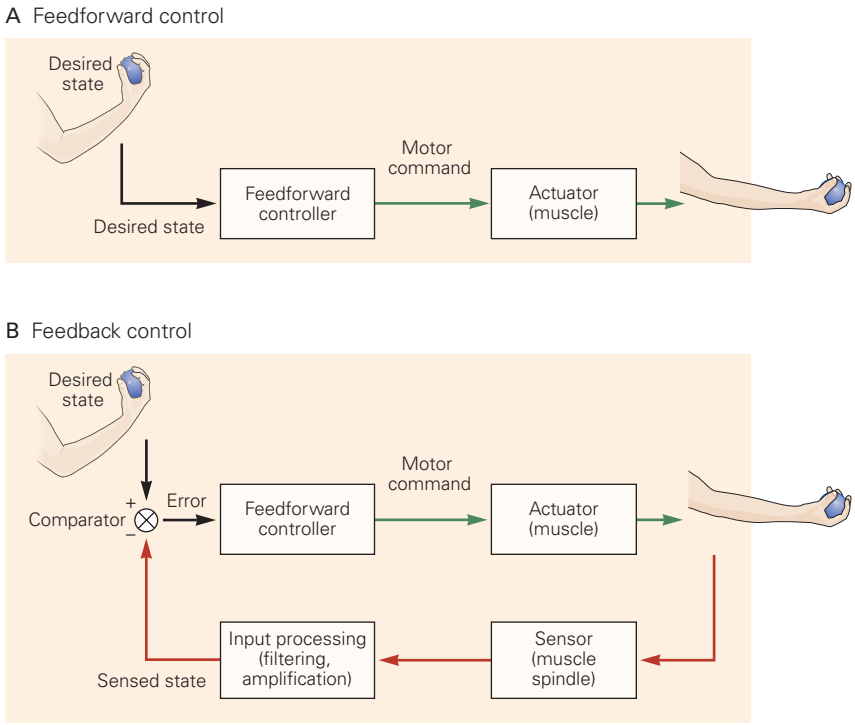

Figure 30–2 Feedforward and feedback control.

A. A feedforward control motor command is based on a desired state. Any errors that arise during the movement are not monitored. Although we illustrate the elements of feedforward control for the arm, only the initial portion of any arm movement is driven by feedforward signals and the movement typically involves feedback control.

B. With feedback control, the desired and sensed states are compared (at the comparator) to generate an error signal, which helps shape the motor command. There can be considerable delay in the feedback of sensory information to the comparator.

invert the dynamics so as to calculate the motor command that will generate the desired motion. The neural mechanism that performs this inversion is called an inverse model, a type of internal model (Box 30–1). An inverse model coupled to open-loop control can determine what motor commands are needed to produce the particular movements necessary to achieve a goal.

Although not monitoring the consequences of an action may seem counterproductive, there are good reasons for not doing so. The main reason, as discussed earlier, is that there are delays in both sensing and acting. That is, the conversion of a stimulus into neural signals by sensory receptors and conveyance of these signals to central neurons take time. For example, visual inputs can take around 60 ms to be processed in the retina and transmitted to the visual cortex. In addition to delays in afferent sensory systems, there are also delays in central processing, in the transmission of efferent signals to motor neurons, and in the response of muscles. In all, the combined sensorimotor loop delay is appreciable, approximately 120 to 150 ms for a motor response to a visual stimulus. This delay means that movements like saccades, which redirect gaze within 30 ms, cannot use sensory feedback to guide movement. Even for slower movements like reaching, which takes on the order of 500 ms, sensory information cannot be used to guide the initial part of a movement, so open-loop control must be used.

Open-loop control also has disadvantages. Any movement errors caused by inaccuracies in planning or execution will not be corrected, and therefore will compound themselves over time or successive movements. The more complex the system under control, the more difficult it is to arrive at an accurate inverse model through learning.

An example of a purely open-loop control system is the control of the eye in response to head rotation. The vestibulo-ocular reflex (Chapter 27) uses open-loop control to fix gaze on an object during head rotation. The vestibular labyrinth senses the head rotation and drives appropriate movements of the eyes through a three-synapse circuit. The reflex does not require (or use) vision during the movement (the eyes maintain a stable gaze when the head is rotated in the dark). Sensory information from the vestibular system does drive the eye movement, but the control is feedforward (any errors that arise are not corrected during the movement). Such precise open-loop control is possible because the dynamic properties of the eye are relatively simple, the rotation of the head can be directly sensed by the vestibular labyrinth, and the eye tends not to be substantially perturbed by external events. In contrast, it is very difficult to optimize an inverse model for a complex musculoskeletal system such as the arm, and thus, the control of arm movement requires some form of error correction.

Box 30–1 Internal Models

The utility of numerical models in the physical sciences has a long history. Numerical models are abstract quantitative representations of complex physical systems. Some start with equations and parameters that represent initial conditions and run *forward*, either in time or space, to generate physical variables at some future state. For example, we can construct a model of the weather that predicts wind speed and temperature 2 weeks from now.

Other models start with a state, a set of physical variables with specific values, and run in the *inverse* direction to determine what parameters in the system account for that state. When we fit a straight line to a set of data points, we are constructing an inverse model that estimates slope and intercept based on the equations of the system being linear. An inverse model thus may allow us to know how to set the parameters of the system to obtain desired outcomes.

Over the past 50 years, the idea that the nervous system has similar predictive models of the physical world to guide behavior has become a major issue in neuroscience. Such a model is termed "internal" because it is instantiated in neural circuits and is therefore internal to the central nervous system. The idea originated in Kenneth Craik's notion of *internal models* for cognitive function. In his 1943 book *The Nature of Explanation*, Craik was perhaps the first to suggest that organisms make use of internal representations of the external world:

> If the organism carries a "small-scale model" of external reality and of its own possible actions within its head, it is able to try out various alternatives, conclude which is the best of them, react to future situations before they arise, use the knowledge of past events in dealing with the present and future, and in every way to react in a much fuller, safer, and more competent manner to the emergencies that face it.

In this view, an internal model allows an organism to contemplate the consequences of potential actions without actually committing itself to those actions. In the context of sensorimotor control, internal models can answer two fundamental questions. First, how can we generate motor commands that act on our muscles so as to control the behavior of our body? Second, how can we predict the consequences of our own motor commands?

The central nervous system must exercise both control and prediction to achieve skilled motor performance. Prediction and control are two sides of the same coin, and the two processes map exactly onto forward and inverse models (Figure 30–3). Prediction turns motor commands into expected sensory consequences, whereas control turns desired sensory consequences into motor commands.

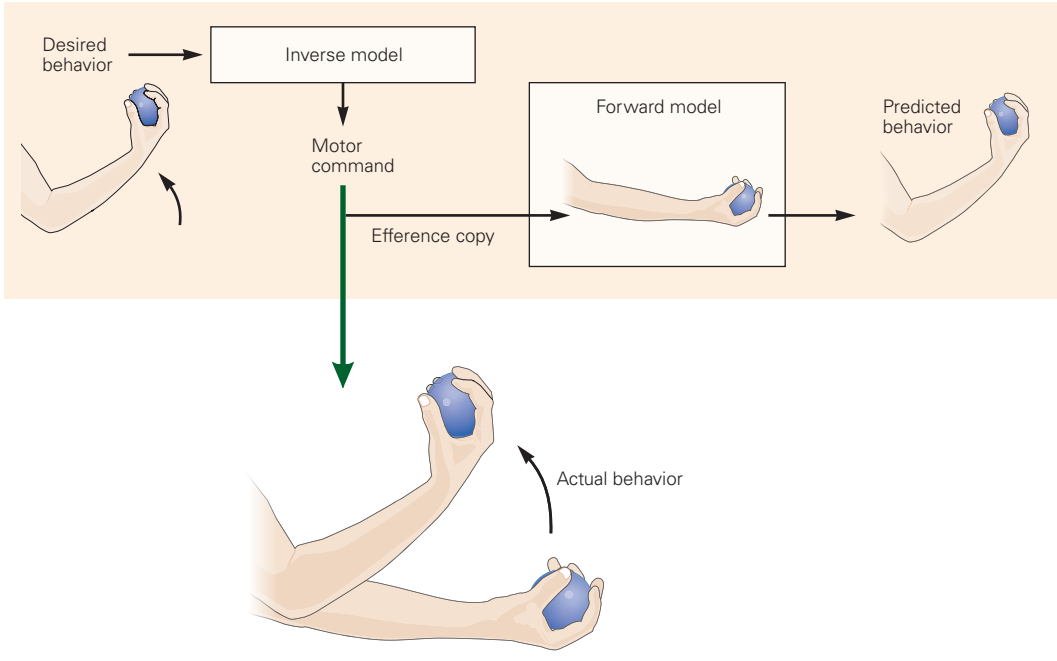

Figure 30–3 Internal sensorimotor models represent relationships of the body and external world. The inverse model determines the motor commands that will produce a behavioral goal, such as raising the arm while holding a ball. A descending motor command acts on the musculoskeletal system to produce the movement. A copy of the motor command is passed to a forward model that simulates the interaction of the motor system and the world and thus can predict behaviors. If both forward and inverse models are accurate, the output of the forward model (the predicted behavior) will be the same as the input to the inverse model (the desired behavior).

Feedback Control Uses Sensory Signals to Correct Movements

To correct movement errors as they arise, movement must be monitored. Systems that perform error correction are known as feedback or closed-loop control because the sensorimotor loop is complete (Figure 30–2B).

The simplest form of feedback control is one in which the control system generates a fixed response when the error exceeds some threshold. Such a system is seen in most central heating systems in which a thermostat is set to a desired temperature. When the house temperature falls below the specified level, the heating is turned on until the temperature reaches that level. Although such a system is simple and can be effective, it has the drawback that the amount of heat being put into the house does not relate to the discrepancy between the actual and desired temperature (the error). A better system is one in which the control signal is proportional to the error.

Such proportional control of movement involves sensing the error between the actual and desired position of, for example, the hand. The size of the corrective motor command is in proportion to the size of the error and in a direction to reduce the error. The amount by which the corrective motor command is increased or decreased per unit of positional error is called the gain. By continuously correcting a movement, feedback control can be robust both to noise in the sensorimotor system and to environmental perturbations.

While feedback control can update commands in response to deviations that arise during the movement, it is sensitive to feedback delays. Without any delay, as the gain of the feedback controller increases, the system will track a desired position with increasing fidelity (Figure 30–4). However, as feedback delay increases, the control system may start to oscillate and eventually become unstable. This is because with a delay the system may respond to errors that no longer exist and may therefore even correct in the wrong direction.

Smooth pursuit eye movement, used to track a moving object, is an example of a movement driven primarily by feedback. Smooth pursuit uses feedback to minimize the velocity error on the retina (the difference between the gaze and target velocity). We can compare the efficiency of feedforward and feedback control in minimizing error. Compare how easy it is to fixate on your outstretched stationary finger when quickly rotating your head back and forth versus trying to track your finger when it is moving it rapidly sinusoidally left and right while your head remains stationary. Although the relative motion of finger to head is the same in both conditions, the former is precise because it uses the vestibulo-ocular reflex, whereas the latter uses feedback (requiring an error in velocity to drive the eye movement) and thus is less precise, particularly as the frequency of motion increases.

In most motor systems, movement control is achieved through a combination of feedforward and feedback processes. We will see later that these two components arise naturally in a unified model of movement production.

Estimation of the Body's Current State Relies on Sensory and Motor Signals

Accurate control of movement requires information about our body's current state, for example, the positions and velocities of the different segments of the body. To grasp an object, we need to know not only the location, shape, and surface properties of the object but also the current configuration of our arm and fingers so as to appropriately shape and position the hand.

Estimating the state of the body is not a trivial problem. First, as we have seen, sensory signals are delayed due to sensory transduction and conduction time. Therefore, signals from our muscles, joints, and vision are all out of date by the time they reach the central nervous system. Second, the sensory signals we receive are often imprecise and corrupted by neural noise. For example, if you touch the underside of a table with the finger of one hand and try to estimate its location on the top of the table with your other hand, you can be off by a considerable distance. Third, we often do not have sensors that directly communicate relevant information. For example, although we have sensors that report muscle length and joint angle, we have no sensors within the limb that directly determine the location of the hand in space. Therefore, sophisticated computation is required to estimate current body states as accurately as possible. Several principles have emerged as to how the brain estimates state.

First, state estimation relies on internal models of sensorimotor transformations. Given the fixed lengths of our limb segments, there is a mathematical relation between the muscle lengths or joint angles of the arm and the location of the hand in space. A neural representation of this relation allows the central nervous system to estimate hand position if it knows the joint angles and segment lengths. Neural circuits that compute such sensorimotor transformations are examples of internal models (Box 30–1).

Second, state estimation can be improved by combining multiple sensory modalities. For example, information about the state of our limbs arrives from

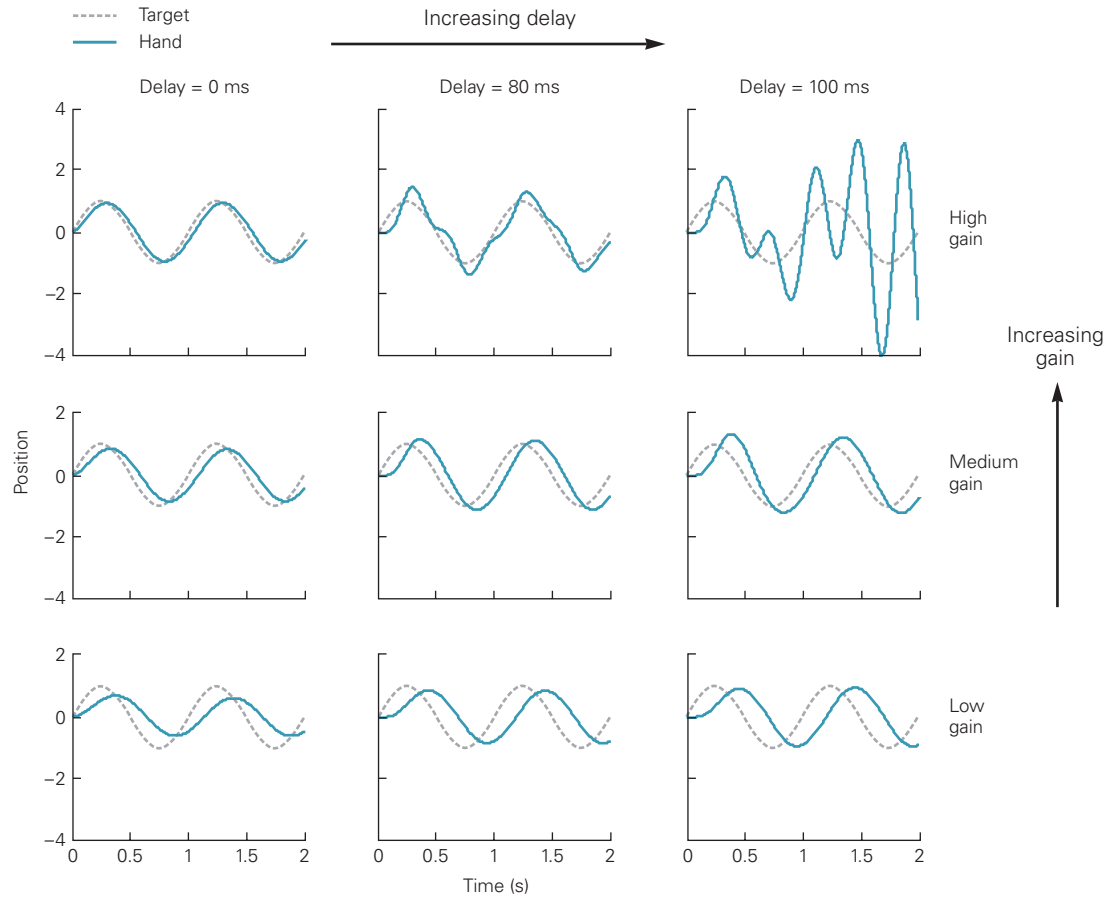

Figure 30–4 The interplay of gain and delay in feedback control. Performance of a feedback controller trying to track a target moving sinusoidally in one dimension. The sensory feedback signal that conveys error in the position arrives after some period of time (the delay), and the motor system tries to correct for the error by increasing or decreasing the size of its command relative to the error (the gain).

The plots show the performance in which there is either instantaneous feedback (no delay) of error (**left column**) or feedback with delay of 80 or 100 ms (**middle and right columns**). When the gain is high and the delay is low, tracking is very good. However, when the delay increases, because the controller is compensating for errors that existed 80 or 100 ms earlier, the correction may be inappropriate for the current error. The gain can be lowered to maintain stability, but as the feedback controller corrects errors only slowly, tracking becomes inaccurate.

At low gain (**bottom row**), the feedback controller corrects errors only slowly and tracking is inaccurate. As the gain increases (**middle row**), the feedback controller corrects errors more rapidly and tracking performance improves. At high gain (**top row**), the system corrects rapidly but is prone to overcorrect, leading to instability when the time delay in feedback is on the order of physiological time delays (**top right**). Because the controller is compensating for errors that existed 100 ms earlier, the correction may therefore be inappropriate for the current error. This overcorrection leads to oscillations and is one mechanism proposed to account for some forms of oscillatory tremor seen in neurological disease.

proprioceptive information from muscle spindles, the stretch of the skin, and the sight of the arm. These modalities have different amounts of variability (or noise) associated with them, and just as we average a set of experimental data to reduce measurement error, these sensory modalities can be combined to reduce the overall uncertainty in the state estimate.

The optimal way to combine these sources is for higher brain centers to take the uncertainty of each modality into account and rely on the more certain modalities. For example, the location of the hand can be sensed both by proprioception and vision. The sight of your hand in front of you tends to be more reliable than proprioception for estimating location along the azimuth (right–left) but less reliable for depth (forward–back). Therefore, visual input should be given greater weight than proprioceptive input when estimating the azimuth location of your hand, and vice versa for depth. By measuring the precision of each modality when used alone, it is possible to predict the increased

Box 30–2 Bayesian Inference

Bayesian inference is a mathematical framework for making estimates about the world based on uncertain information. The fundamental idea is that probabilities (between 0 and 1) can be used to represent the degree of belief in different alternatives, such as the belief that the chance of your rolling a six with fair dice is 1 in 6.

The beauty of Bayesian inference is that by using the rules of probability we can specify how beliefs should be formed and updated based on our experience and new information from sensory input. For example, when playing tennis, we want to estimate where the ball will land. Because vision does not provide perfect information about the ball's position and velocity in flight, there is uncertainty as to the landing location. However, if we know the level of noise in our sensory system, then the current sensory input can be used to compute the *likelihood* (ie, probability) of the particular sensory input for different potential landing locations.

We can learn additional information from repeated experience of the game: The position where the ball lands is not equally probable over the court. For example, bounce locations are likely to be concentrated near the boundary lines where it is most difficult to return the ball. This distribution is termed the *prior*.

The Bayes rule defines how to combine the prior and likelihood to make an optimal estimate of the bounce location. While the Bayesian approach was originally developed in statistics, it now provides a unifying framework to understand how the brain deals with uncertainty in the perceptual, motor, and cognitive domains.

precision when both are used at the same time. Experiments have shown that this process is often close to optimal. Precision can also be improved by combining prior knowledge with sensory inputs using the mathematics of Bayesian inference (Box 30–2).

Third, the motor command can also provide valuable information. If both the current state of the body and the descending motor command are known, the next state of the body can be estimated. This estimate can be derived from an internal model that represents the causal relation between actions and their consequences. This is called a forward model because it estimates future sensory inputs based on motor outputs (Box 30–1). Thus, a forward model can be used to anticipate how the motor system's state will change as the result of a motor command. A copy of a descending motor command is passed into a forward model that acts as a neural simulator of the musculoskeletal system moving in the environment. This copy of the motor command is known as an efference copy (or corollary discharge). Forward and inverse models can be better understood if we place the two in series. If the structure and parameter values of each model are correct, the output of the forward model (the predicted behavior) will be the same as the input to the inverse model (the desired behavior) (Figure 30–3).

Using the motor command to estimate the state of the body is advantageous as, unlike sensory information that is delayed, the motor command is available before it acts on the musculoskeletal system and therefore can be used to anticipate changes in the state. However, this estimate will tend to drift over time if the forward model is not perfectly accurate, and therefore, sensory feedback is used to correct the state estimate, albeit with a delay.

It may seem surprising that the motor command is used in state estimation. In fact, the first demonstration of a forward model used a motor system that relies on only the motor command to estimate state, that is, the position of the eye within the orbit. The concept of motor prediction was first considered by Helmholtz when trying to understand how we localize visual objects. To calculate the location of an object relative to the head, the central nervous system must know both the retinal location of the object and the gaze direction of the eye. Helmholtz's ingenious suggestion was that the brain, rather than sensing the gaze direction, predicted it based on a copy of the motor command to the eye muscles.

Helmholtz used a simple experiment on himself to demonstrate this. If you move your own eye without using the eye muscles (cover one eye and gently press with your finger on your open eye through the eyelid), the retinal locations of visual objects change. Because the motor command to the eye muscles is required to update the estimate of the eye's state, the predicted eye position is not updated. However, because the retinal image has changed, this leads to the false percept that the world must have moved. A more dramatic example is that if the eye muscles are temporarily paralyzed with curare, then trying to move the eyes leads to a percept that the world is moving. This is because

the command leads to a state estimate that the eye has moved, but with a fixed retinal input (due to the paralysis), the only consistent interpretation is that the world has moved.

Finally, the best estimate of state is achieved by combining sensory modalities with motor commands. The drawbacks of using only sensory feedback or only motor prediction can be ameliorated by monitoring both and using a forward model to estimate the current state. A neural apparatus that does this is known as an *observer model.* The major objectives of the observer model are to compensate for sensorimotor delays and to reduce uncertainty in the estimate of current state arising from noise in both the sensory and motor signals (Figure 30–5). Such a model has been supported by empirical studies of how the nervous system estimates hand position, posture, and head orientation. We will see how such models are used to decode neural signals in brain–machine interfaces (Chapter 39).

State estimation is not a passive process. Skilled performance requires the effective and efficient gathering and processing of sensory information relevant to an action. The quality of sensory information depends on our actions because what we see, hear, and touch is

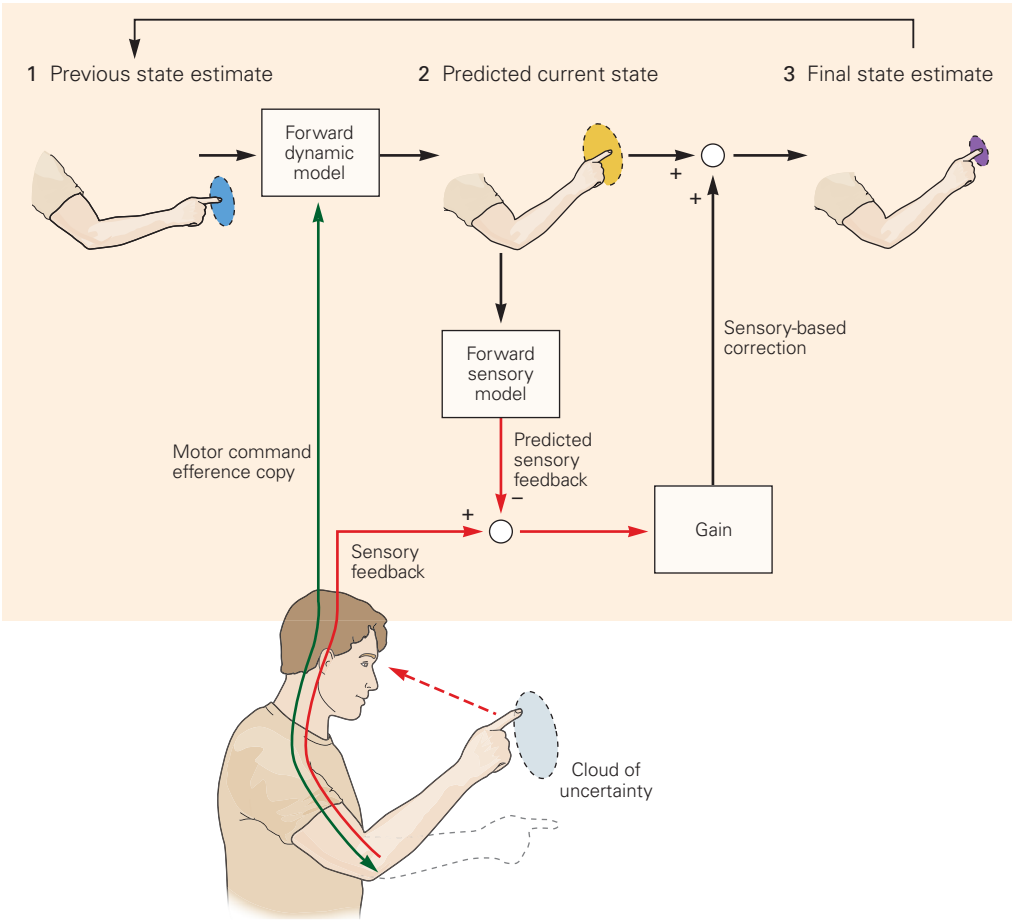

Figure 30–5 **An observer model.** The model is being used to estimate the finger's location during movement of the arm. A previous estimate of the distribution of possible finger positions (**1, blue cloud**) is updated (**2, yellow cloud**) using an efference copy of the motor command and a forward model of the dynamics. The updated distribution of finger positions is larger than that of the previous estimate. The model then uses a forward sensory model to predict the sensory feedback that would occur for these new finger positions, and the error between the predicted and actual sensory feedback is used to correct the estimate of current finger position. This correction changes the sensory error into state errors and also determines the relative reliance on the efference copy and sensory feedback.

The final estimate of current finger position (**3, purple cloud**) has less uncertainty. This estimate will become the new previous estimate for subsequent movement as this sequence is repeated many times. Delays in sensory feedback that must be compensated have been omitted from the diagram for clarity.

influenced by our movements. For example, the ocular motor system controls the eyes' sensory input by orienting the fovea to points of interest within the visual scene. Thus, movement can be used to efficiently gather information, a process termed *active sensing*. Active sensing involves two main processes: perception, by which we process sensory information and make inferences about the world, and action, by which we choose how to sample the world to obtain useful sensory information. Eye movements can betray the difference between skilled and amateur performers. For example, a batsman in the game of cricket will make a predictive saccade to the place where he expects a bowled ball to hit the ground, wait for it to bounce, and use a pursuit eye movement to follow the ball's trajectory after the bounce. A shorter latency for this first saccade distinguishes expert from amateur batsmen. Therefore, the motor system can also be used to improve our sensing of the world so as to gather information that, in turn, helps us achieve our motor goals.

Prediction Can Compensate for Sensorimotor Delays

As we have seen, delays in feedback can lead to problems during a movement, as the delayed information does not reflect the present state of the body and world. Two strategies, intermittency and prediction, can compensate for such delays and thus increase accuracy of information during movement. With intermittency, movement is momentarily interrupted by rest, as in eye saccades and manual tracking. Provided the interval of rest is greater than the time delay of the sensorimotor loop, intermittency fosters more accurate sensory feedback. Prediction is a better strategy and, as we have seen, can form a major component of a state estimator.

The nervous system uses different modes of control that depend on prediction and sensory feedback to different extents. These modes are nicely illustrated by differences in object manipulation under different conditions. When an object's behavior is unpredictable, sensory feedback provides the most useful signal for estimating load. For example, when flying a kite, we need to adjust our grip almost continuously in response to unpredictable wind currents. When dealing with such unpredictability, grip force needs to be high to prevent slippage because adjustments to grip tend to lag behind changes in load force (Figure 30–6A).

However, when handling objects with stable properties, predictive control mechanisms can be effective. For example, when the load is increased by a self-generated action, such as moving the arm, the grip force increases instantaneously with load force (Figure 30–6B). Sensory detection of the load would be too slow to account for this rapid increase in grip force.

Such predictive control is essential for the rapid movements commonly observed in dexterous behavior. Indeed, this predictive ability can be demonstrated easily with the "waiter task." Hold a weighty book on the palm of your hand with an outstretched arm. If you then use your other hand to remove the book (like a waiter removing objects from a tray), the supporting hand remains stationary. This shows our ability to anticipate a change in load caused by our own action and thus generate an appropriate and exquisitely timed change in muscle activity. In contrast, if someone else removes the book from your hand, even though you are watching the removal, it is close to impossible to maintain the hand stationary. We will see how cerebellar lesions affect this ability to predict, leading to a lack of such a coordinated response (Chapter 37).

Detecting any discrepancies between predicted and actual sensory feedback is also essential in motor control. This discrepancy, termed sensory prediction error, can drive learning of internal models and also be used for control. For example, when we pick up an object, we anticipate when the object will lift off the surface. The brain is particularly sensitive to the occurrence of unexpected events or the nonoccurrence of expected events (ie, to sensory prediction errors). Thus, if an object is lighter or heavier than expected and therefore lifts off too early or cannot be lifted, reactive responses are initiated.

In addition to its use in compensating for delays, prediction is a key element in sensory processing. Sensory feedback can arise as a consequence of both external events and our own movements. In the sensory receptors, these two sources are not distinguishable, as sensory signals do not carry a label of "external stimulus" or "internal stimulus." Sensitivity to external events can be amplified by reducing the feedback from our own movement. Thus, subtracting predictions of sensory signals that arise from our own movements from the total sensory feedback enhances the signals that carry information about external events. Such a mechanism is responsible for the fact that self-tickling is a less intense experience than tickling by another. When subjects were asked to tickle themselves using a robotic interface, but a time delay was introduced between the motor command and the resulting tactile input, the ticklishness increased. With such delayed tactile input, the predictions become inaccurate and thus fails to cancel the sensory feedback, resulting in the increased tickle sensation. Such predictive modulation of sensory

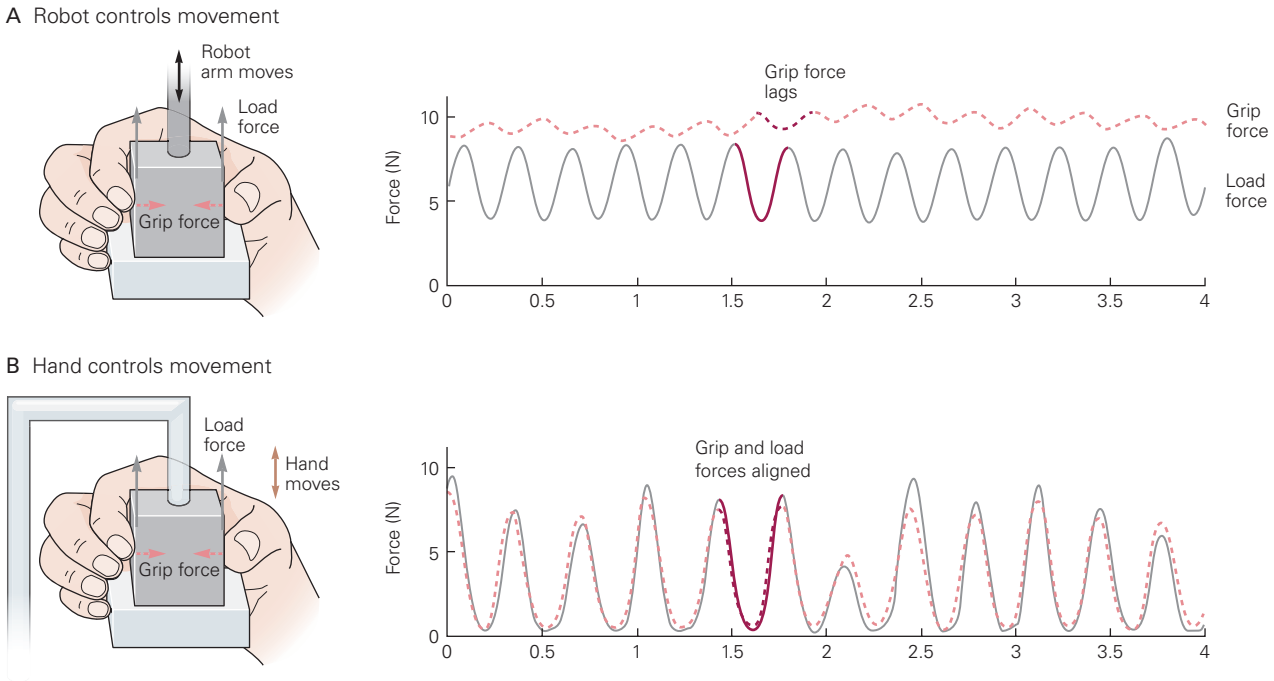

Figure 30–6 Anticipatory control of self-generated actions. (Adapted, with permission, from Blakemore, Goodbody, and Wolpert 1998. Copyright © 1998 Society for Neuroscience.

A. When a subject is instructed to hold an object to which a sinusoidal load force is mechanically applied, the grip force of the fingers is high to prevent slippage, and the grip force modulation lags behind the changes in load force. This is highlighted for a portion of the load force modulation (**dark red solid line**) that leads to a corresponding grip force (**dark red dashed line**), which is delayed. (Trial duration 4 s).

B. When a subject generates a similar load profile by pulling down on the fixed object, the load force can be anticipated, and thus, the grip force is lower and also tracks the load force without delay.

signals by motor actions is a fundamental property of many sensory systems.

Sensory Processing Can Differ for Action and Perception

A growing body of research supports the idea that the sensory information used to control actions is processed in neural pathways that are distinct from the afferent pathways that contribute to perception. It has been proposed that visual information flows in two streams in the brain (Chapter 25). A dorsal stream that projects to the posterior parietal cortex is particularly involved in the use of vision for action (Chapter 34), while a ventral stream that projects to the inferotemporal cortex is involved in conscious visual perception.

This distinction between the uses of vision for action and perception is based on a double dissociation seen in patient studies. For example, the patient D.F. developed visual agnosia after damage to her ventral stream. She is unable, for example, to indicate the orientation of a slot either verbally or with her hand. However, when asked to perform a simple action, such as putting a card through the slot, she has no difficulty orienting her hand appropriately to put the card through the slot (Chapter 59). Conversely, patients with damage to the dorsal stream can develop optic ataxia in which perception is intact but control is affected.

Although the distinction between perception and action arose from clinical observations, it can also be seen in normal people, as in the size–weight illusion. When lifting two objects of different size but equal weight, people report that the smaller object feels heavier. This illusion, first documented more than 100 years ago, is both powerful and robust. It does not lessen when a person is informed that the objects are of equal weight and does not weaken with repeated lifting.

When subjects begin to lift large and small objects that weigh the same, they generate larger grip and load forces for the larger object because they assume that larger objects are heavier. After alternating between the two objects, they rapidly learn to scale their fingertip forces precisely for the true object weight (Figure 30–7). This shows that the sensorimotor system recognizes that the two weights are equal. Nevertheless, the size–weight illusion persists, suggesting not only that

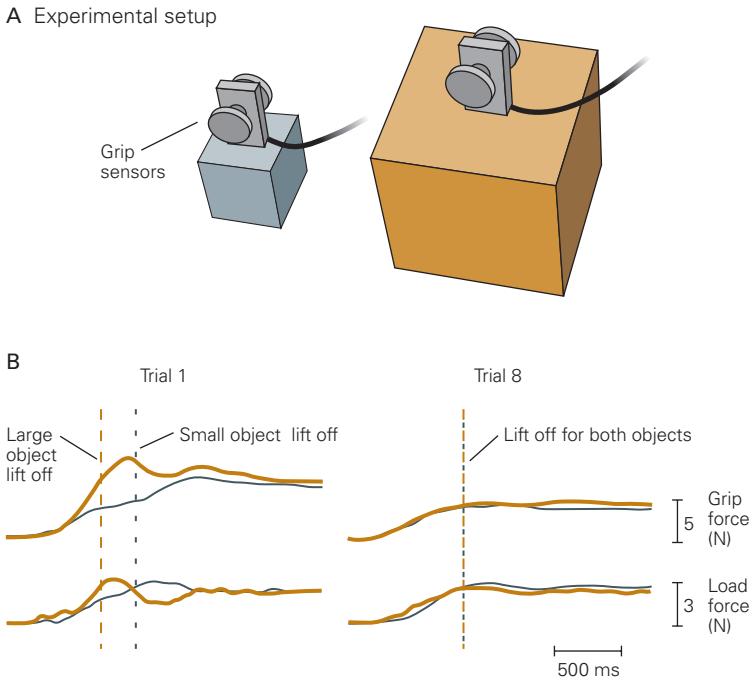

Figure 30–7 The size–weight illusion.

A. In each trial, subjects alternately lifted a large object and a small object that weighed the same. Subjects thought the smaller object felt heavier than it actually was.

B. In the first trial, subjects generated greater grip and load forces for the bigger object (**orange traces**) as it was expected to be heavier than the small object. In the eighth trial, the grip and load forces are the same for the two objects, showing that the sensorimotor system for this action generates grip and load forces appropriate to the weights of the two objects despite the persistent conscious perception of a difference in weight. the illusion is a result of high-level cognitive centers in the brain but also that the sensorimotor system can operate independently of these centers.

Motor Plans Translate Tasks Into Purposeful Movement

Real-world tasks are expressed as goals: I want to pick up a glass, dance, or have lunch. However, action requires a detailed specification of the temporal sequence of movements powered by the 600 or so muscles in the human body. There is clearly a gap between the statement of a goal and a motor plan that recruits specific muscles in pursuit of that goal.

Stereotypical Patterns Are Employed in Many Movements

The ability of the motor systems to achieve the same task in many different ways is called redundancy. If one way of achieving a task is not practical, there is usually an alternative. For example, the simplest of all tasks, reaching for an object, can be achieved in infinitely many ways.

The duration of the movement can be freely selected from a wide range and, given a particular choice of duration, the path and speed profile of the hand along the path (ie, trajectory) can take on many different patterns. Even selecting one trajectory still allows for infinitely many joint configurations to hold the hand on any given point of the path. Finally, holding the arm in a fixed posture can be achieved with a wide range of muscular co-contraction levels. Therefore, for any movement, a choice must be made from a large number of alternatives.

Do we all choose to move in our own way? The answer is clearly no. Repetitions of the same behavior by one individual as well as comparisons between individuals have shown that the patterns of movement are very stereotypical.

Invariance in stereotypical patterns of movement tells us something about the principles the brain uses when planning and controlling our actions. For example, when reaching, our hand tends to follow roughly a straight path and the hand speed over time is typically smooth, unimodal, and roughly symmetric (bell-shaped, Figure 30–8). The tendency to make straight-line movements characterizes a large class of movements and is surprising given that the muscles act to rotate joints.

To achieve such a straight-line movement of the hand requires complex joint rotations. The motions of the joints in series (the shoulder, elbow, and wrist) are complicated and vary greatly with different initial and final positions. Because rotation at a single joint would

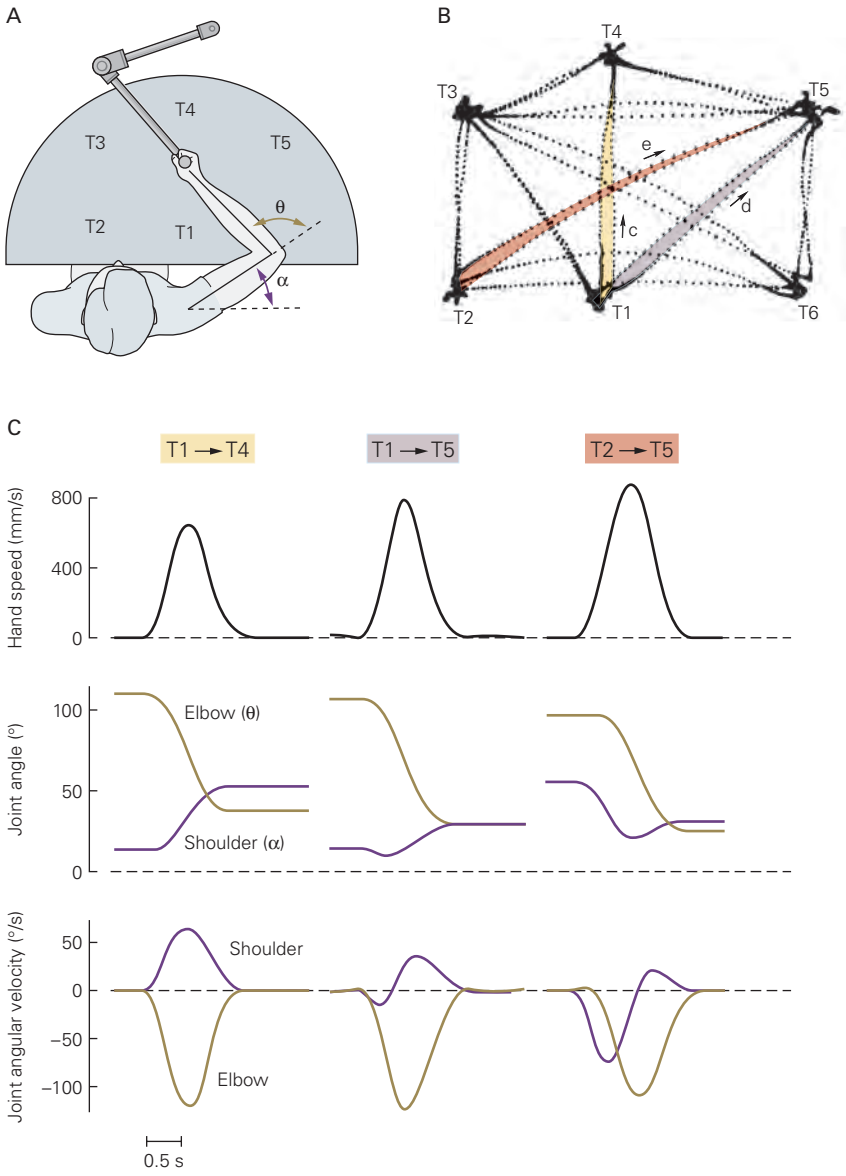

Figure 30–8 Hand path and velocity have stereotypical features. (Adapted, with permission, from Morasso 1981. Copyright © 1981 Springer Nature.)

A. The subject sits in front of a semicircular plate and grasps the handle of a two-jointed apparatus that moves in the horizontal plane and records hand position. The subject is instructed to move the hand between various targets (**T1–T6**).

B. The paths traced by one subject while moving his hand between targets.

C. Kinematic data for three hand paths (**c**, **d**, and **e**) shown in panel **B**. All paths are roughly straight, and all hand speed profiles have the same shape and scale in proportion to the distance covered. In contrast, the profiles for the angular velocity of the elbow and shoulder for the three hand paths differ. The straight hand paths and common profiles for speed suggest that planning is done with reference to the hand because these parameters can be linearly scaled. Planning with reference to joints would require computing nonlinear combinations of joint angles.

produce an arc at the hand, both elbow and shoulder joints must be rotated concurrently to produce a straight path. In some directions, the elbow moves more than the shoulder; in others, the reverse occurs. When the hand is moved from one side of the body to the other (Figure 30–8, movement from T2 to T5), one or both joints may have to reverse direction in midcourse. The fact that hand trajectories are more invariant than joint trajectories suggests that the motor system is more concerned with controlling the hand, even at the cost of generating complex patterns of joint rotations.

Such task-centered motor plans can account for our ability to perform a specific action, such as writing, in different ways with more or less the same result. Handwriting is structurally similar regardless of the size of the letters or the limb or body segment used to produce it (Figure 30–9). This phenomenon, termed motor equivalence, suggests that purposeful movements are represented in the brain abstractly rather than as sets of specific joint motions or muscle contractions. Such abstract representations of movement, which are able to drive different effectors, provide a degree of flexibility of action not practical with preset motor programs.

Motor Planning Can Be Optimal at Reducing Costs

Why do humans choose one particular manner of performing a task out of the infinite number of possibilities?

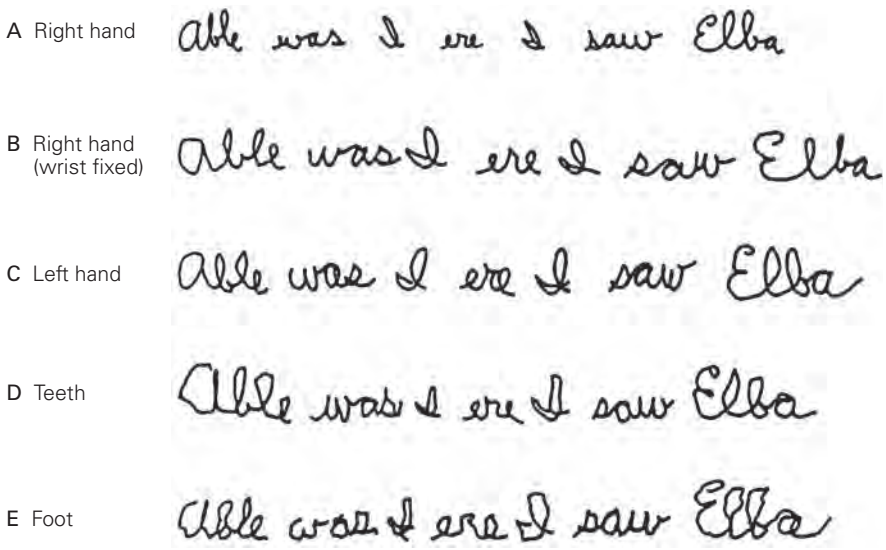

Figure 30–9 Motor equivalence. The ability of different motor systems to achieve the same behavior is called motor equivalence. For example, writing can be performed using different parts of the body. The examples here were written by the same person using the right (dominant) hand (**A**), the right hand with the wrist immobilized (**B**), the left hand (**C**), the pen gripped between the teeth (**D**), and the pen attached to the foot (**E**). (Reproduced, with permission, from Raibert 1977.)

Extensive research has attempted to answer this question, and the fundamental idea that has emerged is that planning can be equated with choosing the best way to achieve a task. Mathematically, this is equivalent to the process of optimizing (ie, minimizing) a cost associated with the movement. The cost is a way of quantifying what is good or bad about a movement (eg, energy, accuracy, stability) with a single number.

Different ways of achieving a task will lead to different costs. This allows all possible solutions to be ranked, thus identifying the one with the lowest cost. Invariances in our movements will reflect the particular cost we care about for that type of movement. Many costs have been proposed, but currently, most successful theories propose that there are two main components to movement cost: task success and effort. The effort component means that we want to achieve success but with minimal energetic cost.

To understand how task success is a component of the cost, it is useful to understand what leads to lack of success. Having inaccurate internal models or processing clearly limits our ability to complete tasks, and motor learning is designed to keep these processes accurate. However, low-level components in the motor system, such as motor noise, limit success. Movements tend to be variable, and the variability tends to increase with the speed or force of the movement. Part of this increase is caused by random variation in both the excitability of motor neurons and the recruitment of additional motor units needed to increase force. Incremental increases in force are produced by progressively smaller sets of motor neurons, each of which produces disproportionately greater increments of force (Chapter 31). Therefore, as force increases, fluctuations in the number of motor neurons lead to greater fluctuations in force.

The consequences of this can be observed experimentally by asking subjects to generate a constant force. The variability of such force production increases with the level of the force. Over a large range, this increase in variability is captured by a constant coefficient of variation (the standard deviation divided by the mean force). This dependence of variability on force also increases the variability of pointing movements as the speed of movement increases (as greater speed requires greater muscle force). The decrease in movement accuracy with increasing speed is known as the speed–accuracy trade-off (Figure 30–10). This relationship is not fixed, and part of skill learning, such as learning to play the piano, involves being able to increase speed without sacrificing accuracy.

In general, effort and accuracy are in conflict. Accuracy requires energy because corrections require muscular activity and thus comes at some cost. The trade-off between accuracy and energy varies for different movements. When walking, we could choose to step gingerly to ensure we never trip, but this would require substantial energy use. Therefore, we are willing to save energy by allowing ourselves the risk of occasionally tripping. In contrast, while eating with a knife and fork, we prioritize accuracy over energy to ensure the fork does not end up in our cheek.

The optimal movement is thus the one that minimizes the bad consequences of noise while saving energy. One way to do this is to specify a desired

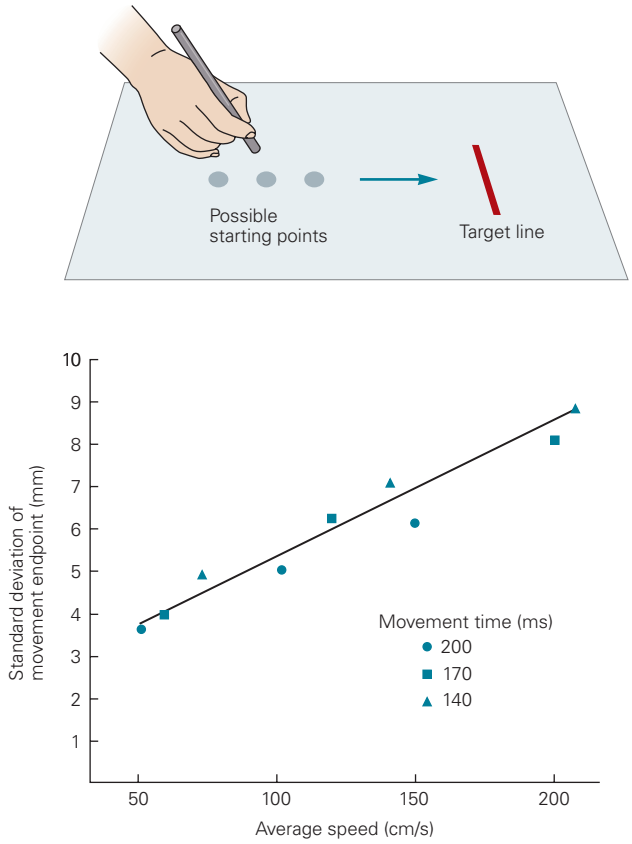

Figure 30–10 Accuracy of movement varies in direct proportion to its speed. Subjects held a stylus and had to hit a straight line lying perpendicular to the direction in which they moved the stylus. Subjects started from one of three different initial positions and were required to complete the movement within three different times (140, 170, or 200 ms). A trial was successful if the subject completed the movement within 10% of the required time. Only successful trials were used for analysis. Subjects were informed when a trial was not successful. The variability in the motion of the subjects' arm movements is shown in the plot as the standard deviation of the movement endpoint plotted against average speed (for each of three movement starting points and three movement times, giving nine data points). The variability in movement increases in proportion to the speed and therefore to the force producing the movement. (Adapted, with permission, from Schmidt et al. 1979.)

movement trajectory or sequence of states that can be considered optimal. Although noise and environmental disturbances can cause the motor system to deviate from the desired behavior, the role of feedback is simply to return the movement back to the desired trajectory. However, this approach is not necessarily computationally efficient. Rather than specifying the desired state of the body, we can specify an optimal feedback controller to generate the movement.

Optimal Feedback Control Corrects for Errors in a Task-Dependent Manner

Optimal feedback control aims to minimize a cost such as a combination of energy and task inaccuracy (Chapter 34). This type of feedback control is based on the idea that people do not plan a trajectory given a particular cost. Instead, the cost is used to create a feedback controller that specifies, for example, how the feedback gain for positional errors (and other errors such as velocity and force) changes over time. Therefore, given the goal of the task, the controller specifies the motor command suitable for different possible states of the body. The trajectory is then simply a consequence of applying the feedback control law to the current estimate of the state of the body (Figure 30–11). The feedback controller is optimal in that it can minimize the cost even in the presence of potential disturbances.

Optimal feedback control, therefore, does not make a hard distinction between feedforward and feedback control. Rather, during a task, the balance between feedforward and feedback control varies along a continuum that depends on the extent to which the estimate of current body state is influenced by predictions (feedforward) or by sensory input (feedback).

An important feature of optimal feedback control is that it will correct only for deviations that are task relevant and allow variation in task-irrelevant deviations. For example, when reaching to open an exit door that has a long horizontal handle, it is of little importance where along the handle one makes contact, so deviations in the horizontal direction can be ignored. Such considerations lead naturally to the minimal intervention principle that one should only intervene in an ongoing task if deviations will affect task success.

Intervening will generally add noise into the system (and require an increased effort), so intervening unnecessarily will lead to a decrement in performance. The aim of optimal feedback control is not to eliminate all variability, but to allow it to accumulate in dimensions that do not interfere with the task while minimizing it in the dimensions relevant for the task completion. The minimal intervention principle is supported by studies that show that feedback does not always return the system to the unperturbed trajectory but often acts in a manner to reduce the effect of the disturbance on the achievement of the task goal and to ensure that corrections are task-dependent.

Optimal feedback control emphasizes the setting of feedback gains, which can be partially instantiated by reflexes that generate rapid motor responses. Optimal feedback control proposes that these rapid responses should be highly tuned to the task at hand.

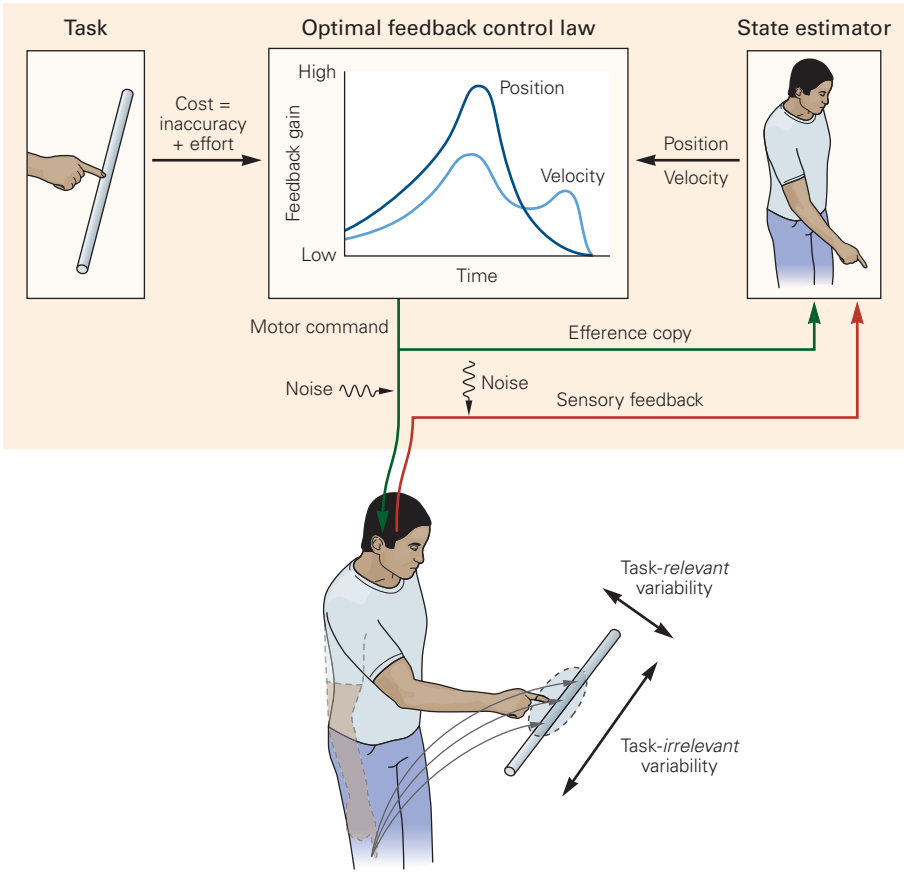

Figure 30–11 Optimal feedback control. In order to generate a movement for a given task, such as touching a horizontal bar, the sensorimotor system specifies a cost that is a combination of accuracy (eg, distance of the finger to the bar) and effort. To generate a movement that minimizes this cost, the sensorimotor system sets up an optimal feedback control rule that specifies the time-varying gains. These gains specify how the motor command should depend on states such as positional error and hand velocity. The form of this feedback control law assures that the movement is the best it can be in the presence of internal noise and external perturbations. The optimal behavior tends to let variability (**blue ellipsoid**, showing the possible final locations of the hand) accumulate in dimensions that do not affect task success (task-irrelevant variability), such as along the axis of the bar, while controlling variability that would lead to the hand missing the bar (task-relevant variability). Three paths for reaching from the same starting point are shown; corrections are made only in the task-relevant dimension.

Although the short-latency (monosynaptic) stretch reflex responds only to muscle stretch, the long-latency response has long been known to respond to task-dependent factors (Chapter 32). Optimal feedback control is important because it combines trajectory generation, noise, and motor cost and provides a clear comparison for the results of experimental work.

Multiple Processes Contribute to Motor Learning

Animals have a remarkable capacity for learning new motor skills simply through everyday interaction with their environment. Although evolution can hard wire some innate behaviors, such as the ability of a foal to stand or a spider to spin a web, motor learning is required to adapt to new and varying environments.

New motor skills cannot be acquired by fixed neural systems. Sensorimotor systems must constantly adapt over a lifetime as body size and proportions change, thereby maintaining an appropriate relationship between motor commands and body mechanics. In addition, learning is the only way to acquire motor skills that are defined by social convention, such as writing or dancing.

Most forms of motor learning involve *procedural* or *implicit* learning, so-called because subjects are generally unable to express what it is they have learned. Implicit learning often takes place without consciously thinking about it and can be retained for extended periods of time without practice (Chapter 52). Typical examples of procedural learning are learning to ride a

bicycle or play the piano. In contrast, *declarative* or *explicit* learning refers to knowledge that can be expressed in statements about the world and is available to introspection (Chapter 52). Memorizing the names of the cranial nerves or the directions to the local hospital are examples of explicit learning. Declarative memory tends to be easily forgotten, although repeated exposure can lead to long-lasting retention. We use explicit learning strategies when initially learning some motor tasks, such as driving a car, but the skill becomes automatic with time and practice.

Motor learning can occur more or less immediately or over time. We learn to pick up an object of unknown weight almost immediately, and we learn to ride a bicycle after a few weeks of practice, but mastering the piano requires years. These different timescales may reflect the intrinsic difficulty of the task as well as evolutionary constraints that have to be unlearned to perform the task. For example, piano playing requires learning precise control of individual fingers, whereas in normal movements, such as reaching and grasping, individuated finger movements are rare. Sensorimotor learning can be divided into two broad, but overlapping, classes: adaptations to alterations in the properties of sensorimotor systems and learning new skills. We focus on each in turn.

Error-Based Learning Involves Adapting Internal Sensorimotor Models

Error-based learning is the driving force behind many well-studied sensorimotor adaptation paradigms. For example, the relation between the visual and proprioceptive location of a limb can be altered by wearing prismatic glasses (or even spectacles). This shifts the visual input so that a person's reach for an object is misdirected. Over repeated attempts, the reach trajectories are adjusted to account for the discrepancy between vision and proprioception, a process termed visuomotor learning. Similarly, to control a computer mouse, we must learn the kinematic relation between the movement of the mouse and the cursor on the screen. In addition, the properties of the limbs change with both growth and tool use. The brain must adapt to such changes by reorganizing or adjusting motor commands.

In error-based learning, the sensorimotor system senses the outcome of each movement and compares this to both the desired outcome and the predicted outcome. For example, when shooting a basketball the desired outcome is for the ball to go through the hoop. However, once you let go of the ball you may predict that the ball will miss to the right of the hoop. The difference between the prediction and actual outcome, termed the sensory prediction error, can be used to update the internal model of how the ball responds to your actions. The difference between the actual and desired outcome, termed the target error, can be used to adjust your plan (i.e. aim direction) to reduce the error. Both sensory prediction errors and target errors are important for driving learning.

Additional transformations may have to be applied to the error signal before it can be used to train an internal model. For example, when we throw a dart, errors are received in visual coordinates. This sensory error must be converted into motor command errors suitable for updating a control process such as an inverse model. Error-based learning tends to lead to trial-by-trial reduction in error as the motor system learns the novel sensorimotor properties.

An example of such error-based learning in reaching occurs when the dynamics of the arm are unexpectedly changed. As we saw earlier, we normally move the hand with a straight-line path to reach an object. Unexpected dynamic interactions can produce curved paths, but subjects learn to anticipate and compensate for these effects. This learning is conveniently studied by having subjects make reaching movements while holding the end of a robotic apparatus that can introduce novel forces on the arm (Figure 30–12A–C). Applying a force that is proportional to the speed of the hand but that acts at right angles to the direction of movement will produce a curved movement before finally reaching the target. Over time, the subject adapts to this perturbation and is able to maintain a straight-line movement (Figure 30–12D).

Subjects might adapt to such a situation in either of two ways. Subjects could co-contract the muscles in their arm, thereby stiffening the arm and reducing the impact of the perturbation, or they could learn an internal model that compensates for the anticipated force. By examining the aftereffects (movements after the robot is turned off), we can distinguish between these two forms of learning. If the arm simply stiffens, it should continue to move in a straight path. If a new internal model is learned, the new model should compensate for a force that no longer exists, thereby producing a path in the direction opposite from the earlier perturbation. Early in learning, co-contraction is used to reduce the errors before an internal model can be learned, but the co-contraction then decreases as the internal model is able to compensate for the perturbation. Therefore, when the force is turned off after learning, subjects normally show a large aftereffect in the opposite direction, demonstrating that they have compensated for the perturbation (Figure 30–12D).

Such error-based processes appear to underlie adaptation across a number of different movement

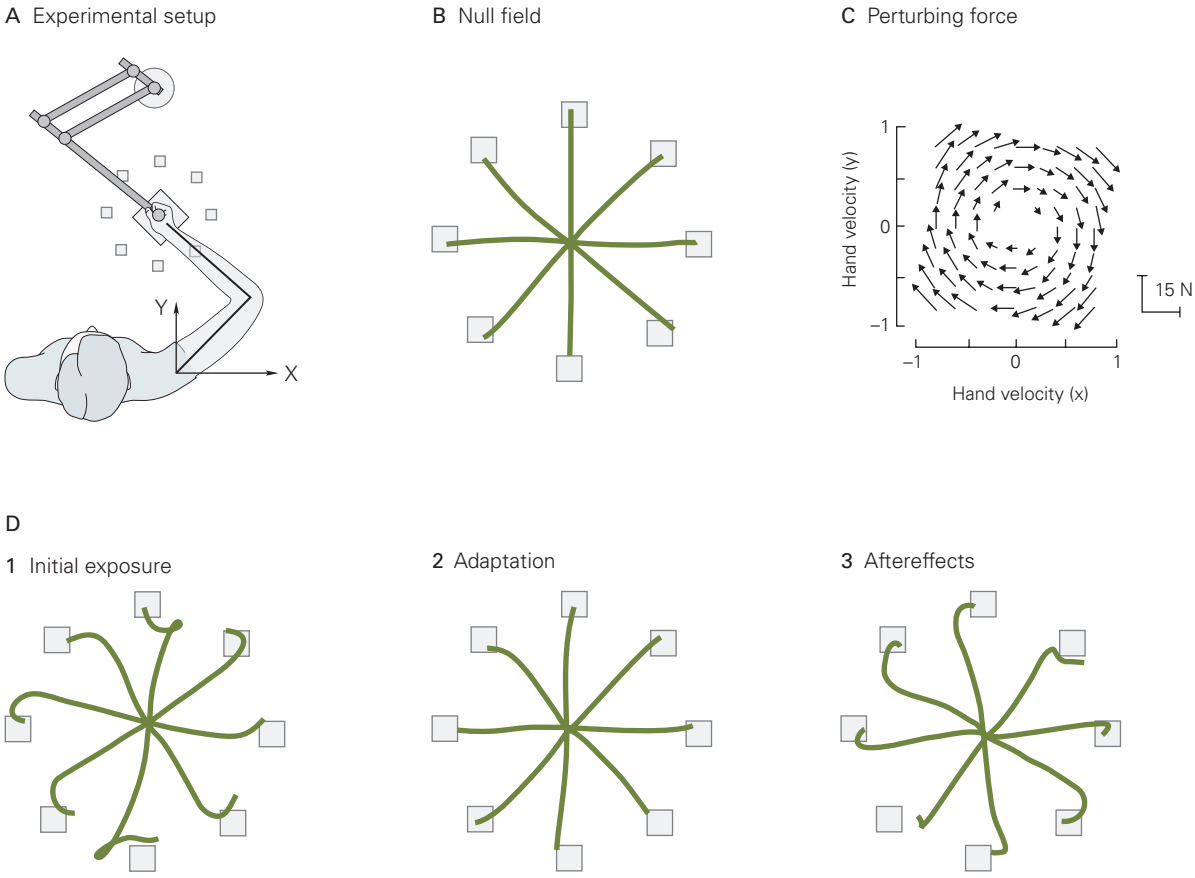

Figure 30–12 Learning improves the accuracy of reaching in a novel dynamic environment. (Adapted, with permission, from Brashers-Krug, Shadmehr, and Bizzi 1996. Copyright © 1996 Springer Nature.)

A. A subject holds a robotic apparatus that measures the position and velocity of the hand and applies forces to the hand.

B. When the motors are off (null field), the subject makes approximately straight movements from the center of the workspace to targets arrayed in a circle.

C. A clockwise force is then applied to the hand, shown as a function of hand velocity. This field produces a force proportional to the speed of the hand that always acts at right angles to the current direction of motion.

D. Initially, the hand paths are severely perturbed in response to the perturbing force (1). After some time, the subject adapts and can again follow a straight path during the entire movement (2). When the motors are then turned off, movement is again perturbed, but in a direction opposite to the earlier perturbation (3).

types and effectors, from the eye to whole-body movements. For example, our normal symmetric pattern of gait seems to rely on error-based learning. When the gait pattern of subjects is perturbed by walking on a split-belt treadmill in which one belt moves faster than the other, they initially limp. However, step by step the gait pattern naturally regains its symmetry (Figure 30–13), thus showing that error-based learning can drive complex whole-body coordinated movements. There is extensive evidence that fast trial-by-trial error-based learning relies on the cerebellum (Chapter 37).

Motor adaptation may not be a single unitary process. Recent evidence suggests that adaptation is driven by interacting processes whose outputs are combined. These interacting processes could have different temporal properties: one process quickly adapting to perturbations but also rapidly forgetting what was learned and the other learning more slowly but retaining learning for a longer period (Figure 30–13B). The advantage of such a mechanism is that the learning processes can be matched to the temporal properties of the perturbations, which can range from short-lived (fatigue) to long-lasting (growth).

Although motor learning often takes much practice, once a task is no longer performed, deadaptation is typically faster. However, the sensory inputs associated with the particular action can be enough to switch behavior. When subjects wear prismatic glasses

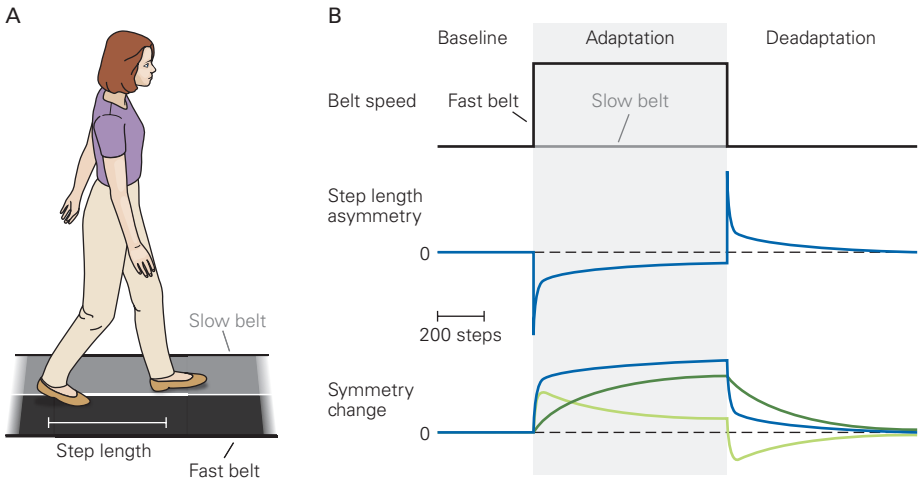

Figure 30–13 Learning new coordination patterns in walking.

A. A subject walks on a split-belt treadmill. When the two belts move at the same speed, subjects have a symmetric gait pattern with equal step lengths.

B. In an adaptation study, the speeds of the belts are initially the same, then become split so that the right belt moves faster than the left, and then finally return to the same speed (**top**). Step length symmetry is initially lost when the belts move at different speeds, causing the subject to limp. Over time, the symmetry is restored and the limping is abolished. When the belts are once again moving at the same speed, an aftereffect is seen (**middle**). Maurice Smith and colleagues have shown that this type of adaptation is composed of multiple underlying processes that adapt on different timescales (**bottom**). The change in the step length symmetry is composed of two processes: a fast process (**light green line**) that adapts quickly but also rapidly forgets what has been learned, and a slow process (**dark green line**) that learns more slowly but has better retention. These processes both adapt to learn from the error, and the sum of these processes is the final adaptation (**blue line**). This dual-rate learning system gives rise to the typical double exponential learning curves seen in many forms of adaptation in which adaptation is initially fast but tends to slow down as learning proceeds. (Adapted, with permission, from Roemmich, Long, and Bastian 2016.)

that shift visual space, for example, they initially miss when reaching to targets but soon learn to reach correctly. After repeated trials, the mere feel of the glasses, without the prisms in place, is sufficient to evoke the adaptive behavior appropriate for the prisms.

In general, we can quantify performance with two measurements, accuracy and precision. Accuracy is a measure of systematic errors or biases, for example, on average how far a series of thrown darts are away from the target. In contrast, precision is a measure of random errors, or statistical variability, in our actions. Both accuracy and precision contribute to performance. In general, accuracy can be improved by adapting or calibrating motor commands so as to reduce systematic errors. Although there is always some variability in movement arising from irreducible sensory and motor noise, the variability, as we have seen, can be reduced through planning so as to have minimal impact on task success. Most motor learning tends to become automatic (ie, implicit) with time, but early learning of some tasks can be aided by explicit learning (ie, strategy), such as a verbal instruction on how best to approach the task.

Not all sensory modalities are equally important in learning all motor tasks. In learning dynamic tasks, proprioception and tactile input are more important than vision. We normally learn dynamic tasks equally well with or without vision. However, individuals who have lost proprioception and tactile input have particular difficulty controlling the dynamic properties of their limbs or learning new dynamic tasks without vision (Box 30–3).

Skill Learning Relies on Multiple Processes for Success

In contrast to error-based learning in which the sensorimotor system adapts to a perturbation to return to preperturbation performance, learning skills such as tying one's shoelaces, juggling, typing, or playing the piano instead involves improving performance in the absence of a perturbation. Such learning tends to improve the speed–accuracy trade-off. Initially, we may be able to hit the correct keys on a keyboard when paced 1 second apart, but with practice, the same accuracy can be achieved at an increasingly quickening pace.

Box 30–3 Proprioception and Tactile Sense Are Critical for Sensorimotor Control

While visual impairment certainly has limiting effects on sensorimotor control, blind people are able to walk normally and reach and grasp known objects with ease. This is in stark contrast to the rare loss of proprioceptive and tactile sense.

Some sensory neuropathies selectively damage the large-diameter sensory fibers in peripheral nerves and dorsal roots that carry most proprioceptive information. Impairments in motor control resulting from loss of proprioception have fascinated neurologists and physiologists for well over a century. Studies of patients with sensory neuropathies provide invaluable insight into the interactions between sensation and movement planning.

As expected, such patients lose joint position sense, vibration sense, and fine tactile discrimination (as well as tendon reflexes), but both pain and temperature senses are fully preserved. Patients with peripheral neuropathies are unable to maintain a steady posture, for example, while holding a cup or standing, with the eyes closed. Movements also become clumsy, uncoordinated, and inaccurate.

Some recovery of function may occur over many months as the patient learns to use vision as a substitute for proprioception, but this compensation still leaves patients completely incapacitated in the dark. Some of this difficulty reflects an inability to detect errors that develop during unseen movements, as occurs if the weight of an object differs from expectation.

Peripheral neuropathies are particularly incapacitating when patients try to make movements with rapid direction reversals. Analyses of the joint torques during these movements show that subjects with intact proprioception anticipate intersegmental torques, whereas those without proprioception fail to do so (Figure 30–14).

However, the same patients easily adapt to drastic kinematic changes, such as tracing a drawing while viewing their hand in a mirror. In fact, they perform better than normal subjects, perhaps because they have learned to guide their movements visually and, because they lack proprioception, do not experience any conflict between vision and proprioception.

Even in normal subjects, the relative importance of tactile input in manipulation tasks can be easily demonstrated. It is relatively easy to light a match with one's eyes closed. However, if the tips of the digits are made numb with local anesthetic, then even under full vision the task is remarkably hard because the match tends to slip from the fingers.

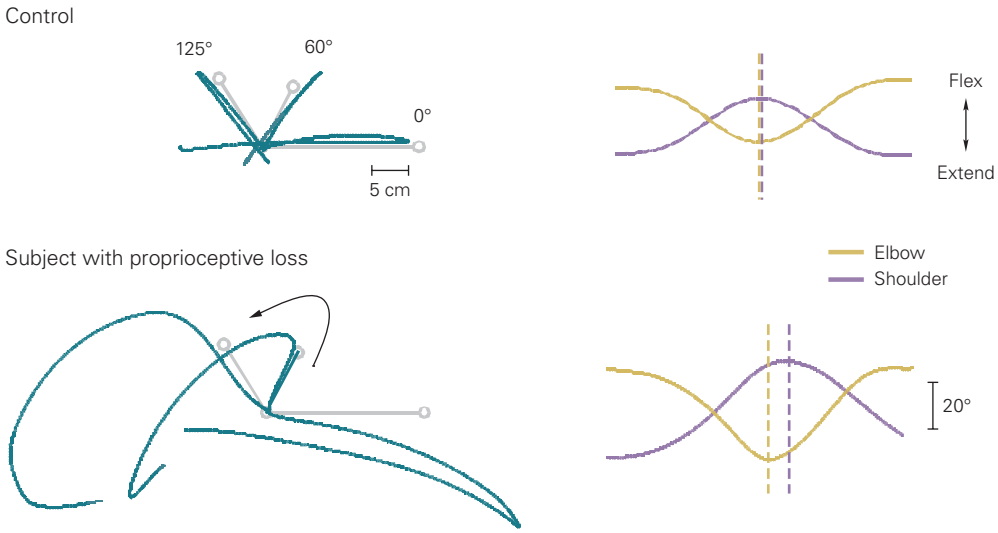

Figure 30–14 Patients lacking proprioception cannot make an accurate movement that requires a rapid reversal in path. (*Left*) The subject tries to trace a template (gray line) while her hand is hidden from view. The joint angles for the elbow and shoulder of a normal subject show good alignment (*Right top*), leading to an accurate reversal (*Left top*). In contrast, the timing of the joint reversal is poor in subjects who lack proprioceptive input (*Right bottom*), leading to large errors in the path (*Left bottom*). These patients cannot anticipate and correct for the intersegmental dynamics that occur around the path reversal. (Adapted, with permission, from Sainburg et al. 1995.)

For some skills, there can be a complex relation between the actions performed and success or failure at the task. For example, when children first sit on a swing, they have to learn the complex sequence of leg and body movements required to make the swing go higher. In contrast to error-based learning, there is no readily available error signal that can be used to adjust the current action because the swing's height is not directly determined by the current action but by a long history of body and leg motion. Learning in such complex scenarios can be achieved using reinforcement learning in which the sensorimotor system adjusts its commands in an effort to maximize reward, that is, task success. In the most general form, the performance measure that the reinforcement learning tries to maximize is the sum of all future rewards. However, as we tend to favor an immediate versus time-delayed reward, the sum is typically weighted to reflect this by progressively discounting future rewards.

Reinforcement learning is more general than error-based learning in that the training signal is success or failure, rather than an error at each point in time. Another distinguishing property of reinforcement learning is that the success or failure that the learning system receives can depend in nontrivial ways on the history of the actions taken. For tasks that require a complex sequence of actions to take place to achieve a goal, such as tying one's shoelaces, and the outcome or reward is removed in time from the action, error-based learning cannot easily be applied. A key problem that reinforcement solves is that of credit assignment: Which action within a sequence should we credit or blame when we eventually succeed or fail? This is just the sort of problem reinforcement learning algorithms are good at solving.

There are two main classes of reinforcement learning, those that depend on an internal model and those that do not. Model-based reinforcement builds a model of the task (eg, the structure of a maze). With such a model, the learner can efficiently plan in a goal-directed manner. In contrast, with model-free reinforcement learning, the learner simply associates movements with success or failure; those that lead to success are more likely to be performed again. Such learning can lead to motor habits. While model-free learning avoids the computational burden of building a model, it is also less able to generalize to novel situations. These two types of reinforcement learning can even act together, and different tasks can rely on them to different extents. Dopaminergic systems in the basal ganglia have been tied to signals that one would expect in reinforcement learning, such as expected reward. Moreover, dysfunction in these systems is related to movement disorders, addiction, and other problems that could be related to reinforcement signals (Chapter 38).

Finally, the development of efficient strategies plays a key part in motor skill acquisition. Skill learning for real-world tasks typically involves a sequence of decision-making processes at different spatiotemporal scales. The skill of a tennis player, for example, is not only determined by the precision with which she can strike the ball but also by the speed with which she can make the correct decision on where to aim it and how well she uses her senses to extract task-relevant information.

Sensorimotor Representations Constrain Learning

The information obtained during a single movement is often too sparse or noisy to unambiguously determine the source of error. For example, if a tennis player hits a shot into the net on the serve, the problem could be that the ball was not thrown high enough, the ball was hit too early, the racquet strings are loose, there was a gust of wind, or the player is fatigued. If the racquet dynamics have changed, the player would do well to adapt to these for the next shot. If a temporary gust of wind was the problem, then no adjustment is needed. To resolve this issue, the sensorimotor learning system constrains the way in which the system is updated in response to errors. These constraints reflect the internal assumptions about the task structure and the source of errors and determine how the system represents the task. Indeed, on a slower timescale, learning itself can alter the representation.

While the final output of the motor system is the contraction of its 600 or so muscles, it is not the case that the brain controls each independently. In current models of sensorimotor control, motor commands are generated by multiple modules that can be selectively engaged depending on the requirements of the task. Examples of modular architectures include multiple internal models, motor primitives, and motor synergies (Chapter 36).

Motor primitives can be thought of as neural control modules that can be flexibly combined to generate a large repertory of behaviors. A primitive might represent the temporal profile of a particular muscle activity or a set of muscles that are activated together, termed a synergy. The overall motor output will be the sum of all primitives, weighted by the level of the activation of each module. The makeup of the population of such primitives then determines which structural constraints are imposed on learning. For example, a behavior for which the motor system has many primitives will be easy to learn, whereas a behavior that cannot be approximated by any existing primitives would be impossible to learn.

Highlights

1. The primary purpose of the elaborate information processing and storage that occurs in the brain is to enable us to interact with our environment through our motor system.
2. Our infinitely varied and purposeful motor behaviors are governed by the integrated actions of the motor systems, including the motor cortex, spinal cord, cerebellum, and basal ganglia.
3. To control action, the central nervous system uses a hierarchy of sensorimotor transformations that convert incoming sensory information into motor outputs.
4. There is a trade-off in the speed versus sophistication of the different levels of sensorimotor response from rapid reflexes to slower voluntary control.
5. The motor systems generate commands using feedforward circuits or error-correcting feedback circuits; most movement involves both types of control.
6. The brain uses internal models of the sensorimotor system to facilitate control.
7. The state of the body is estimated using both sensory and motor signals together with a forward predictive mode to reduce the adverse effects of delays in feedback.
8. Variability in the sensory inputs and motor outputs together with inaccuracies in sensorimotor transformations underlie the errors and variability in movement, leading to the trade-off between speed and accuracy.
9. Motor planning can use the redundancy of the motor system to move in such a way as to reduce the negative consequences of motor noise while reducing effort.
10. Motor control circuits are not static but undergo continual modification and recalibration throughout life.
11. Motor learning improves motor control in novel situations, and different forms of sensory information are vital for learning. Error-based learning is particularly important for adapting to simple sensorimotor perturbations. Reinforcement learning is particularly important for more complex skill learning and can rely on a model (model-based) or on simply reinforcing motor actions directly (model-free).
12. The motor representations used by the brain constrain the way the sensorimotor system updates during learning.
13. Studies of sensorimotor control have focused on developing a detailed understanding of relatively simple tasks, such as reaching and walking. Although these tasks are amenable to analysis and modeling, they do not capture the full complexity of real-world motor control. The challenge will be to determine if these principles can be generalized to tasks such as tying shoelaces and learning to skateboard.

The Motor Unit and Muscle Action

Any action—ascending a flight of stairs, typing on a keyboard, even holding a pose—requires coordinating the movement of body parts. This is accomplished by the interaction of the nervous system with muscle. The role of the nervous system is to activate the muscles that provide the forces needed to move in a particular way. This is not a simple task. Not only must the nervous system decide which muscles to activate, how much to activate them, and the sequence in which they must be activated in order to move one part of the body, but it must also control the influence of the resultant muscle forces on other body parts and maintain the required posture.

This chapter examines how the nervous system controls muscle force and how the force exerted by a limb depends on muscle structure. We also describe how muscle activation changes to perform different types of movement.

The Motor Unit Is the Elementary Unit of Motor Control

A Motor Unit Consists of a Motor Neuron and Multiple Muscle Fibers

The nervous system controls muscle force with signals sent from motor neurons in the spinal cord or brain stem to the muscle fibers. A motor neuron and the muscle fibers it innervates are known as a motor unit, the basic functional unit by which the nervous system controls movement, a concept proposed by Charles Sherrington in 1925.

A typical muscle is controlled by a few hundred motor neurons whose cell bodies are clustered in a motor nucleus in the spinal cord or brain stem. The axon of each motor neuron exits the spinal cord through the ventral root or through a cranial nerve in the brain stem and runs in a peripheral nerve to the

muscle. When the axon reaches the muscle, it branches and innervates from a few to several thousand muscle fibers (Figure 31–1).

Once synaptic input depolarizes the membrane potential of a motor neuron above threshold, the neuron generates an action potential that is propagated along the axon to its terminals in the muscle. The action potential releases acetylcholine at the neuromuscular synapse, triggering an action potential at the sarcolemma of the muscle fiber (Chapter 12). A muscle fiber has electrical properties similar to those of a large-diameter, unmyelinated axon, and thus, action potentials propagate along the sarcolemma, although more slowly due to the higher capacitance of the fiber resulting from the transverse tubules (see Figure 31–9). Because the action potentials in all the muscle fibers of a motor unit occur at approximately the same time, they contribute to extracellular currents that sum to generate a field potential near the active muscle fibers.

Most muscle contractions involve the activation of many motor units, whose currents sum to produce signals (*compound action potentials*) that can be detected by electromyography. The electromyogram (EMG) is typically large and can be easily recorded with electrodes

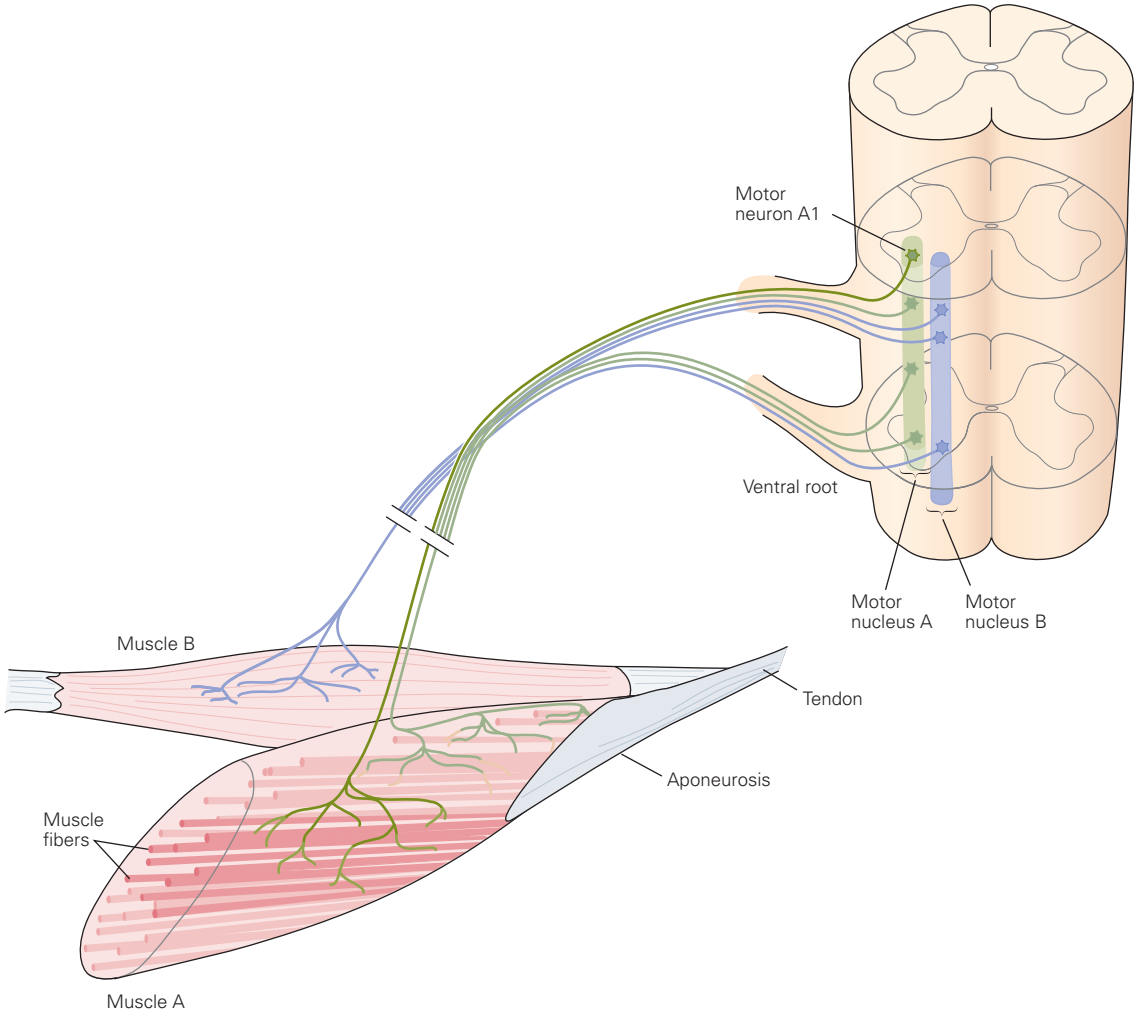

Figure 31–1 A typical muscle consists of many thousands of muscle fibers working in parallel and organized into a smaller number of motor units. A motor unit comprises a motor neuron and the muscle fibers it innervates, illustrated here by motor neuron A1. The motor neurons innervating one muscle are usually clustered into an elongated motor nucleus that may extend over one to four segments within the ventral spinal cord. The axons from a motor nucleus exit the spinal cord in several ventral roots and peripheral nerves but are collected into one nerve bundle near the target muscle. In the figure, motor nucleus A includes all those motor neurons innervating muscle A; likewise, motor nucleus B includes all the motor neurons that innervate muscle B. The extensively branched dendrites of each motor neuron (not shown in the figure) tend to intermingle with those of motor neurons from other nuclei.

placed on the skin over the muscle. The timing and amplitude of EMG activity, therefore, reflect the activation of muscle fibers by the motor neurons. EMG signals are useful for studying the neural control of movement and for diagnosing pathology (Chapter 57).

Each fiber in most mature vertebrate muscles is innervated by a single motor neuron. The number of muscle fibers innervated by one motor neuron, the *innervation number*, varies across muscles. In human skeletal muscles, the innervation number ranges from average values of 5 for an eye muscle to 1,800 for a leg muscle (Table 31–1). Because innervation number denotes the number of muscle fibers within a motor unit, differences in innervation number determine the differences in increments in force produced by activation of different motor units in the same muscle. Thus, the innervation number also indicates the fineness of control of the muscle at low forces; the smaller the innervation number, the finer the control achieved by varying the number of activated motor units.

The differences in innervation numbers between motor units in the same muscle can be substantial. For example, motor units of the first dorsal interosseous muscle of the hand have innervation numbers ranging from approximately 21 to 1,770. The strongest motor unit in the hand's first dorsal interosseous muscle can exert approximately the same force as the average motor unit in the leg's medial gastrocnemius muscle due to different ranges of innervation numbers in the two muscles.

Table 31–1 Innervation Numbers in Human Skeletal Muscles

Muscle	Alpha motor axons	Muscle fibers	Average innervation number
Biceps brachii	774	580,000	750
Brachioradialis	333	129,200	410
Cricothyroid	112	18,550	155
Gastrocnemius (medial)	579	1,042,000	1,800
Interossei dorsales (1)	119	40,500	340
Lumbricales (1)	96	10,269	107
Masseter	1,452	929,000	640
Opponens pollicis	133	79,000	595
Platysma	1,096	27,100	25
Posterior cricoarytenoid	140	16,200	116
Rectus lateralis	4,150	22,000	5
Temporalis	1,331	1,247,000	936
Tensor tympani	146	1,100	8
Tibialis anterior	445	272,850	613
Transverse arytenoid	139	34,470	247

The muscle fibers of a single motor unit are distributed throughout the muscle and intermingle with fibers innervated by other motor neurons. The muscle fibers innervated by a single motor unit can be distributed across 8% to 75% of the volume in a limb muscle, with 2 to 5 muscle fibers belonging to the same motor unit among 100 muscle fibers. Therefore, the muscle fibers in a cross-section through the middle of an entire muscle are associated with 20 to 50 different motor units. This distribution and even the number of motor units change with age and with some neuromuscular disorders (Chapter 57). For example, muscle fibers that lose their innervation after the death of a motor neuron can be reinnervated by collateral sprouts from neighboring axons.

Some muscles comprise discrete compartments that are each innervated by a different primary branch of the muscle nerve. Branches of the median and ulnar nerves in the forearm, for example, innervate distinct compartments in three multitendon extrinsic hand muscles that enable the fingers to be moved relatively independently. The muscle fibers belonging to each motor unit in such muscles tend to be confined to one compartment. A muscle can therefore consist of several functionally distinct regions.

The Properties of Motor Units Vary

The force exerted by a muscle depends not only on the number of motor units that are activated during a contraction but also on three properties of motor units: contraction speed, maximal force, and fatigability. These properties are assessed by examining the force exerted by individual motor units in response to variations in the number and rate of evoked action potentials.

The mechanical response to a single action potential is known as a *twitch contraction.* The time it takes the twitch to reach its peak force, the *contraction time,* is one measure of the contraction speed of the muscle fibers that compose a motor unit. The motor units in a muscle typically exhibit a range of contraction times from slow to fast contracting. The mechanical response to a series of action potentials that produce overlapping twitches is known as a *tetanic contraction* or *tetanus.*

The force exerted during a tetanic contraction depends on the extent to which the twitches overlap

and summate (ie, the force varies with the contraction time of the motor unit and the rate at which the action potentials are evoked). At lower rates of stimulation, the ripples in the tetanus denote the peaks of individual twitches (Figure 31–2A). The peak force achieved during a tetanic contraction varies as a sigmoidal function of action potential rate, with the shape of the curve depending on the contraction time of the motor unit (Figure 31–2B). Maximal force is reached at lower action potential rates for slow-contracting motor units than the rates needed to achieve maximal force in fast-contracting units.

The functional properties of motor units vary across the population and between muscles. At one end of the distribution, motor units have long twitch contraction times and produce small forces, but are less fatigable. At the other end of the distribution, motor units have short contraction times, produce large forces, and are

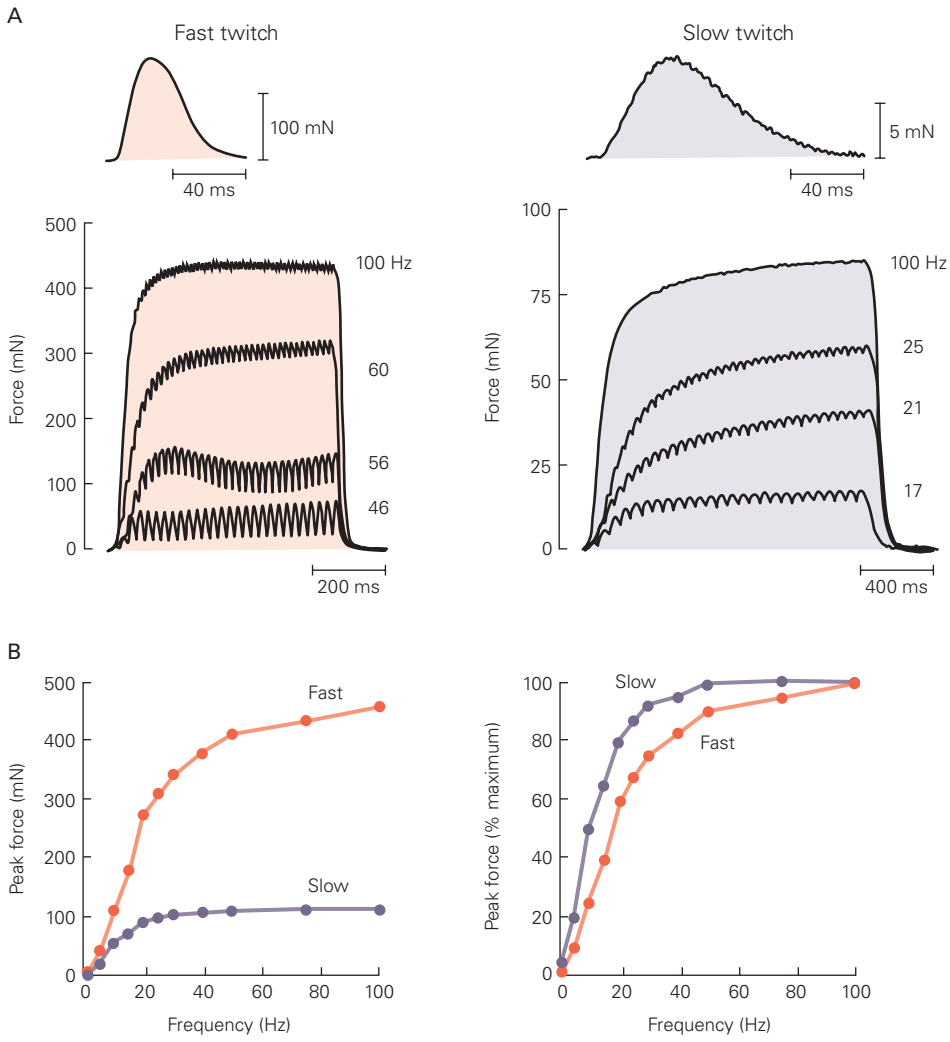

Figure 31–2 The force exerted by a motor unit varies with the rate at which its neuron generates action potentials.

A. Traces show the forces exerted by fast- and slow-contracting motor units in response to a single action potential (**top trace**) and a series of action potentials (set of **four traces below**). The time to the peak twitch force, or contraction time, is briefer in the faster unit. The rates of the action potentials used to evoke the tetanic contractions range from 17 to 100 Hz in the slow-contracting unit to 46 to 100 Hz in the fast-contracting unit. The peak tetanic force evoked by 100-Hz stimulation is greater for the fast-contracting unit. Note the different force scales for the two sets of traces. (Adapted, with permission, from Botterman, Iwamoto, and Gonyea 1986; adapted from Fuglevand, Macefield, and Bigland-Ritchie 1999; and Macefield, Fuglevand, and Bigland-Ritchie 1996.)

B. Relation between peak force and the rate of action potentials for fast- and slow-contracting motor units. The absolute force (*left plot*) is greater for the fast-contracting motor unit at all frequencies. At lower stimulus rates (*right plot*), the force evoked in the slow-contracting motor unit (longer contraction time) sums to a greater relative force (percent of peak force) than in the fast-contracting motor unit (shorter contraction time).

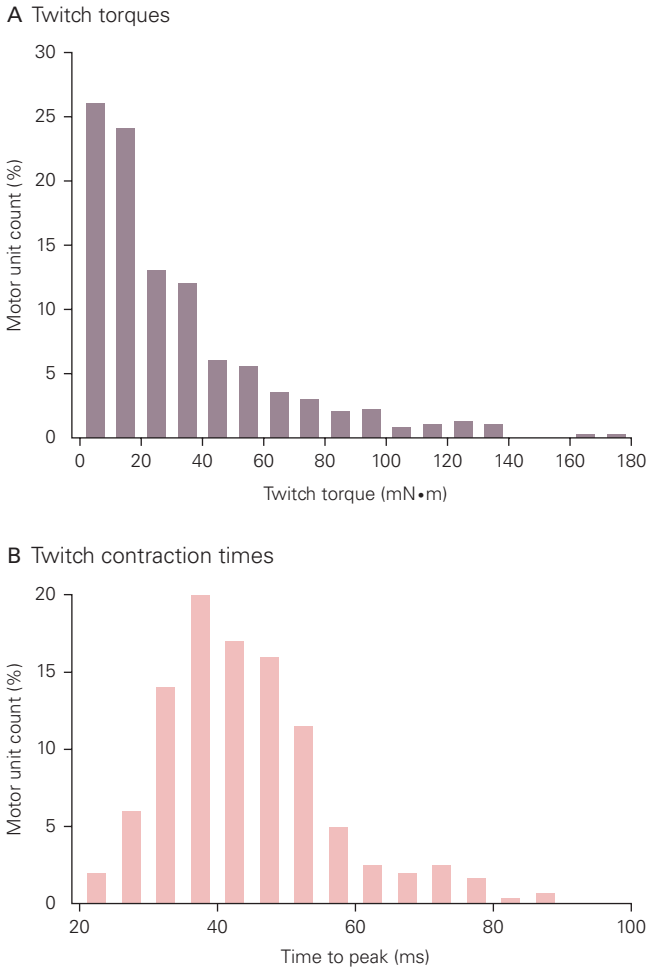

Figure 31–3 Most human motor units produce low forces and have intermediate contraction times. (Reproduced, with permission, from Van Cutsem et al. 1997. © Canadian Science Publishing.)

B. Distribution of twitch contraction times for 528 motor units in the tibialis anterior muscle.

more fatigable. The order in which motor units are recruited during a voluntary contraction begins with the slow-contracting, low-force units and proceeds up to the fast-contracting, high-force units. As observed by Jacques Duchateau and colleagues, most motor units in humans produce low forces and have intermediate contraction times (Figure 31–3).

The range of contractile properties exhibited by motor units is partly attributable to differences in the structural specializations and metabolic properties of muscle fibers. One commonly used scheme to characterize muscle fibers is based on their reactivity to histochemical assays for the enzyme myosin adenosine triphosphatase (ATPase), which is used as an index of contractile speed. Histochemical stains for myosin ATPase can identify two types of muscle fibers: type I (low levels of myosin ATPase) and type II (high levels of myosin ATPase). Slow-contracting motor units contain type I muscle fibers, and fast-contracting units include type II fibers. The type II fibers can be further classified as being less fatigable (type IIa) or more fatigable (type IIb, IIx, or IId), due to the association between myosin ATPase content and the relative abundance of oxidative enzymes. Another commonly used scheme distinguishes muscle fibers on the basis of genetically defined isoforms of the myosin heavy chain (MHC). Muscle fibers in slow-contracting motor units express MHC-I, those in the less fatigable fast-contracting units express MHC-IIA, and those in the more fatigable fast-contracting units express MHC-IIX.

In actuality, the contractile properties of single muscle fibers are less distinct than the two classification schemes suggest (Figure 31–4). In addition to the variability in the contractile properties of each type of muscle fiber (MHC-I, -IIA, or -IIX), some muscle fibers co-express more than one MHC isoform. Such hybrid muscle fibers exhibit contractile properties that are intermediate between the muscle fibers that compose a

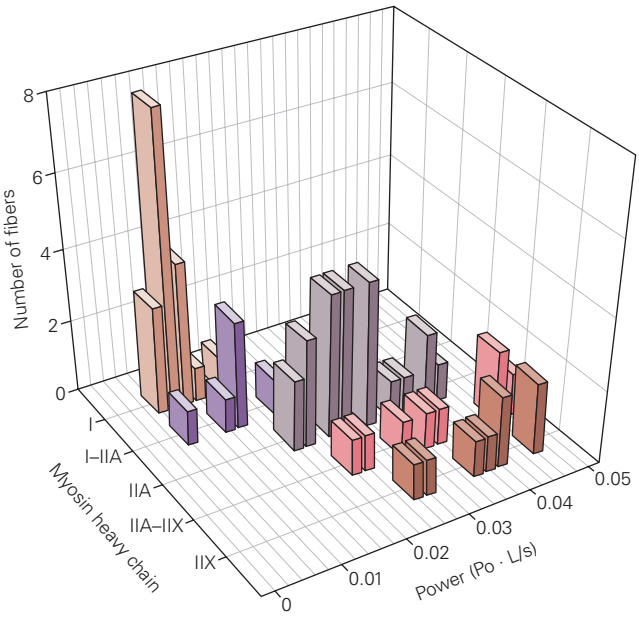

Figure 31–4 The contractile properties of muscle fiber types are distributed continuously. Peak power produced by segments of single muscle fibers from the vastus lateralis muscle with different types of myosin heavy chain (MHC) isoforms. Two types of hybrid fibers (I-IIA and IIA-IIX) contain isoforms of both types of MHCs. Power is calculated as the product of peak tetanic force (P_o) and maximal shortening velocity (segment length per second [L/s]). (Adapted, with permission, from Bottinelli et al. 1996. Copyright © 1996 The Physiological Society.)

single isoform. The relative proportion of hybrid fibers in a muscle increases with age. As with the distribution of contractile properties across motor units (Figure 31–3), the distribution across individual muscle fibers is also continuous, from slow to fast contracting and from least to most powerful (Figure 31–4).

Physical Activity Can Alter Motor Unit Properties

Alterations in habitual levels of physical activity can influence the three contractile properties of motor units (contraction speed, maximal force, and fatigability). A decrease in muscle activity, such as occurs with aging, bed rest, limb immobilization, or space flight, reduces the maximal capabilities of all three properties. The effects of increased physical activity vary with the intensity and duration of the activity. Brief sets of strong contractions performed a few times each week can increase motor unit force (strength training); brief sets of rapid contractions performed a few times each week can increase motor unit discharge rate (power training); and prolonged periods of weaker contractions can reduce motor unit fatigability (endurance training).

Changes in the contractile properties of motor units involve adaptations in the structural specializations and biochemical properties of muscle fibers. The improvement in contraction speed caused by power training, for example, is associated with an increase in the maximal shortening velocity of a muscle fiber caused by an increase in the quantity of myosin ATPase in the fiber. Similarly, the increase in maximal force is associated with the enlarged size and increased intrinsic force capacity of the muscle fibers produced by an increase in the number and density of the contractile proteins.

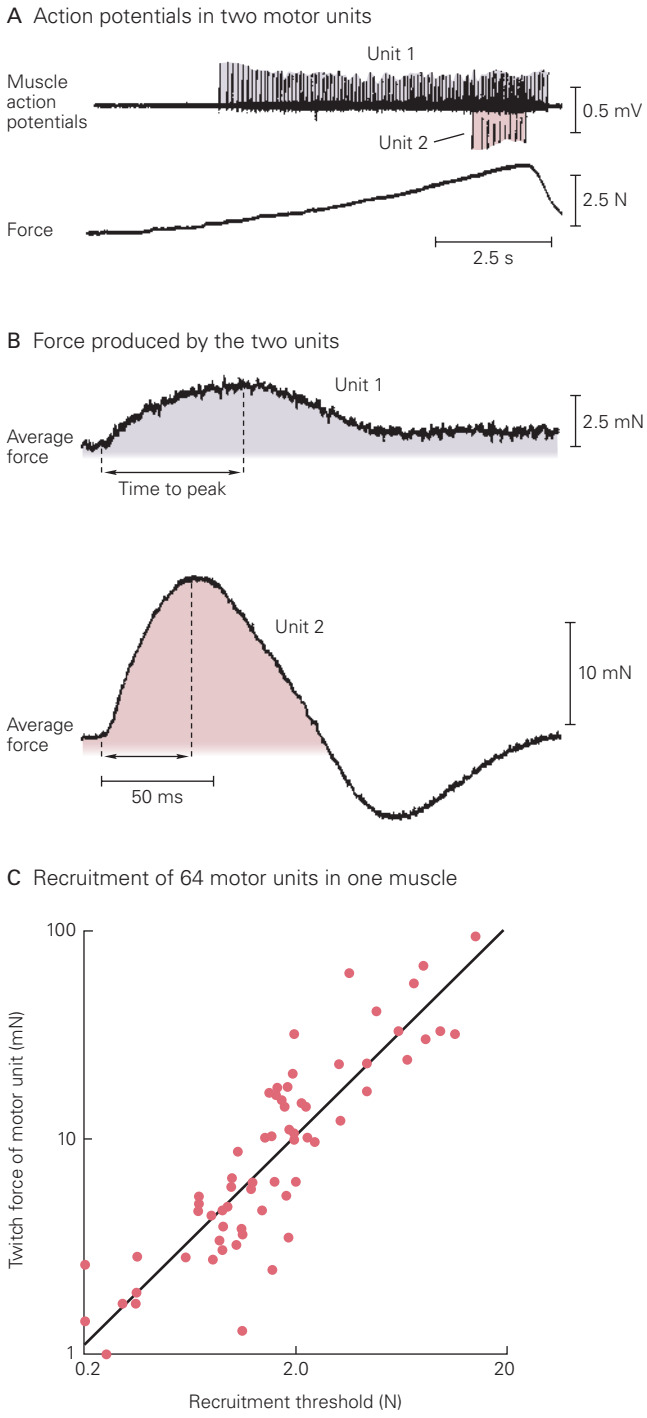
In contrast, decreases in the fatigability of a muscle fiber can be caused by many different adaptations, such as increases in capillary density, number of mitochondria, efficiency of the processes involved in activating the contractile proteins (excitation-contraction coupling), and oxidative capacity of the muscle fibers. Although the adaptive capabilities of muscle fibers decline with age, the muscles remain responsive to exercise even at 90 years of age.

Despite the efficacy of strength, power, and endurance training in altering the contractile properties of muscle fibers, these training regimens have little effect on the composition of a muscle's fibers. Although several weeks of exercise can change the relative proportion of type IIA and IIX fibers, it produces no change in the proportion of type I fibers. All fiber types adapt in response to exercise, although to varying extents depending on the type of exercise. For example, strength training of leg muscles for 2 to 3 months can increase the cross-sectional area of type I fibers by 0% to 20% and of type II fibers by 20% to 60%, increase the proportion of type IIa fibers by approximately 10%, and decrease the proportion of type IIx fibers by a similar amount. Furthermore, endurance training may increase the enzyme activities of oxidative metabolic pathways without noticeable changes in the proportions of type I and type II fibers, but the relative proportions of type IIa and IIx fibers do change as a function of the duration of each exercise session. Conversely, although several weeks of bed rest or limb immobilization do not change the proportions of fiber types in a muscle, they do decrease the size and intrinsic force capacity of muscle fibers. Adaptations in fiber type properties and proportions in turn alter the distribution of contractile properties in muscle fibers (Figure 31–4) and motor units (Figure 31–3).

Although physical activity has little influence on the proportion of type I fibers in a muscle, more substantial interventions can have an effect. Space flight, for example, exposes muscles to a sustained decrease in gravity that reduces the proportion of type I fibers in some leg muscles and decreases contractile properties. Similarly, surgically changing the nerve that innervates a muscle alters the pattern of activation and eventually causes the muscle to exhibit properties similar to those of the muscle that was originally innervated by the transplanted nerve. Connecting a nerve that originally innervated a rapidly contracting leg muscle to a slowly contracting leg muscle, for example, will cause the slower muscle to become more like a faster muscle. In contrast, a history of performing powerful contractions with leg muscles is associated with a modest reduction in the proportion of type I fibers, a marked increase in the proportion of type IIx fibers, and a huge increase in the power that can be produced by the type IIa and IIx fibers.

Muscle Force Is Controlled by the Recruitment and Discharge Rate of Motor Units

The force exerted by a muscle during a contraction depends on the number of motor units that are activated and the rate at which each of the active motor neurons discharges action potentials. Force is increased during a muscle contraction by the activation of additional motor units, which are recruited progressively from the weakest to the strongest (Figure 31–5). A motor unit's recruitment threshold is the force during the contraction at which the motor unit is activated. Muscle force decreases gradually by terminating the activity of motor units in the reverse order from strongest to weakest.



The order in which motor units are recruited is highly correlated with several indices of motor unit size, including the size of the motor neuron cell bodies, the diameter and conduction velocity of the axons, and the amount of force that the muscle fibers can exert. Because individual sources of synaptic input are broadly distributed across most neurons in a motor nucleus, the orderly recruitment of motor neurons is not accomplished by the sequential activation of different sets of synaptic inputs that target specific motor neurons. Rather, recruitment order is determined by intrinsic differences in the responsiveness of individual motor neurons to relatively uniform synaptic input.

One of these factors is the anatomical size of a neuron's soma and dendrites. Smaller neurons have a higher input resistance (R_{in}) to current and, due to Ohm's law ($\Delta V_m = I_{syn} \times R_{in}$), experience a greater change in membrane potential (ΔV_m) in response to a given synaptic current (I_{syn}). Consequently, increases in the net excitatory input to a motor nucleus cause the levels of depolarization to reach threshold in an ascending order of motor neuron size: Contraction force is increased by recruiting the smallest motor neuron first and the largest motor neuron last (Figure 31–6). This effect is known as the size principle of motor neuron recruitment, a concept enunciated by Elwood Henneman in 1957.

The size principle has two important consequences for the control of movement by the nervous system. First, the sequence of motor neuron recruitment is determined by the properties of the spinal neurons and not by supraspinal regions of the nervous system. This means that the brain cannot selectively activate specific motor units. Second, the axons arising from small motor neurons are thinner than those associated with

Figure 31–5 (Left) Motor units that exert low forces are recruited before those that exert greater forces. (Adapted, with permission, from Desmedt and Godaux 1977; Milner-Brown, Stein, and Yemm 1973. Copyright © 1973 The Physiological Society.)

A. Action potentials in two motor units were recorded concurrently with a single intramuscular electrode while the subject gradually increased muscle force. Motor unit 1 began discharging action potentials near the beginning of the voluntary contraction, and its discharge rate increased during the contraction. Motor unit 2 began discharging action potentials near the end of the contraction.

B. Average twitch forces for motor units 1 and 2 as extracted with an averaging procedure during the voluntary contraction.

C. The plot shows the net muscle forces at which 64 motor units in a hand muscle of one person were recruited (recruitment threshold) during a voluntary contraction relative to the twitch forces of the individual motor units.

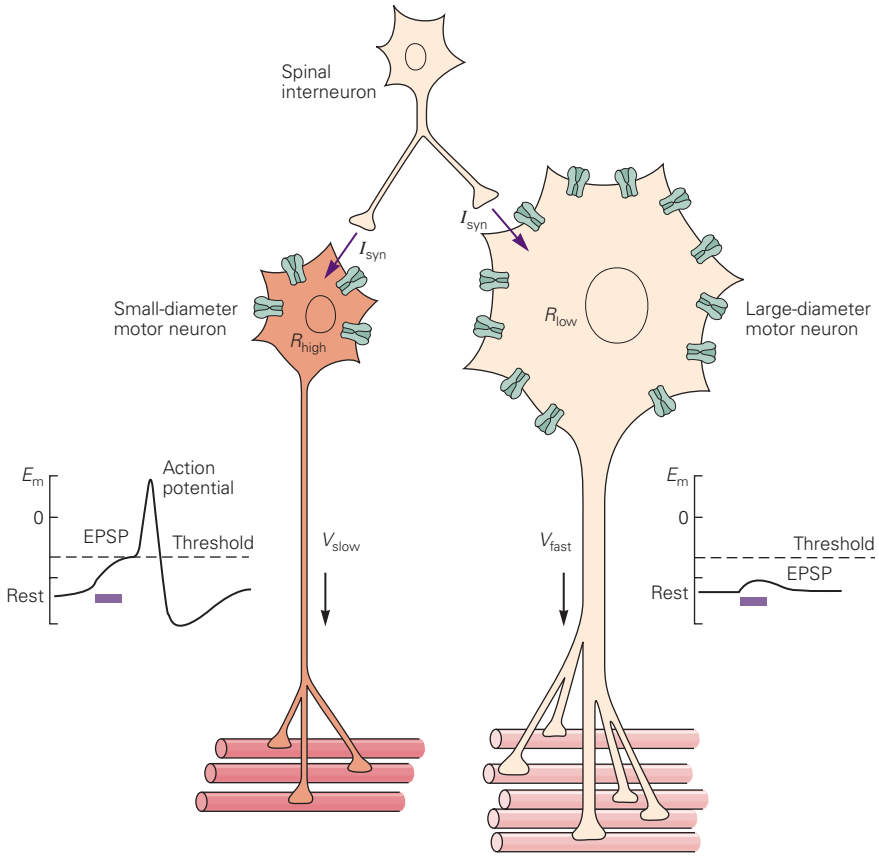


Figure 31–6 The size principle of motor neuron recruitment. Two motor neurons of different sizes have the same resting membrane potential (V_r) and receive the same excitatory synaptic current (I_{syn}) from a spinal interneuron. Because the small motor neuron has a smaller surface area, it has fewer parallel ion channels and therefore a higher input resistance (R_{high}). According to Ohm's law ($V = IR$), I_{syn} in the small neuron produces a large excitatory postsynaptic potential (**EPSP**) that reaches threshold, resulting in the discharge of an action potential. However, the axon of the small motor neuron has a small diameter and thus conducts the action potential at a relatively low velocity (V_{slow}) and to fewer muscle fibers. In contrast, the large motor neuron has a larger surface area, which results in a lower transmembrane resistance (R_{low}) and a smaller EPSP that does not reach threshold in response to I_{syn}; however, when synaptic input does reach threshold, the action potential is conducted relatively rapidly (V_{fast}) (Chapter 9).

large motor neurons and innervate fewer muscle fibers. Because the number of muscle fibers innervated by a motor neuron is a key determinant of motor unit force, motor units are activated in order of increasing strength, so the earliest recruited motor units are the weakest ones.

As suggested by Edgar Adrian in the 1920s, the muscle force at which the last motor unit in a motor nucleus is recruited varies between muscles. In some hand muscles, all the motor units have been recruited when the force reaches approximately 60% of maximum during a slow muscle contraction. In the biceps brachii, deltoid, and tibialis anterior muscles, recruitment continues up to approximately 85% of the maximal force. Beyond the upper limit of motor unit recruitment, changes in muscle force depend solely on variations in the rate at which motor neurons generate action potentials. Over most of the operating range of a muscle, the force it exerts depends on concurrent changes in discharge rate and the number of active motor units (Figure 31–7). Except at low forces, however, variation in

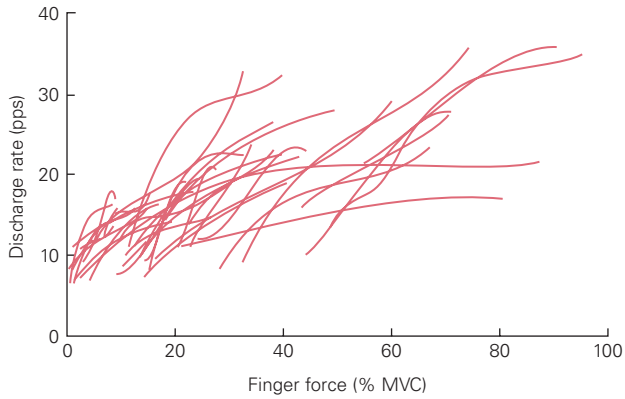

Figure 31–7 Muscle force can be adjusted by varying the number of active motor units and their discharge rate. Each line shows the discharge rate (pulses per second [**pps**]) for a single motor unit in a hand muscle over a range of finger forces (maximal voluntary contraction [**MVC**]). The finger force was produced by the action of a single hand muscle. The leftmost point of each line indicates the threshold force at which the motor unit is recruited, whereas the rightmost point corresponds to the peak force at which the motor unit could be identified. The range of discharge rates was often less for motor units with lower recruitment thresholds. Increases in finger force were produced by concurrent increases in discharge rate and the number of activated motor units. (Adapted, with permission, from Moritz et al. 2005.)

discharge rate has a greater influence on muscle force than does changes in the number of active motor units.

The order in which motor units are recruited does not change with contraction speed. Due to the time involved in excitation-contraction coupling, faster contractions require the action potential for each motor unit to be generated earlier than during a slow contraction. As a result of this adjustment, the upper limit of motor unit recruitment during the fastest muscle contractions is approximately 40% of maximum. Consequently, it is possible to manipulate the rate at which motor units are recruited by varying contraction speed.

The Input–Output Properties of Motor Neurons Are Modified by Input From the Brain Stem

The discharge rate of motor neurons depends on the magnitude of the depolarization generated by excitatory inputs and the intrinsic membrane properties of the motor neurons in the spinal cord. These properties can be profoundly modified by input from monoaminergic neurons in the brain stem (Chapter 40). In the absence of this input, the dendrites of motor neurons passively transmit synaptic current to the cell body, resulting in a modest depolarization that immediately ceases when the input stops. Under these conditions, the relation between input current and discharge rate is linear over a wide range.

The input–output relation becomes nonlinear, however, when the monoamines serotonin and norepinephrine induce a huge increase in conductance by activating L-type Ca^{2+} channels that are located on the dendrites of the motor neurons. The resulting inward Ca^{2+} currents can enhance synaptic currents by three- to five-fold (Figure 31–8). In an active motor neuron, this augmented current can sustain an elevated discharge rate after a brief depolarizing input has ended, a behavior known as *self-sustained firing*. A subsequent brief inhibitory input, such as from a spinal reflex pathway, can terminate such self-sustained firing.

Because the properties of motor neurons are strongly influenced by monoamines, the excitability of the pool of motor neurons innervating a single muscle is partly under control of the brain stem. In the awake state, moderate levels of monoaminergic input to the motor neurons of slowly contracting motor units promote self-sustained firing. This is probably the source of the sustained force exerted by slower motor units to maintain posture (Chapter 36). Conversely, the withdrawal of monoaminergic drive during sleep decreases excitability and helps ensure a relaxed motor state. Thus, monoaminergic input from the brain stem can adjust the gain of the motor unit pool to meet the demands of different tasks. This flexibility does not compromise the size principle of orderly recruitment because the threshold for activation of the persistent inward currents is lowest in the motor neurons of slower contracting motor units, which are the first recruited even in the absence of monoamines.

Muscle Force Depends on the Structure of Muscle

Muscle force depends not only on the amount of motor neuron activity but also on the arrangement of the fibers in the muscle. Because movement involves the controlled variation of muscle force, the nervous system must take into account the structure of muscle to achieve specific movements.

The Sarcomere Is the Basic Organizational Unit of Contractile Proteins

Individual muscles contain thousands of fibers that vary from 1 to 50 mm in length and from 10 to 60 µm in diameter. The variation in fiber dimensions reflects differences in the quantity of contractile protein. Despite this quantitative variation, the organization of contractile proteins is similar in all muscle fibers. The proteins are arranged in repeating sets of thick and thin filaments, each set known as a *sarcomere* (Figure 31–9). The in vivo length of a sarcomere, which is bounded by Z disks, ranges from 1.5 to 3.5 µm within and across muscles. Sarcomeres are arranged in series to form a *myofibril*, and the myofibrils are aligned in parallel to form a muscle fiber (myocyte).

The force that each sarcomere can generate arises from the interaction of the contractile thick and thin filaments. The thick filament consists of several hundred myosin molecules arranged in a structured sequence. Each myosin molecule comprises paired coiled-coil domains that terminate in a pair of globular heads. The myosin molecules in the two halves of a thick filament point in opposite directions and are progressively displaced so that the heads, which extend away from the filament, protrude around the thick filament (Figure 31–9C). The thick filament is anchored in the middle of the sarcomere by the protein titin, which connects each end of the thick filament with neighboring strands of actin in the thin filament and with the Z-disc. To maximize the interaction between the globular heads of myosin and the thin filaments, six thin filaments surround each thick filament.

The primary components of the thin filament are two helical strands of fibrous F-actin, each of which

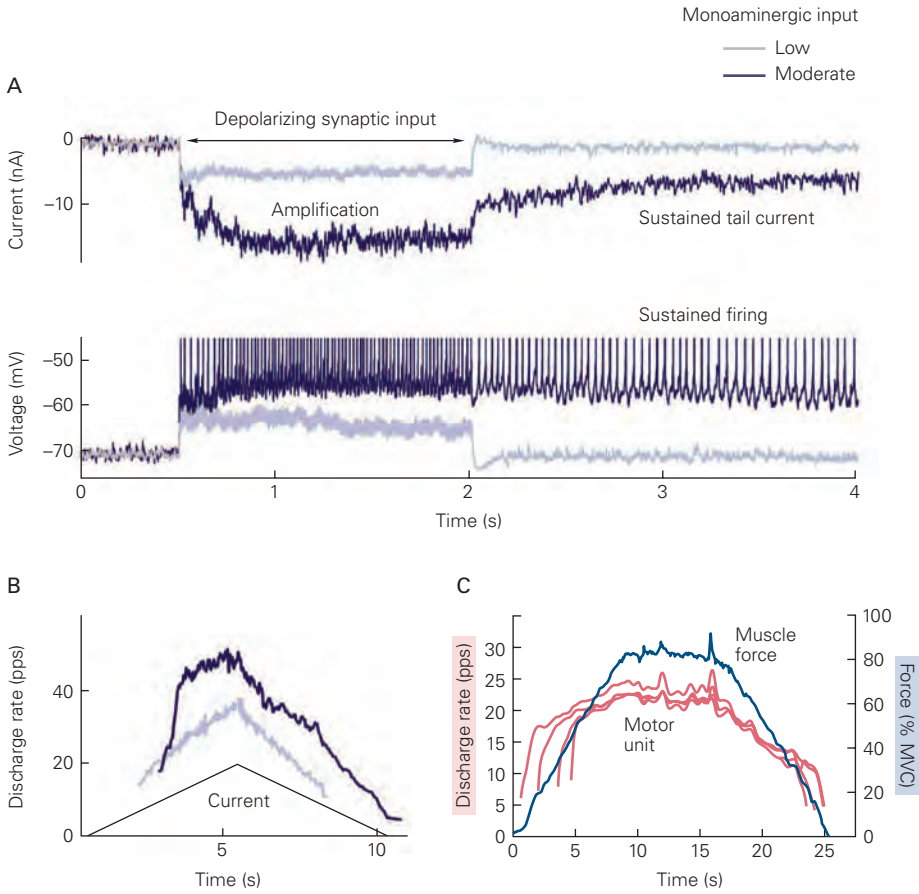

Figure 31–8 **Monoaminergic input enhances the excitability of motor neurons.** (Part **A**, adapted, with permission, of Heckman et al. 2009. A. Membrane currents and potentials in spinal motor neurons of adult cats that were either deeply anesthetized (low monoaminergic drive) or decerebrate (moderate monoaminergic drive). When monoaminergic input is absent or low, a brief excitatory input produces an equally brief synaptic current during voltage clamp (**upper record**). This current is not sufficient to bring the membrane potential of the neuron to threshold for generating action potentials in the unclamped condition (**lower record**). The same brief excitatory input during moderate levels of monoaminergic input activates a persistent inward current in the dendrites, which amplifies the excitatory synaptic current and decays slowly following cessation of synaptic input (**upper record**). This persistent inward current causes a high discharge rate during the input and sustains a lesser discharge rate after the input ceases (**lower record**). A brief inhibitory input will return the neuron to its resting state.

B. High levels of monoaminergic input to a motor neuron give rise to a persistent inward current in response to injected current, resulting in a much greater discharge rate for a given amount of current.

C. The **blue** trace represents the force exerted by the dorsiflexor muscle during a contraction that gradually increased to 80% of maximal voluntary isometric contraction (**MVC**) force in a human subject. Each of the four **pink** traces indicates the change in the rate at which a single motor unit discharged action potentials during the contraction. The leftmost point (start) of each of these four traces shows the time when the motor unit was recruited, and the rightmost point (end) denotes the time at which the motor neuron stopped discharging action potentials. The rapid increase in discharge rate during the increase in muscle force is similar to the change in rate observed in the presence of moderate levels of monoaminergic input (see part **B**).

contains approximately 200 actin monomers. Superimposed on F-actin are tropomyosin and troponin, proteins that control the interaction between actin and myosin. Tropomyosin consists of two coiled strands that lie in the groove of the F-actin helix; troponin is a small molecular complex that is attached to tropomyosin at regular intervals (Figure 31–9C).

The thin filaments are anchored to the Z disk at each end of the sarcomere, whereas the thick filaments occupy the middle of the sarcomere (Figure 31–9B). This organization accounts for the alternating light and dark bands of striated muscle. The light band contains only thin filaments, whereas the dark band contains both thick and thin filaments. When a muscle is

activated, the width of the light band decreases but the width of the dark band does not change, suggesting that the thick and thin filaments slide relative to one another during a contraction. This led to the *sliding filament hypothesis* of muscle contraction proposed by A. F. Huxley and H. E. Huxley in the 1950s.

The sliding of the thick and thin filaments is triggered by the release of Ca^{2+} from within the sarcoplasm of a muscle fiber in response to an action potential that travels along the fiber's membrane, the sarcolemma. Varying the amount of Ca^{2+} in the sarcoplasm controls the interaction between the thick and thin filaments. The Ca^{2+} concentration in the sarcoplasm is kept low under resting conditions by active pumping of Ca^{2+} into the sarcoplasmic reticulum, a network of longitudinal tubules and chambers of smooth endoplasmic reticulum. Calcium is stored in the terminal cisternae, which are located next to intracellular extensions of the sarcolemma known as transverse tubules (T-tubules). The transverse tubules, terminal cisternae, and sarcoplasmic reticulum constitute an activation system that transforms an action potential into the sliding of the thick and thin filaments (Figure 31–9A).

As an action potential propagates along the sarcolemma, it invades the transverse tubules and causes the rapid release of Ca^{2+} from the terminal cisternae into the sarcoplasm. Once in the sarcoplasm, Ca^{2+} diffuses among the filaments and binds reversibly to troponin, which results in the displacement of the troponin–tropomyosin complex and enables the sliding of the thick and thin filaments. Because a single action potential does not release enough Ca^{2+} to bind all available troponin sites in skeletal muscle, the strength of a contraction increases with the action potential rate.

The sliding of the filaments depends on mechanical work performed by the globular heads of myosin, work that uses chemical energy contained in adenosine triphosphate (ATP). The actions of the myosin heads are regulated by the *cross-bridge cycle*, a sequence of detachment, activation, and attachment (Figure 31–10). In each cycle, a globular head undergoes a displacement of 5 to 10 nm. Contractile activity continues as long as Ca^{2+} and ATP are present in the cytoplasm in sufficient amounts.

Once the contractile proteins have been activated by the release of Ca^{2+}, sarcomere length may increase, remain the same, or decrease depending on the magnitude of the load against which the muscle is acting. The force generated by an activated sarcomere when its length does not change or decreases can be explained by the cross-bridge cycle involving the thick and thin filaments. When the length of the activated sarcomere increases, however, the force developed by the extension of titin adds significantly to the sarcomere force. The force produced by titin during the stretch of an activated sarcomere is augmented by its ability to increase stiffness, which is accomplished when titin binds Ca^{2+} and then attaches at specific locations on actin to reduce the length that it can be stretched. The force produced by activated sarcomeres therefore depends on the interactions of three filaments (actin, myosin, and titin).

Noncontractile Elements Provide Essential Structural Support

Structural elements of the muscle fiber maintain the alignment of the contractile proteins within the fiber and facilitate the transmission of force from the sarcomeres to the skeleton. A network of proteins (nebulin, titin) maintains the orientation of the thick and thin filaments within the sarcomere, whereas other proteins (desmin, skelemins) constrain the lateral alignment of the myofibrils (Figure 31–9B). These proteins contribute to the elasticity of muscle and maintain the appropriate alignment of cellular structures when the muscle acts against an external load.

Although some of the force generated by the cross bridges is transmitted along the sarcomeres in series, most of it travels laterally from the thin filaments to an extracellular matrix that surrounds each muscle fiber, through a group of transmembrane and membrane-associated proteins called a *costamere* (see inset for Figure 31–9B). The lateral transmission of force follows two pathways through the costamere, one through a dystrophin–glycoprotein complex and the other through vinculin and members of the integrin family. Mutations of genes that encode components of the dystrophin–glycoprotein complex cause muscular dystrophies in humans, which are associated with substantial decreases in muscle force.

Contractile Force Depends on Muscle Fiber Activation, Length, and Velocity

The force that a muscle fiber can exert depends on the number of cross bridges formed and the force produced by each cross bridge. These two factors are influenced by the Ca^{2+} concentration in the sarcoplasm, the amount of overlap between the thick and thin filaments, and the velocity with which the thick and thin filaments slide past one another.

The influx of Ca^{2+} that activates formation of the cross bridges is transitory because continuous pump activity quickly returns Ca^{2+} to the sarcoplasmic reticulum. The release and reuptake of Ca^{2+} in response to a single action potential occurs so quickly that only some

of the potential cross bridges are formed. This explains why the peak force of a twitch is less than the maximal force of the muscle fiber (see Figure 31–2A). Maximal force can be achieved only with a series of action potentials that sustains the Ca^{2+} concentration in the sarcoplasm, thus maximizing cross bridge formation.

Although Ca^{2+} activates formation of the cross bridges, cross bridges can be formed only when the thick and thin filaments overlap. This overlap varies as the filaments slide relative to one another (Figure 31–11A). The amount of overlap between actin and myosin is optimal at an intermediate sarcomere length (L_o), and the relative force is maximal. Increases in sarcomere length reduce the overlap between actin and myosin and the force that can be developed. Decreases in sarcomere length cause the thin filaments to overlap, reducing the number of binding sites available to the myosin heads. Although many muscles operate over a narrow range of sarcomere lengths (approximately 94 ± 13% L_o, mean ± standard deviation), among muscles, there is considerable diversity in sarcomere lengths during movement.

Because structures that connect the contractile proteins to the skeleton also influence the force that a muscle can exert, muscle force increases with length over its operating range. This property enables muscle to function like a spring and to resist changes in length. Muscle stiffness, which corresponds to the slope of the relation between muscle force and muscle length (N/m), depends on the structure of the muscle. A stiffer muscle, similar to a stronger spring, is more resistant to changes in length.

Once activated, cross bridges perform work and cause the thick and thin filaments to slide relative to one another. Due to the elasticity of intracellular cytoskeletal proteins and the extracellular matrix, sarcomeres will shorten when the cross bridges are activated and the length of the muscle fiber is held fixed (*isometric contraction*). When the length of the muscle fiber is not kept constant, the direction and rate of change in sarcomere length depend on the amount of muscle fiber force relative to the magnitude of the load against which the fiber acts. Sarcomere length decreases when the muscle fiber force exceeds the load (*shortening contraction*) but increases when the force is less than the load (*lengthening contraction*). The maximal force that a muscle fiber can exert decreases as shortening velocity increases but increases as lengthening velocity increases (Figure 31–11B).

The maximal rate at which a muscle fiber can shorten is limited by the peak rate at which cross bridges can form. The variation in fiber force as contraction velocity changes is largely caused by differences in the average force exerted by each cross bridge. For example, the decrease in force during a shortening contraction is attributable to a reduction in cross-bridge displacement during each power stroke and the failure of some myosin heads to find attachment sites. Conversely, the increase in force during a lengthening contraction reflects the stretching of incompletely activated sarcomeres, the more rapid reattachment of cross bridges after they have been pulled apart, and the attachment of Ca^{2+} to titin.

The rate of cross-bridge cycling depends not only on contraction velocity but also on the preceding activity of the muscle. For example, the rate of cross-bridge cycling increases after a brief isometric contraction. When a muscle is stretched while in this state, such as would occur during a postural disturbance, muscle stiffness is enhanced, and the muscle is more effective at resisting the change in length. This property is known as *short-range stiffness*. Conversely, the cross-bridge cycling rate decreases after shortening contractions, and the muscle does not exhibit short-range stiffness.

Figure 31–9 (Opposite) **The sarcomere is the basic functional unit of muscle.** (Adapted from Bloom and Fawcett 1975.)

A. This section of a muscle fiber shows its anatomical organization. Several myofibrils lie side by side in a fiber, and each myofibril is made up of sarcomeres arranged end to end and separated by Z disks (see part **B**). The myofibrils are surrounded by an activation system (the transverse tubules, terminal cisternae, and sarcoplasmic reticulum) that initiates muscle contraction.

B. Sarcomeres are connected to one another and to the muscle fiber membrane by the cytoskeletal lattice. The cytoskeleton influences the length of the contractile elements, the thick and thin filaments (see part **C**). It maintains the alignment of these filaments within a sarcomere, connects adjacent myofibrils, and transmits force to the extracellular matrix of connective tissue through costameres. One consequence of this organization is that the force generated by the contractile elements in a sarcomere can be transmitted along and across sarcomeres (through desmin and skelemin), within and between sarcomeres (through nebulin and titin), and to the sarcolemma through the costameres. The Z disk is a focal point for many of these connections.

C. The thick and thin filaments comprise different contractile proteins. The thin filament includes polymerized actin along with the regulatory proteins tropomyosin and troponin. The thick filament is an array of myosin molecules; each molecule includes a stem that terminates in a pair of globular heads. The protein titin maintains the position of each thick filament in the middle of the sarcomere.

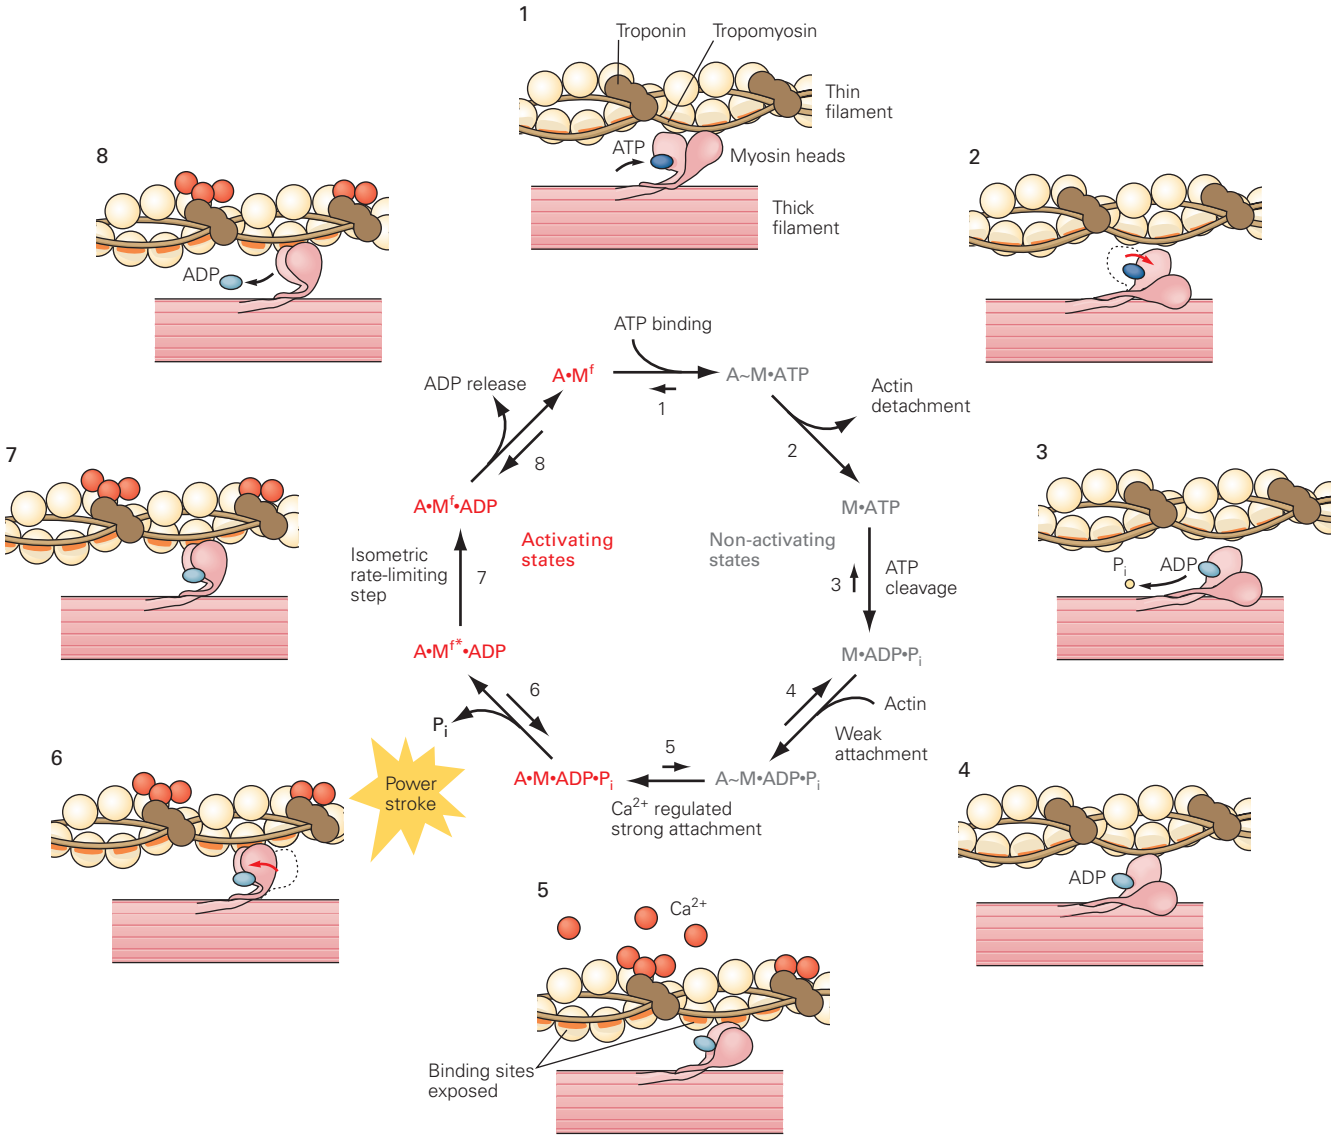

Figure 31–10 **The cross-bridge cycle.** Several nonactivating states are followed by several activating states triggered by Ca^{2+}. The cycle begins at the top (**step 1**) with the binding of adenosine triphosphate (**ATP**) to the myosin head. The myosin head detaches from actin (**step 2**), ATP is cleaved to phosphate (P_i) and adenosine diphosphate (**ADP**) (**step 3**), and the myosin becomes weakly bound to actin (**step 4**). The binding of Ca^{2+} to troponin causes tropomyosin to slide over actin and enables the two myosin heads to close (**step 5**). This results in the release of P_i and the extension of the myosin neck, the power stroke of the cross-bridge cycle (**step 6**). Each cross-bridge exerts a force of approximately 2 pN during a structural change (**step 7**) and the release of ADP (**step 8**). (•, strong binding; ~, weak binding; M^f, cross-bridge force of myosin; and M^{f*}, force-bearing state of myosin.) (Adapted, with permission, from Gordon, Regnier, and Homsher 2001.)

Muscle Torque Depends on Musculoskeletal Geometry

The anatomy of a muscle has a pronounced effect on its force capacity, range of motion, and shortening velocity. The anatomical features that influence function include the arrangement of the sarcomeres in each muscle fiber, the organization of the muscle fibers within the muscle, and the location of the muscle's attachments on the skeleton. These features vary widely among muscles.

At the level of a single muscle fiber, the number of sarcomeres in series and in parallel can vary. The number of sarcomeres in series determines the length

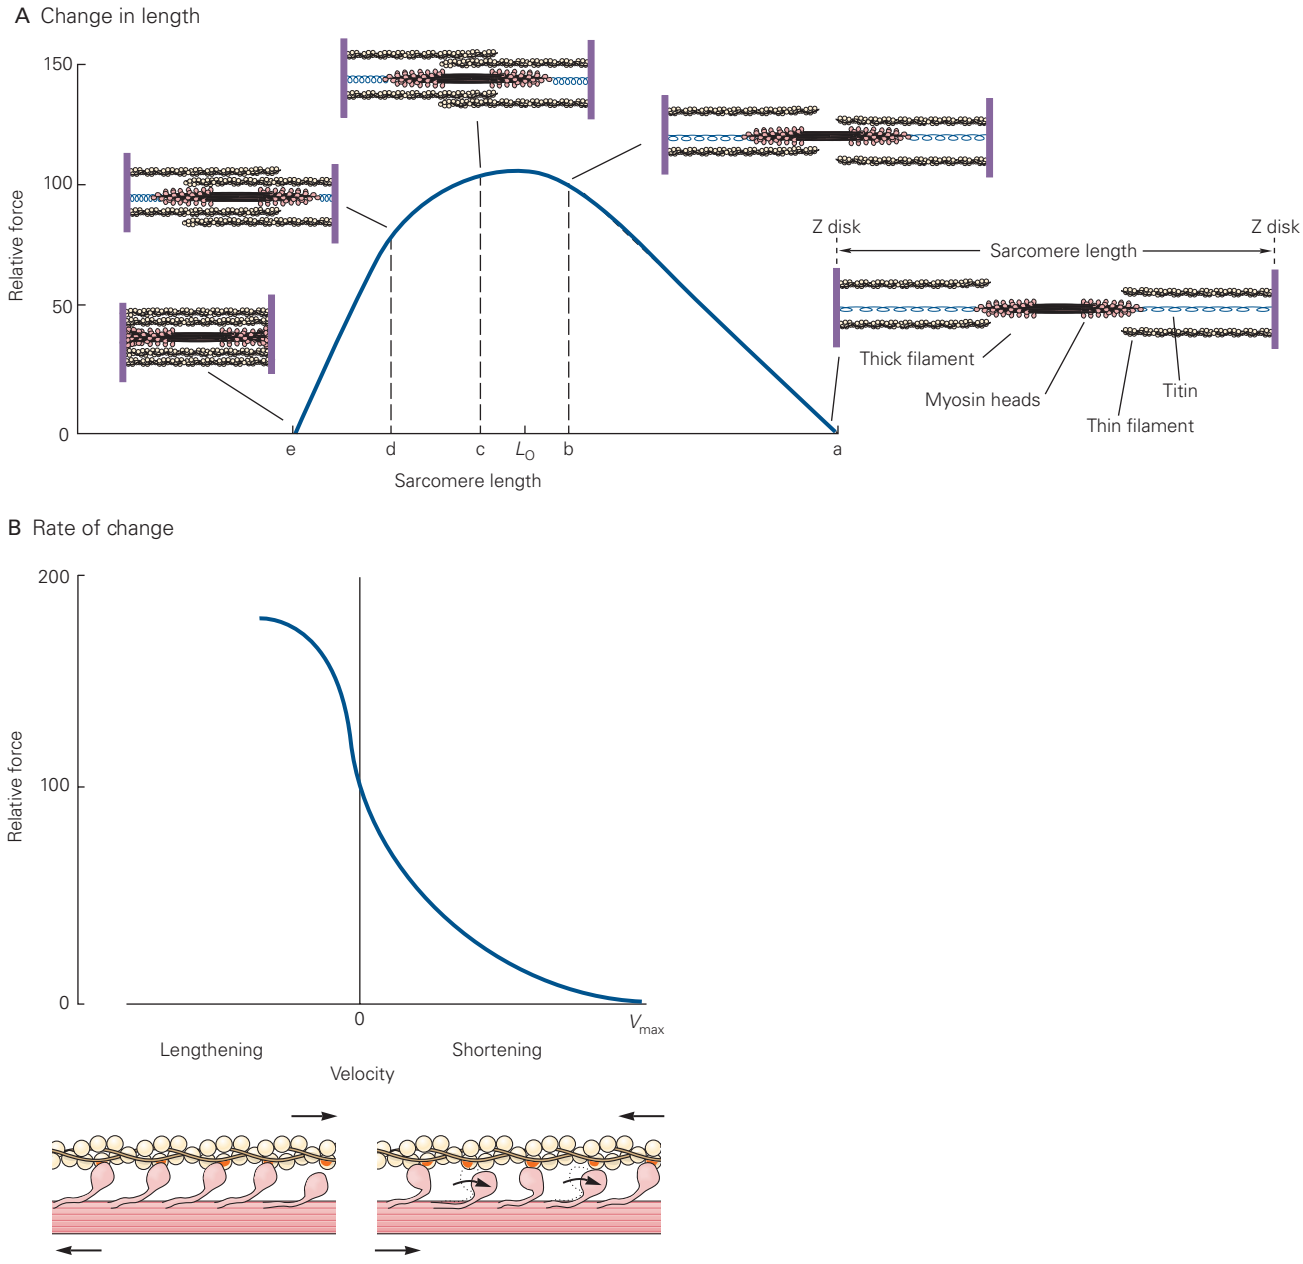

Figure 31–11 Contractile force varies with the change in sarcomere length and velocity.

A. At an intermediate sarcomere length, L_o, the amount of overlap between actin and myosin is optimal and the relative force is maximal. When the sarcomere is stretched beyond the length at which the thick and thin filaments overlap (length **a**), cross bridges cannot form and no force is exerted. As sarcomere length decreases and the overlap of the thick and thin filaments increases (between lengths **a** and **b**), the force increases because the number of cross bridges increases. With further reductions in length (between lengths **c** and **e**), the extreme overlap of the thin filaments with each other occludes potential attachment sites and the force decreases.

B. Contractile force varies with the rate of change in sarcomere length. Relative to the force that a sarcomere can exert during an isometric contraction (zero velocity), the peak force declines as the rate of shortening increases. Muscle force reaches a minimum at the maximal shortening velocity (V_{max}). In contrast, when the sarcomere is lengthened while being activated, the peak force increases to values greater than those during an isometric contraction. Shortening causes the myosin heads to spend more time near the end of their power stroke, where they produce less contractile force, and more time detaching, recocking, and reattaching, during which they produce no force. When the muscle is actively lengthened, the myosin heads spend more time stretched beyond their angle of attachment and little time unattached because they do not need to be recocked after being pulled away from the actin in this manner. Titin also contributes significantly to sarcomere force during lengthening contractions.

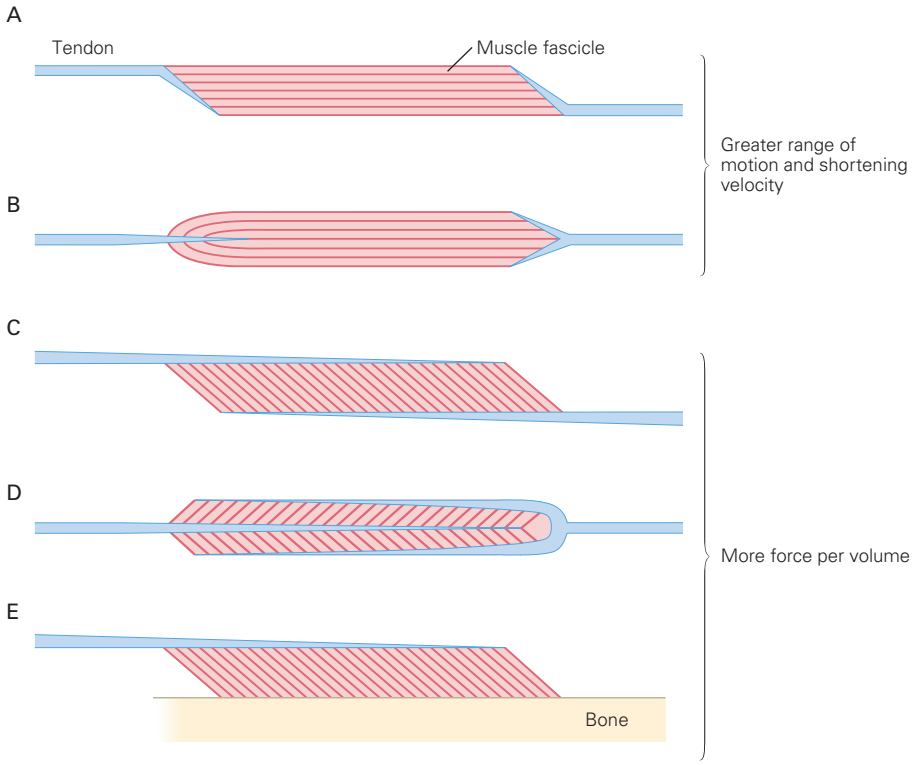

Figure 31–12 Five common arrangements of tendon and muscle. The fundamental distinction between these arrangements is whether or not the muscle fascicles are aligned with the line of pull of the muscles. The fascicles in muscles A and B are parallel to the line of pull (longitudinal axis of the muscle), whereas the fascicles in muscles C, D, and E are rotated away from the line of pull. The magnitude of this rotation is expressed as the pennation angle. (Reproduced, with permission, from Alexander and Ker 1990.)

of the myofibril and thus the length of the muscle fiber. Because one sarcomere can shorten by a certain length with a given maximal velocity, both the range of motion and the maximal shortening velocity of a muscle fiber are proportional to the number of sarcomeres in series. The force that a myofibril can exert is equal to the average sarcomere force and is not influenced by the number of sarcomeres in series. Rather, the force capacity of a fiber depends on the number of sarcomeres in parallel and hence on the diameter or cross-sectional area of the fiber. At the level of the muscle, the functional attributes of the fibers are modified by the orientation of the fascicles (bundles of muscle fibers) to the line of pull of the muscle and the length of the fiber relative to the muscle length. In most muscles, the fascicles are not parallel to the line of pull but fan out in feather-like (pennate) arrangements (Figure 31–12).

The relative orientation, or pennation angle of the fascicles, ranges from close to 0° (biceps brachii, sartorius) to approximately 30° (soleus). Because more fibers can fit into a given volume as the pennation angle increases, muscles with large pennation angles typically have more fascicles in parallel and hence large cross-sectional areas when measured perpendicular to the long axis of individual muscle fibers. Given the linear relation between cross-sectional area (quantity of contractile proteins in parallel) and maximal force (~22.5 N • cm^{-2}), these muscles are capable of a greater maximal force. However, the fibers in pennate muscles are generally short and have a lesser maximal shortening velocity than those in nonpennate muscles.

The functional consequences of this anatomical arrangement can be seen by comparing the contractile properties of two muscles with different numbers of fibers and fiber lengths. If the two muscles have identical fiber lengths but one has twice as many fibers, the range of motion of the two muscles will be similar because it is a function of fiber length, but the maximal force capacity will vary in proportion to the number of muscle fibers. If the two muscles have identical numbers of fibers but the fibers in one muscle are twice as long, the muscle with the longer fibers will have a greater range of motion and a greater maximal shortening velocity, even though the two muscles have a similar force capacity. Because of this effect, the muscle with longer fibers is able to exert more force and produce more power (the product of force and velocity) at a given absolute shortening velocity (Figure 31–13).

Muscle fiber lengths and cross-sectional areas vary substantially throughout the human body, which suggests that the contractile properties of individual muscles also differ markedly (Table 31–2). In the leg,

for example, pennation angle ranges from 1° (sartorius) to 30° (vastus medialis), fiber length ranges from 4 mm (soleus) to 40 mm (sartorius), and cross-sectional area ranges from 2 cm^2 (sartorius) to 52 cm^2 (soleus). In addition, the fact that muscle fiber length is usually less than muscle length indicates that muscle fibers are connected serially within a muscle. Functionally coupled muscles tend to have complementary combinations of these properties. For example, the three vasti muscles have similar muscle fiber lengths (10 cm), but they differ in pennation angle (intermedius is the smallest) and cross-sectional area (lateralis is the largest). A similar relation exists for soleus and the two heads (medial and lateral) of gastrocnemius.

Movement involves the muscle-controlled rotation of adjacent body segments, which means that the capacity of a muscle to contribute to a movement also depends on its location relative to the joint that it spans. The rotary force exerted by a muscle about a joint is referred to as *muscle torque* and is calculated as the product of the muscle force and the *moment arm*, the shortest perpendicular distance from the line of pull of the muscle to the joint's center (Figure 31–14).

The moment arm usually changes as a joint rotates through its range of motion; the amount of change depends on where the muscle is attached to the skeleton relative to the joint. If the force exerted by a muscle remains relatively constant throughout the joint's range of motion, muscle torque varies in direct proportion to the change in the moment arm. For many muscles, the moment arm is maximal in the middle of the range of motion, which usually corresponds to the position of maximal muscle force and hence greatest muscle torque.

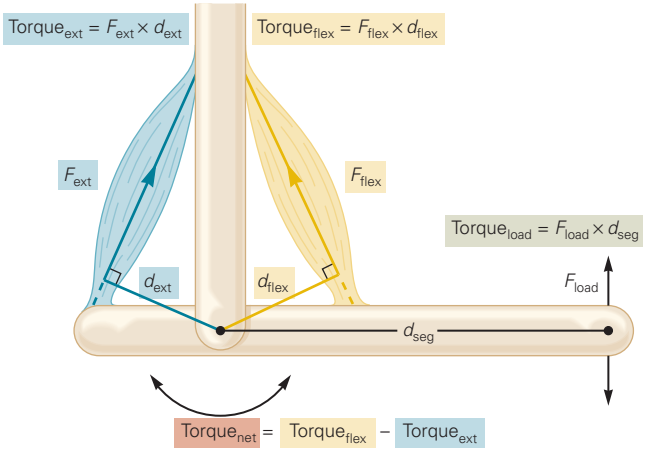

Figure 31–14 Muscle torque varies over the range of motion about a joint. A muscle's torque about a joint is the product of its contractile force (F) and its moment arm relative to the joint (d). The moment arm is the shortest perpendicular distance from the line of pull of the muscle to the center of rotation of the joint. Because the moment arm changes when the joint rotates, muscle torque varies with angular displacement about the joint. The net torque about a joint, which determines the mechanical action, is the difference in the torques exerted by opposing muscles, such as extensors (ext) and flexors (flex). Similarly, a force applied to the limb (F_{load}) will exert a torque about the joint that depends on F_{load} and its distance from the joint (d_{seg}).

Different Movements Require Different Activation Strategies

The human body has approximately 600 muscles, each with a distinct torque profile about one or more joints. To perform a desired movement, the nervous system must activate an appropriate combination of muscles with adequate intensity and timing of activity. The activation must be appropriate for the contractile properties and musculoskeletal geometry of many muscles, as well as the mechanical interactions between body segments. As a result of these demands, activation strategies differ with the details of the movement.

Contraction Velocity Can Vary in Magnitude and Direction

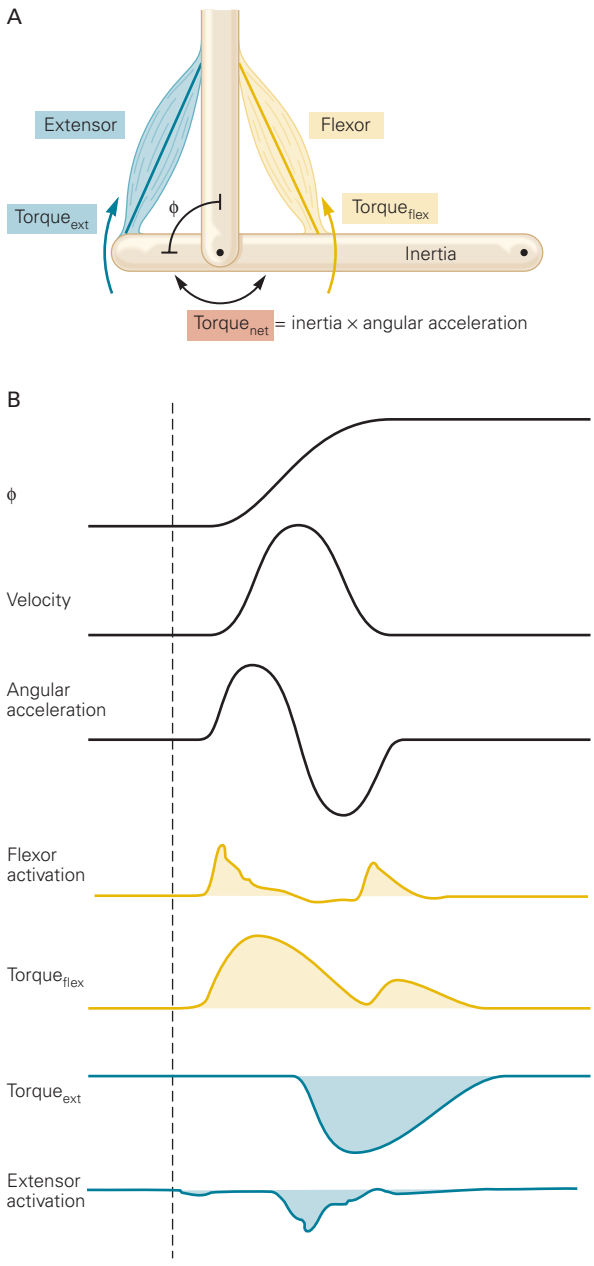
Movement speed depends on the contraction velocity of a muscle. The only ways to vary contraction velocity are to alter either the number of motor units recruited or the rates at which they discharge action potentials. The velocity of a contraction can vary in both magnitude and direction (see Figure 31–11B). To control the velocity of a contraction, the nervous system must scale the magnitude of the net muscle torque relative to the load torque (Figure 31–14), which includes both the weight of the body part and any external load acting on the body.

When muscle torque exceeds load torque, the muscle shortens as it performs a shortening contraction. When muscle torque is less than load torque, the muscle lengthens as it performs a lengthening contraction. For the example shown in Figure 31–14, the load is lifted with a shortening contraction of the flexor and lowered with a lengthening contraction of the flexor. Both types of contractions are common in daily activities.

Shortening and lengthening contractions are not simply the result of adjusting motor unit activity so that the net muscle torque is greater or less than the load torque. When the task involves lifting a load with a prescribed trajectory, activation of the motor units must be aligned so that the sum of the rise times produce the appropriate torque so as to match the desired trajectory while lifting (shortening contractions), whereas while lowering the load (lengthening contractions), the sum of the decay times must be similarly

controlled. The nervous system accomplishes this with different descending input and sensory feedback during the two types of contractions. Because of these differences in required motor unit activity, the control of the two types of contraction respond differently to stresses imposed on the system. Declines in the capacity to control motor unit activity, such as observed in older adults and persons performing rehabilitation exercises after an orthopedic procedure, are associated with greater difficulty in performing lengthening contractions.

The amount of motor unit activity relative to the load also influences the contraction velocity. This effect depends on both the number of motor units recruited and the maximal rates at which the motor units can discharge action potentials. As described previously, physical training with rapid contractions, such as power training, increases the rate at which motor units can discharge trains of action potentials, which can be mimicked by step injections of current into a motor neuron. Changes in the maximal shortening velocity of a muscle after a change in the habitual level of physical activity are the result, at least partly, of factors that influence the ability of motor neurons to discharge action potentials at high rates.



Movements Involve the Coordination of Many Muscles

In the simplest case, muscles span a single joint and cause the attached body segments to accelerate about a single axis of rotation. Because muscles can exert only a pulling force, motion about a single axis of rotation requires at least two muscles or groups of muscles when the action involves shortening contractions (Figure 31–15A).

Because most muscles attach to the skeleton slightly off center from the axis of rotation, they can cause movement about more than one axis of rotation. If one of the actions is not required, the nervous system must activate other muscles to control the unwanted movement. For example, activation of the radial flexor muscle of the wrist can cause the wrist to flex and abduct. If the intended action is only wrist flexion, then the abduction action must be opposed by another muscle, such as the ulnar flexor muscle, which causes wrist flexion and adduction. Depending on the geometry of the articulating surfaces and the attachment sites of the muscles, the multiple muscles that span a joint are capable of producing movements about one to three axes of rotation. Furthermore, some structures

Figure 31–15 (Left) Antagonist muscles spanning a single joint control movement of a limb about a single axis of rotation.

A. According to Newton's law of acceleration (force = mass × acceleration), force is required to change the velocity of a mass. Muscles exert a torque to accelerate the inertial mass of the skeletal segment around a joint. For angular motion, Newton's law is written as torque = rotational inertia × angular acceleration.

B. The angular velocity for movement of a limb from one position to another has a bell-shaped profile. Acceleration in one direction is followed by acceleration in the opposite direction—the flexor and extensor muscles are activated in succession. The records here show the activation profiles and associated muscle torques for a fast elbow flexion movement. Because contractile force decays relatively slowly, the flexor muscle is usually activated a second time to counter the prolonged acceleration generated by the extensor muscle and to stop the limb at the intended joint angle.

can be displaced linearly (eg, the scapula on the trunk), adding to the degrees of freedom about a joint.

The off-axis attachment of muscles enhances the flexibility of the skeletal motor system; the same movement can be achieved by activating different combinations of muscles. However, this additional flexibility requires the nervous system to control the unwanted actions. A solution used by the nervous system is to organize relations among selected muscles to produce specific actions. A particular sequence of muscle activations is known as a *muscle synergy,* and movement is produced through the coordinated activation of these synergies. For example, EMG recordings of human subjects suggest that variations of movements with the same general purpose, such as grasping various objects with the hand, reaching and pointing in different directions, or walking and running at several speeds, are controlled by approximately five muscle synergies.

The number of muscles that participate in a movement also varies with the speed of the movement. For example, slow lifting of a load requires only that the muscle torque slightly exceed the load torque (see Figure 31–14), and thus, only the flexor muscle is activated. This strategy is used when lifting a handheld weight with the elbow flexor muscles. In contrast, to perform this movement rapidly with an abrupt termination at an intended joint angle, both the flexor and extensor muscles must be activated. First, the flexor muscle is activated to accelerate the limb in the direction of flexion, followed by activation of the extensor muscle to accelerate the limb in the direction of extension, and finally a burst of activity by the flexor muscle to increase the angular momentum of the limb and the handheld weight in the direction of flexion so that it arrives at the desired joint angle (Figure 31–15B). The amount of extensor muscle activity increases with the speed of the movement.

Increases in movement speed introduce another factor that the nervous system must control: unwanted accelerations in other body segments. Because body parts are connected to one another, motion in one part can induce motion in another. The induced motion is often controlled with lengthening contractions, such as

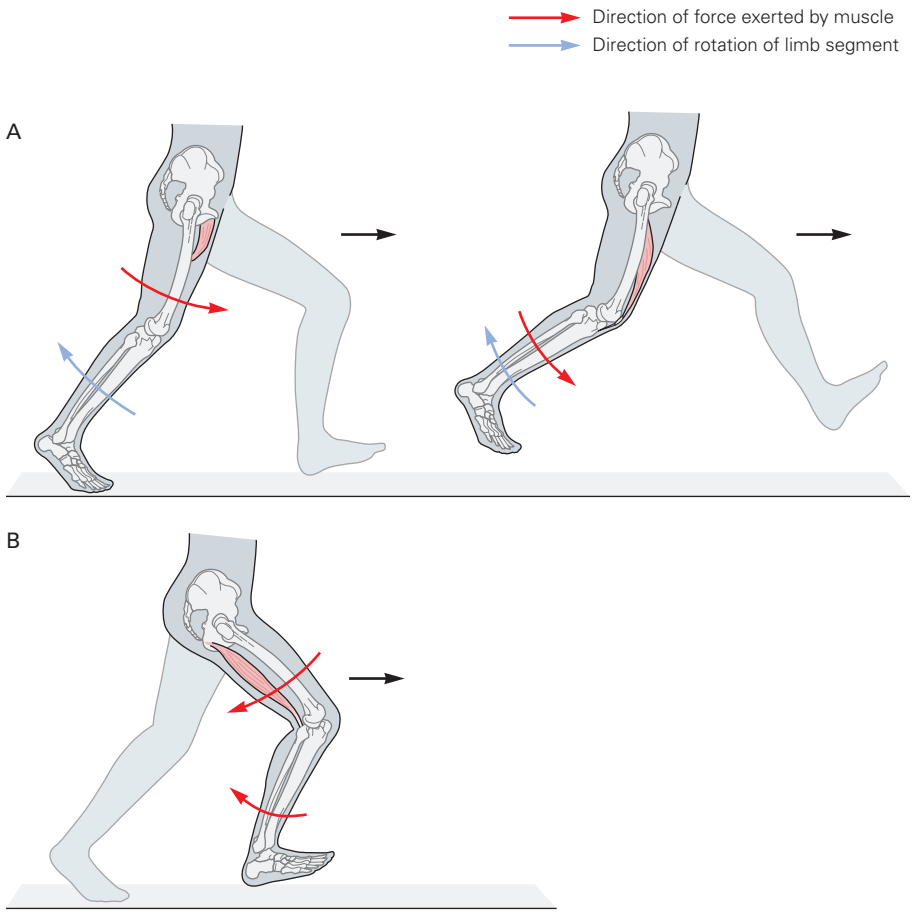


Figure 31–16 A single muscle can influence the motion about many joints.

A. Muscles that cross one joint can accelerate an adjacent body segment. For example, at the beginning of the swing phase while running, the hip flexor muscles are activated to accelerate the thigh forward (**red arrow**). This action causes the lower leg to rotate backward (**blue arrow**) and the knee joint to flex. To control the knee joint flexion during the first part of the swing phase, the knee extensor muscles are activated and undergo a lengthening contraction to accelerate the lower leg forward (**red arrow**) while it continues to rotate backward (**blue arrow**).

B. Many muscles cross more than one joint to exert an effect on more than one body segment. For example, the hamstring muscles of the leg accelerate the hip in the direction of extension and the knee in the direction of flexion (**red arrows**). During running, at the end of the swing phase, the hamstring muscles are activated and undergo lengthening contractions to control the forward rotation of the leg (hip flexion and knee extension). This strategy is more economical than activating individual muscles at the hip and knee joints to control the forward rotation of the leg.

those experienced by thigh muscles during the swing phase of running (Figure 31–16A).

Muscles that span more than one joint can be used to control these motion-dependent interactions between body parts. At the end of the swing phase in running, activation of the hamstring muscles causes both the thigh and lower leg to accelerate backward (Figure 31–16B). If a hip extensor muscle is used to accelerate the thigh backward instead of the hamstring muscles, the lower leg would accelerate forward, requiring activation of a knee flexor muscle to control the unwanted lower leg motion so that the foot could be placed on the ground. Use of the two-joint hamstring muscles is a more economical strategy, but one that can subject the hamstrings to high stresses during fast movements, such as sprinting. The control of such motion-dependent interactions often involves lengthening contractions, which maximize muscle stiffness and the ability of muscle to resist changes in length.

For most movements, the nervous system must establish rigid connections between some body parts for two reasons. First, as expressed in Newton's law of action and reaction, a reaction force must provide a foundation for the acceleration of a body part. For example, in a reaching movement performed by a person standing upright, the ground must provide a reaction force against the feet. The muscle actions that produce the arm movement exert forces that are transmitted through the body to the feet and are opposed by the ground. Different substrates provide different amounts of reaction force, which is why ice or sand can influence movement capabilities.

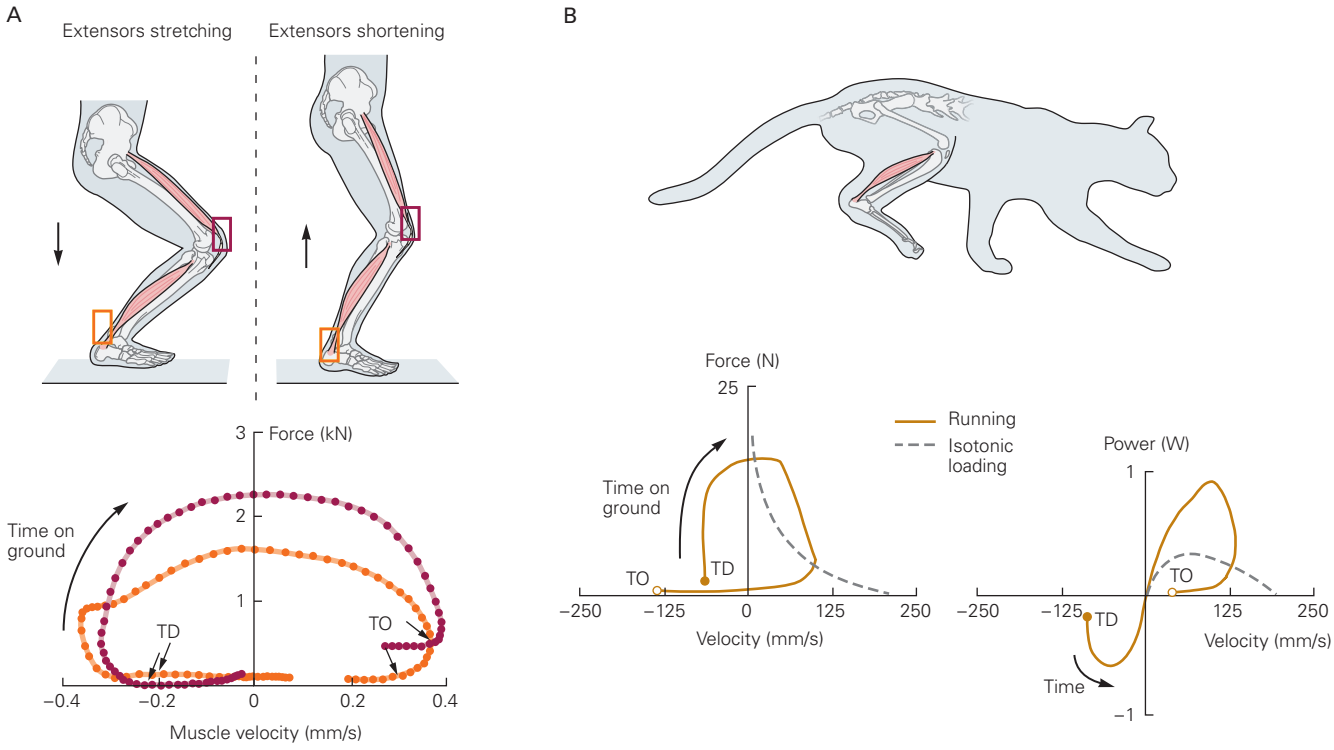

Figure 31–17 **An initial phase of negative work augments subsequent positive work performed by the muscle.** (Reproduced, with permission, from Finni, Komi, and Lepola 2000. Copyright © 2000, Springer-Verlag; Gregor et al. 1988.)

A. The force in the Achilles tendon (**orange**) and patellar tendon (**purple**) vary during the ground-contact phase of two-legged hopping. The feet contact the ground at touchdown (**TD**) and leave the ground at toe-off (**TO**). For approximately the first half of the movement, the quadriceps and triceps surae muscles lengthen, performing negative work (negative velocity). The muscles perform positive work when they shorten (positive velocity). The sites of force transducer measurements are indicated by rectangles.

B. The force exerted by the soleus muscle of a cat running at moderate speed varies from the instant the paw touches the ground (**TD**) until it leaves the ground (**TO**). The force exerted by the muscle during the shortening contraction (positive velocity) is greater than the peak forces measured when the muscle contracts maximally against various constant loads (isotonic loading). Negative velocity reflects a lengthening contraction in the soleus muscle. The power produced by the soleus muscle of the cat during running is greater than that produced in an isolated-muscle experiment (**dashed line**). The phase of negative power corresponds to the lengthening contraction just after the paw is placed on the ground (TD), when the muscle performs negative work.

Second, uncertain conditions are usually accommodated by stiffening the joints through concurrent activation of the muscles that produce force in opposite directions. Coactivation of opposing muscles occurs often when a support surface is unsteady, when the body might experience an unexpected perturbation, or when lifting a heavy load. Because coactivation increases the energetic cost of performing a task, one characteristic of skilled performance is the ability to accomplish a task with minimal activation of muscles that produce opposing actions.

Muscle Work Depends on the Pattern of Activation

Limb muscles in healthy young adults are active 10% to 20% of the time during waking hours. For much of this time, the muscles perform constant-length (*isometric*) contractions to maintain a variety of static body postures. In contrast, muscle length has to change during a movement so that the muscle can perform work to displace body parts. A muscle performs positive work and produces power during a shortening contraction, whereas it performs negative work and absorbs power during a lengthening contraction. The capacity of muscle to do positive work establishes performance capabilities, such as the maximal height that can be jumped.

The nervous system can augment the positive work capacity of muscle by commanding a brief period of negative work before performing positive work. This activation sequence, the *stretch–shorten cycle,* occurs in many movements. When a person jumps in place on two feet, for example, the support phase involves an initial stretch (lengthening) and subsequent shortening of the ankle extensor and knee extensor muscles (Figure 31–17A). The forces in the Achilles and patellar tendons increase during the stretch of the lengthening contraction and reach a maximum at the onset of the shortening phase. As a result, the muscles can perform more positive work and produce more power during the shortening contraction (Figure 31–17B).

Although negative work involves an increase in the length of the muscle, the length of the fascicles in the muscle often remains relatively constant, which indicates that the connective tissue structures are stretched prior to the shortening contraction. Thus, the capacity of the muscle to perform more positive work comes from strain energy that can be stored in the elastic elements of muscle and tendon during the stretch phase and released during the subsequent shortening phase. More strain energy can be stored in long tendons, but short tendons are more advantageous when the movement requires the rapid release of strain energy.

Highlights

1. The basic functional unit for the control of movement by the nervous system is the motor unit, which comprises a motor neuron and the muscle fibers it innervates.
2. The force exerted by a muscle depends in part on the number and properties of the motor units that are activated and the rates at which they discharge action potentials. The key motor unit properties include contraction speed, maximal force, and fatigability, all of which can be altered by physical activity. Motor unit properties vary continuously across the population that innervates each muscle; that is, there are not distinct types of motor units. Due to technological advances, it is becoming possible to characterize the adaptations exhibited by populations of motor units in response to different types of changes in physical activity.
3. Motor units tend to be activated in a stereotypical order that is highly correlated with motor neuron size. The rate at which motor units are recruited during a voluntary contraction increases with contraction speed.
4. The rate at which a motor unit discharges action potentials in response to a given synaptic input can be modulated by descending inputs from the brain stem. The modulatory input is likely critical for establishing the level of excitation in spinal pathways, but this has been difficult to demonstrate in humans.
5. Except at low muscle forces, variation in discharge rate has a greater influence on muscle force than does the number of activated motor units. Moreover, the variability in discharge rate of the motor unit population influences the level of fine motor control.
6. The sarcomere is the smallest element of muscle to include a complete set of contractile proteins. A transient connection between the contractile proteins myosin and actin, known as the cross-bridge cycle, enables muscle to exert a force. The organization of the sarcomeres within a muscle varies substantially and, in addition to motor unit activity, has a major effect on the contractile properties of the muscle.
7. For a given arrangement of sarcomeres, the force a muscle can exert depends on the activation of the cross bridges by Ca^{2+}, the amount of overlap between the thick and thin filaments, and the velocity of the moving filaments. Sarcomere force during lengthening contractions is augmented by a Ca^{2+}-mediated increase in titin stiffness. The force

produced by activated sarcomeres depends on the interactions of three filaments: actin, myosin, and titin.

8. Most of the force generated by activated sarcomeres is transmitted laterally through a network of noncontractile proteins that maintains the alignment of the thick and thin filaments.
9. The functional capability of a muscle depends on the torque that it can exert, which is influenced both by its contractile properties and by the location of its attachments on the skeleton relative to the joint that it spans.
10. To perform a movement, the nervous system activates multiple muscles and controls the torque exerted about the involved joints. The nervous system can vary the magnitude and direction of a movement by altering the amount of motor unit activity, and hence muscle torque, relative to the load acting on the body.
11. Although muscle exerts only a pulling force on the skeleton, it can do so whether the activated muscle shortens or is lengthened by a load torque that exceeds the muscle torque. The force capacity of muscle is greater during lengthening contractions. Motor unit activity differs during shortening and lengthening contractions, but little is known about how the synaptic inputs to motor neurons differ during these two types of contractions.
12. Faster movements elicit motion-dependent interactions between body parts that produce unwanted accelerations. These actions must be controlled by the nervous system to produce an intended movement.
13. The nervous system must coordinate the activity of multiple muscles to provide a mechanical link between moving body parts and the required support from the surroundings. The muscles engaged for each action, such as grasping, reaching, running, and walking, are organized into a few sets that exhibit a stereotypical pattern of activation, but it is not known why particular patterns are preferred.
14. The patterns of muscle activity vary substantially between movements and often include strategies that augment the work capacity of muscles. The patterns can be modified by experience, but little is known about the locus of the adaptations other than that both spinal and supraspinal pathways are involved.

Sensory-Motor Integration in the Spinal Cord

DURING PURPOSEFUL MOVEMENTS the central nervous system uses information from a vast array of sensory receptors to ensure that the pattern of muscle activity suits the purpose. Without this sensory information, movements tend to be imprecise, and tasks requiring fine coordination in the hands, such as buttoning one's shirt, are difficult. The sensory-motor integration that makes the ongoing regulation of movement possible takes place at many levels of the nervous system, but the spinal cord has a special role because of the close coupling in the cord between sensory input and the motor output to the muscles.

Charles Sherrington was among the first to recognize the importance of sensory information in regulating movements. In 1906, he proposed that simple

reflexes—stereotyped movements elicited by activation of receptors in skin or muscle—are the basic units for movement. He also emphasized that all parts of the nervous system are connected and that no part is ever capable of activation without affecting or being affected by other parts. In his words, the simple reflex is a convenient if not a probable fiction.

Laboratory studies of reflexes in animals from the 1950s and onward demonstrated that descending motor pathways and afferent sensory pathways converge on common interneurons in the spinal cord. Later research in intact animals and in humans engaged in normal behavior confirmed that the neural circuitries in the spinal cord take part in conveying and shaping the motor command to the muscles by integrating descending motor commands and sensory feedback signals. Nevertheless, the idea of simple reflexes is convenient for understanding the principles of organization of sensory-motor integration in the spinal cord and of how sensory input to different spinal circuits contributes to movement control.

In this chapter, we explain the principles underlying sensory-motor integration in the spinal cord and describe how this integration regulates movement. For this purpose, we must first have a thorough knowledge of how reflex pathways in the spinal cord are organized.

Reflex Pathways in the Spinal Cord Produce Coordinated Patterns of Muscle Contraction

The sensory stimuli that activate spinal reflex pathways act outside the spinal cord, on receptors in muscles, joints, and skin. By contrast, the neural circuitry responsible for the motor response is entirely contained within the spinal cord. The interneurons in the reflex pathways and the resulting reflexes have traditionally been classified based on the sensory modality and type of sensory fiber that activates the interneurons. As we shall see, this classification is inconsistent with the significant convergence of multiple modalities on common interneurons, but as a starting point, it is still useful to distinguish reflex pathways based on whether the principal sensory input originates from muscle or skin.

The Stretch Reflex Acts to Resist the Lengthening of a Muscle

The simplest and certainly the most studied spinal reflex is the *stretch reflex*, a reflex muscle contraction elicited by lengthening of the muscle. Stretch reflexes were originally thought to be an intrinsic property of muscles. Early in the 20th century, however, Liddell and Sherrington showed that the stretch reflex could be abolished by cutting either the dorsal or ventral root, thus establishing that these reflexes require sensory input from muscle to spinal cord and a return path to muscle (Figure 32–1A).

We now know that the receptor that senses the change of length is the muscle spindle (Box 32–1) and that the type Ia sensory axon from this receptor makes direct excitatory connections with motor neurons. (The classification of sensory fibers from muscle is discussed in Box 32–2.) The afferent axon also connects to interneurons that inhibit the motor neurons innervating antagonist muscles, an arrangement called reciprocal innervation. This inhibition prevents muscle contractions that might otherwise resist the movements produced by the stretch reflexes.

Sherrington developed an experimental model for investigating spinal circuitry that is especially valuable in the study of stretch reflexes. He conducted his experiments on cats whose brain stems had been surgically transected at the level of the midbrain, between the superior and inferior colliculi. This is referred to as a *decerebrate preparation.* The effect of this procedure is to disconnect the rest of the brain from the spinal cord, thus blocking sensations of pain as well as interrupting normal modulation of reflexes by higher brain centers. A decerebrate animal has stereotyped and usually heightened stretch reflexes, making it easier to examine the factors controlling their expression.

Without control by higher brain centers, descending pathways from the brain stem powerfully facilitate the neuronal circuits involved in the stretch reflexes of extensor muscles. This results in a dramatic increase in tone of the extensor muscle that sometimes can suffice to support the animal in a standing position. In normal animals and humans, owing to the balance between facilitation and inhibition, stretch reflexes are weaker and considerably more variable in strength than those in decerebrate animals.

Neuronal Networks in the Spinal Cord Contribute to the Coordination of Reflex Responses

The Stretch Reflex Involves a Monosynaptic Pathway

The neural circuit responsible for the stretch reflex was one of the first reflex pathways to be examined in detail. The physiological basis of this reflex was examined by measuring the latency of the response in

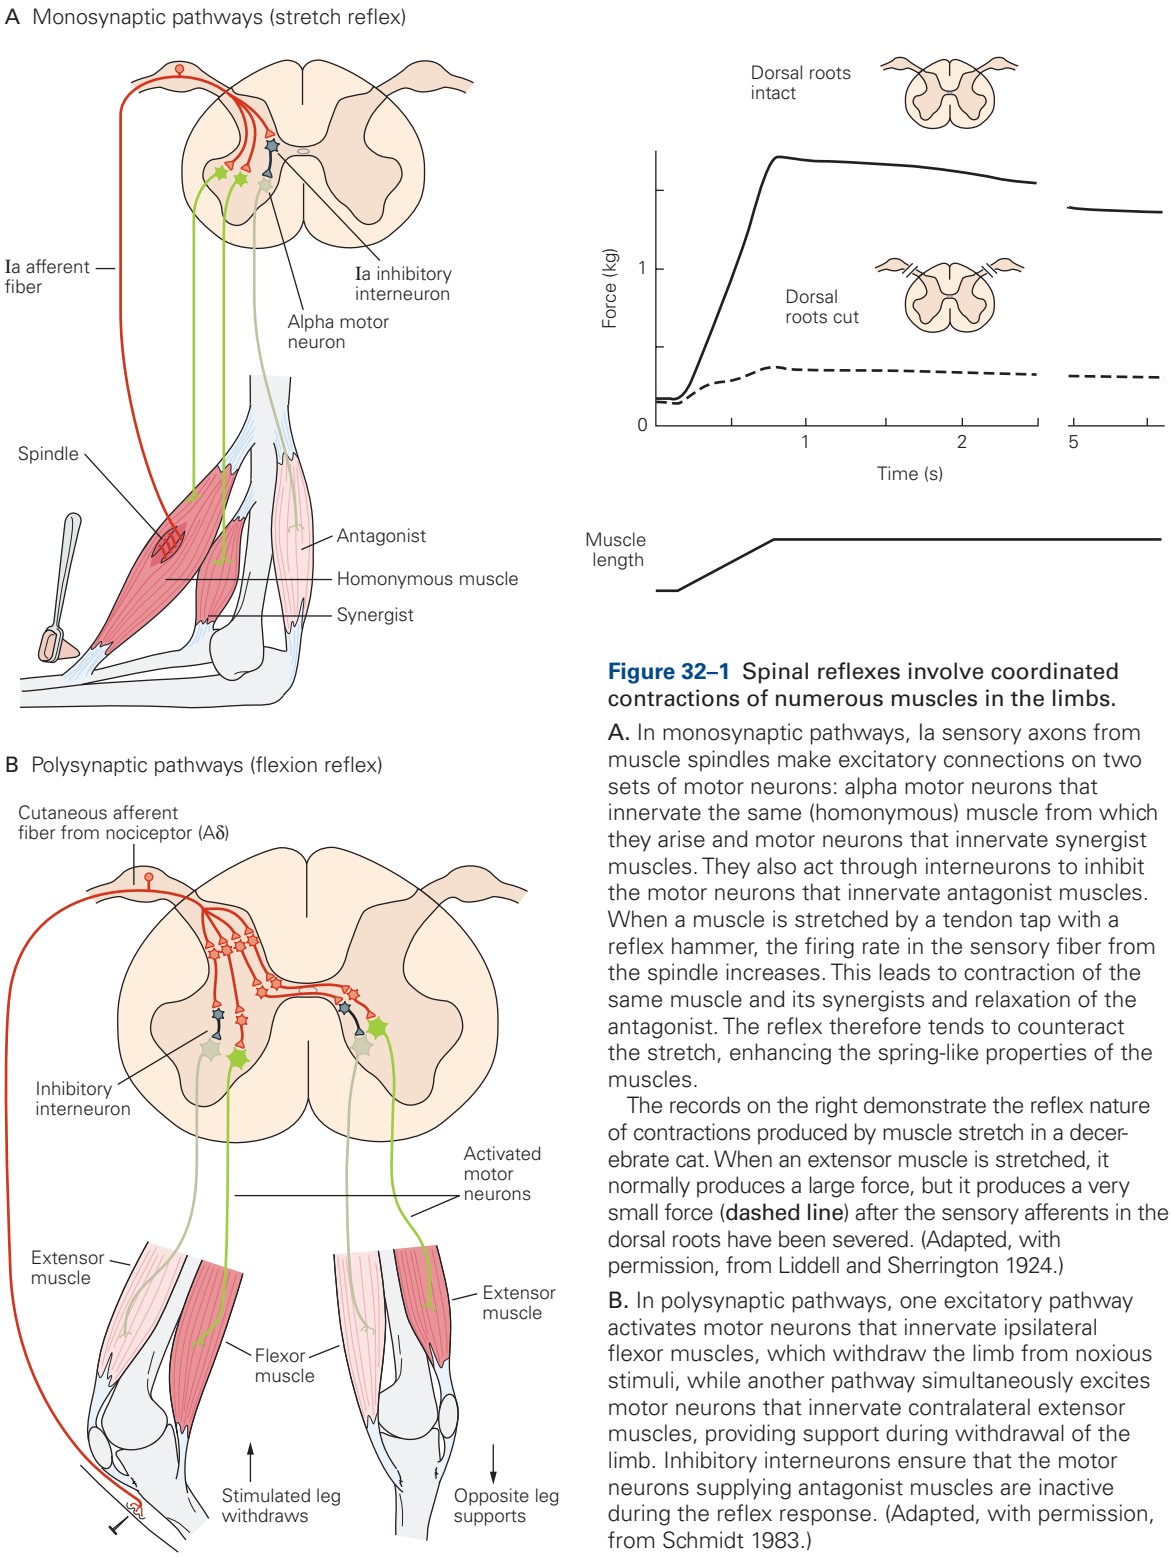

Figure 32–1 Spinal reflexes involve coordinated contractions of numerous muscles in the limbs.

A. In monosynaptic pathways, Ia sensory axons from muscle spindles make excitatory connections on two sets of motor neurons: alpha motor neurons that innervate the same (homonymous) muscle from which they arise and motor neurons that innervate synergist muscles. They also act through interneurons to inhibit the motor neurons that innervate antagonist muscles. When a muscle is stretched by a tendon tap with a reflex hammer, the firing rate in the sensory fiber from the spindle increases. This leads to contraction of the same muscle and its synergists and relaxation of the antagonist. The reflex therefore tends to counteract the stretch, enhancing the spring-like properties of the muscles.

The records on the right demonstrate the reflex nature of contractions produced by muscle stretch in a decerebrate cat. When an extensor muscle is stretched, it normally produces a large force, but it produces a very small force (**dashed line**) after the sensory afferents in the dorsal roots have been severed. (Adapted, with permission, from Liddell and Sherrington 1924.)

B. In polysynaptic pathways, one excitatory pathway activates motor neurons that innervate ipsilateral flexor muscles, which withdraw the limb from noxious stimuli, while another pathway simultaneously excites motor neurons that innervate contralateral extensor muscles, providing support during withdrawal of the limb. Inhibitory interneurons ensure that the motor neurons supplying antagonist muscles are inactive during the reflex response. (Adapted, with permission, from Schmidt 1983.)

Box 32–1 Muscle Spindles

Muscle spindles are small encapsulated sensory receptors that have a spindle-like or fusiform shape and are located within the fleshy part of a muscle. Their main function is to signal changes in the length of the muscle within which they reside. Changes in length of muscles are closely associated with changes in the angles of the joints that the muscles cross. Thus, muscle spindles are used by the central nervous system to sense relative positions of the body segments.

Each spindle has three main components: (1) a group of specialized *intrafusal* muscle fibers with noncontractile central regions; (2) sensory fibers that terminate on the central regions of the intrafusal fibers; and (3) motor axons that terminate on the contractile polar regions of the intrafusal fibers (Figure 32–2A,B).

When the intrafusal fibers are stretched, often referred to as "loading the spindle," the sensory axon endings are also stretched and increase their firing rate. Because muscle spindles are arranged in parallel with the *extrafusal* muscle fibers that make up the main body of the muscle, the intrafusal fibers change in length as the whole muscle changes. Thus, when a muscle is stretched, activity in the sensory axons of muscle spindles increases. When a muscle shortens, the spindle is unloaded and the activity decreases.

The intrafusal muscle fibers are innervated by *gamma* motor neurons, which have small-diameter myelinated axons, whereas the extrafusal muscle fibers are innervated by *alpha* motor neurons, with large-diameter myelinated axons. Activation of gamma motor neurons causes shortening of the polar regions of the intrafusal fibers. This in turn stretches the central region from both ends, leading to an increase in firing rate of the sensory axons or to a greater likelihood that the axons will fire in response to stretch of the muscle. Thus, the gamma motor neurons adjust the sensitivity of the muscle spindles. Contraction of the intrafusal muscle fibers does not contribute significantly to the force of muscle contraction.

The structure and functional behavior of muscle spindles is considerably more complex than this simple description depicts. As a muscle is stretched, the change in length has two phases: a dynamic phase, the period during which length is changing, and a static or steady-state phase, when the muscle has stabilized at a new length. Structural specializations within each component of the muscle spindle enable the sensory axons to signal aspects of each phase separately.

The intrafusal muscle fibers include nuclear bag fibers and nuclear chain fibers. The bag fibers can be classified as dynamic or static. A typical spindle has two or three bag fibers and a variable number of chain fibers, usually about five. Furthermore, the intrafusal fibers receive two types of sensory endings. A single Ia (large diameter) axon spirals around the central region of all intrafusal muscle fibers and serves as the *primary sensory ending* (Figure 32–2B). A variable number of type II (medium diameter) axons spiral around the static bag and chain fibers near their central regions and serve as *secondary sensory endings*.

The gamma motor neurons can also be divided into two classes: Dynamic gamma motor neurons innervate the dynamic bag fibers, whereas the static gamma motor neurons innervate the static bag fibers and the chain fibers.

This duality of structure is reflected in a duality of function. The tonic discharge of both primary and secondary sensory endings signals the steady-state length of the muscle. The primary sensory endings are, in addition, highly sensitive to the velocity of stretch, allowing them to provide information about the speed of movements. Because they are highly sensitive to small changes, the primary endings rapidly provide information about sudden unexpected changes in length, which can be used to generate quick corrective reactions.

Increases in the firing rate of dynamic gamma motor neurons increase the dynamic sensitivity of primary sensory endings but have no influence on secondary sensory endings. Increases in the firing rate of static gamma motor neurons increase the tonic level of activity in both primary and secondary sensory endings, decrease the dynamic sensitivity of primary endings (Figure 32–2C), and can prevent the silencing of primary endings when a muscle is released from stretch. Thus, the central nervous system can independently adjust the dynamic and static sensitivity of the different sensory endings in muscle spindles.

ventral roots to electrical stimulation of dorsal roots. When the Ia sensory axons innervating the muscle spindles were selectively activated, the reflex latency through the spinal cord was less than 1 ms. This demonstrated that the Ia fibers make direct connections on the alpha motor neurons because the delay at a single synapse is typically 0.5 ms to 0.9 ms (Figure 32–3B). In humans, an analog of the monosynaptic stretch reflex, the Hoffmann reflex, may be elicited by electrical stimulation of peripheral nerves (Box 32–3).

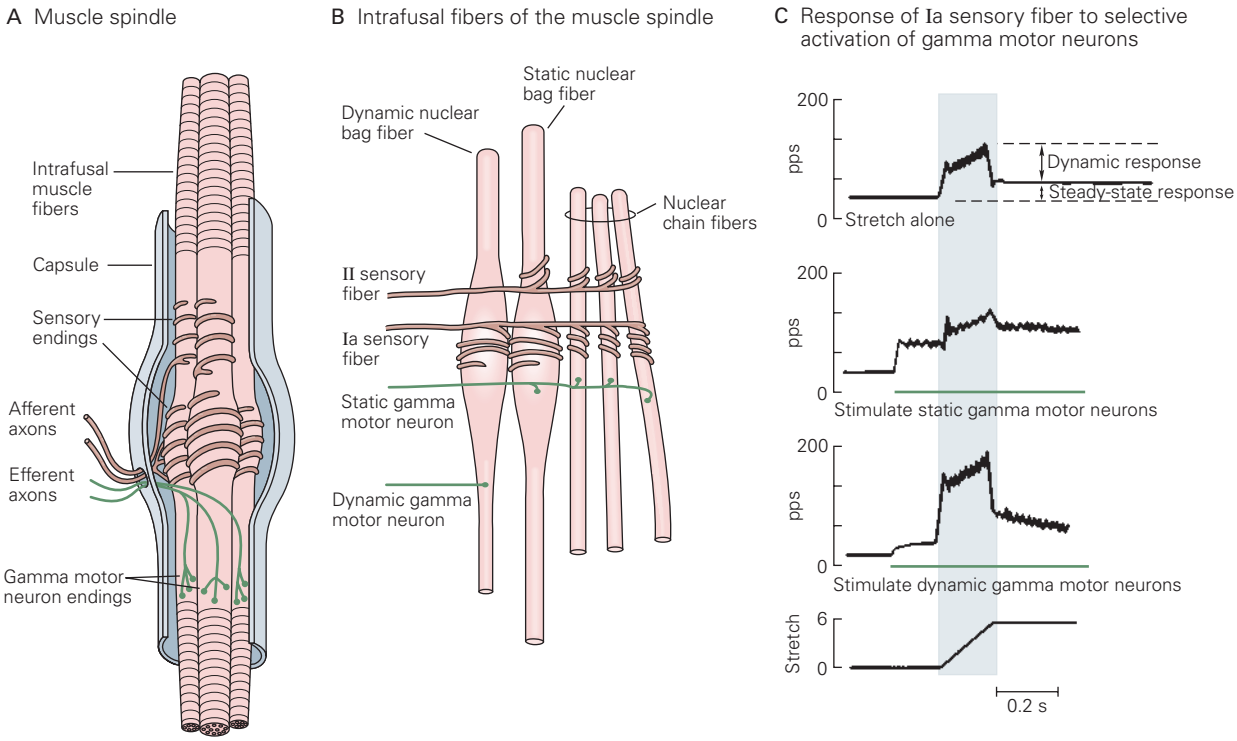

Figure 32–2 The muscle spindle detects changes in muscle length.

A. The main components of the muscle spindle are intrafusal muscle fibers, sensory axon endings, and motor axon endings. The intrafusal fibers are specialized muscle fibers with central regions that are not contractile. Gamma motor neurons innervate the contractile polar regions of the intrafusal fibers. Contraction of the polar regions pulls on the central regions of the intrafusal fiber from both ends. The sensory endings spiral around the central regions of the intrafusal fibers and are responsive to stretch of these fibers. (Adapted, with permission, from Hulliger 1984. Copyright © Springer-Verlag 1984.)

B. The muscle spindle contains three types of intrafusal fibers: dynamic nuclear bag, static nuclear bag, and nuclear chain fibers. A single Ia sensory axon innervates all three types of fibers, forming a primary sensory ending. Type II sensory axons innervate the nuclear chain fibers and static bag fibers, forming a secondary sensory ending. Two types of motor neurons innervate different intrafusal fibers. Dynamic gamma motor neurons innervate only dynamic bag fibers; static gamma motor neurons innervate various combinations of chain and static bag fibers. (Adapted, with permission, from Boyd 1980. Copyright © 1980. Published by Elsevier Ltd.)

C. Selective stimulation of the two types of gamma motor neurons has different effects on the firing of the Ia sensory fibers from the spindle. Without gamma stimulation, the Ia fiber shows a small dynamic response to muscle stretch and a modest increase in steady-state firing. When a static gamma motor neuron is stimulated, the steady-state response of the Ia fiber increases but the dynamic response decreases. When a dynamic gamma motor neuron is stimulated, the dynamic response of the Ia fiber is markedly enhanced, but the steady-state response gradually returns to its original level. (Adapted, with permission, from Brown and Matthews 1966.)

The pattern of connections of Ia fibers to motor neurons can be shown directly by intracellular recording. Ia fibers from a given muscle excite not only the motor neurons innervating that same (*homonymous*) muscle but also the motor neurons innervating other (*heteronymous*) muscles with a similar mechanical action.

Lorne Mendell and Elwood Henneman used a computer enhancement technique called *spike-triggered averaging* to determine the extent to which the action

Box 32–2 Classification of Sensory Fibers From Muscle

Sensory fibers are classified according to their diameter. Axons with larger diameters conduct action potentials more rapidly than those with smaller diameters (Chapters 9 and 18). Because each class of sensory receptors is innervated by fibers with diameters within a restricted range, this method of classification distinguishes to some extent the fibers that arise from different types of receptor organs. The main groups of sensory fibers from muscle are listed in Table 32–1.

The organization of reflex pathways in the spinal cord has been established primarily by electrically stimulating the sensory fibers and recording evoked responses in different classes of neurons in the spinal cord. This method of activation has three advantages over natural stimulation. The timing of afferent input can be precisely established; the responses evoked in motor neurons and other neurons by different classes of sensory fibers can be assessed by grading the strength of the electrical stimulus; and certain classes of receptors can be selectively activated.

The strength of the electrical stimulus required to activate a sensory fiber is measured relative to the strength required to activate the fibers with the largest diameter because these fibers have the lowest threshold for electrical activation. The thresholds of most type I fibers usually range from one to two times that of the largest fibers (with Ia fibers having, on average, a slightly lower threshold than Ib fibers). For most type II fibers, the threshold is 2 to 5 times higher, whereas types III and IV have thresholds in the range of 10 to 50 times that of the largest sensory fibers.

Table 32–1 Classification of Sensory Fibers From Muscle

Type	Axon	Receptor	Sensitivity to
Ia	12–20 μm myelinated	Primary spindle ending	Muscle length and rate of change of length
Ib	12–20 μm myelinated	Golgi tendon organ	Muscle tension
II	6–12 μm myelinated	Secondary spindle ending	Muscle length (little rate sensitivity)
II	6–12 μm myelinated	Nonspindle endings	Deep pressure
III	2–6 μm myelinated	Free nerve endings	Pain, chemical stimuli, and temperature (important for physiological responses to exercise)
IV	0.5–2 μm nonmyelinated	Free nerve endings	Pain, chemical stimuli, and temperature

potentials in single Ia fibers are transmitted to a population of spinal motor neurons. They found that individual Ia axons make excitatory synapses with all homonymous motor neurons innervating the medial gastrocnemius of the cat. This widespread divergence effectively amplifies the signals of individual Ia fibers, leading to a strong excitatory drive to the muscle from which they originate (*autogenic excitation*).

The Ia axons in reflex pathways also provide excitatory inputs to many of the motor neurons innervating synergist muscles (up to 60% of the motor neurons of some synergists) (Figure 32–1A). Although widespread, these connections are not as strong as the connections to homonymous motor neurons.

The Ia fibers also send inhibitory signals via the *Ia inhibitory interneurons* to the alpha motor neurons innervating antagonistic muscles. This disynaptic inhibitory pathway is the basis for reciprocal innervation: When a muscle is stretched, its antagonists relax.

Gamma Motor Neurons Adjust the Sensitivity of Muscle Spindles

Activity of muscle spindles may be modulated by changing the level of activity in the gamma motor neurons, which innervate the intrafusal muscle fibers of muscle spindles (Box 32–1). This function of gamma motor neurons, often referred to as the fusimotor

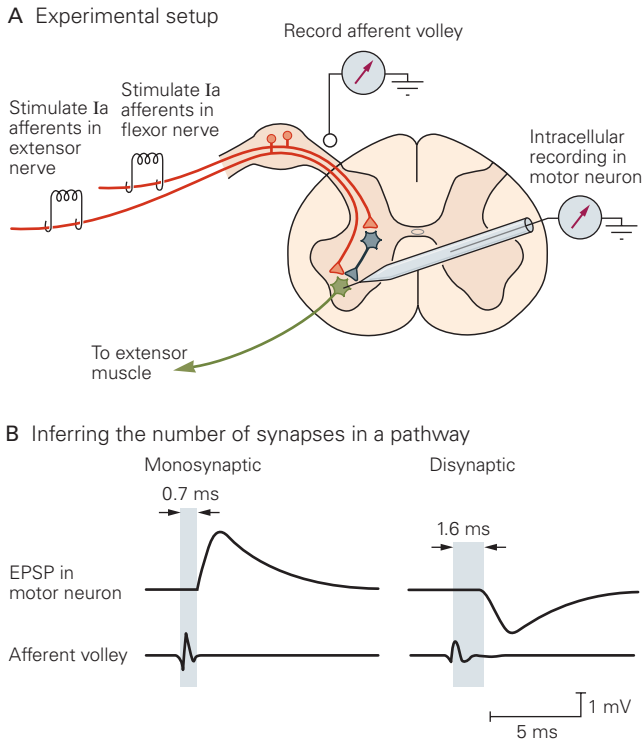

Figure 32–3 The number of synapses in a reflex pathway can be inferred from intracellular recordings.

A. An intracellular recording electrode is inserted into the cell body of a spinal motor neuron that innervates an extensor muscle. Stimulation of Ia sensory fibers from flexor or extensor muscles produces a volley of action potentials at the dorsal root.

B. *Left:* When Ia fibers from an extensor muscle are stimulated, the latency between the recording of the afferent volley and the excitatory postsynaptic potential (EPSP) in the motor neuron is only 0.7 ms, approximately equal to the duration of signal transmission across a single synapse. Thus, it can be inferred that the excitatory action of the stretch reflex pathway is monosynaptic. *Right:* When Ia fibers from an antagonist flexor muscle are stimulated, the latency between the recording of the afferent volley and the inhibitory postsynaptic potential in the motor neuron is 1.6 ms, approximately twice the duration of signal transmission across a single synapse. Thus, it can be inferred that the inhibitory action of the stretch reflex pathway is disynaptic.

system, can be demonstrated by selectively stimulating the alpha and gamma motor neurons under experimental conditions.

When only alpha motor neurons are stimulated, the firing of the Ia fiber from the muscle spindle pauses during contraction of the muscle because the muscle is shortening and therefore unloading (slackening) the spindle. However, if gamma motor neurons are activated at the same time as alpha motor neurons, the pause is eliminated. The contraction of the intrafusal fibers by the gamma motor neurons keeps the spindle under tension, thus maintaining the firing rate of the Ia fibers within an optimal range for signaling changes in length, whatever the actual length of the muscle (Figure 32–5). This *alpha-gamma co-activation* is recruited for many voluntary movements because it stabilizes the sensitivity of the muscle spindles.

In addition to the axons of gamma motor neurons, collaterals of alpha motor neuron axons sometimes innervate the intrafusal fibers. Axons that innervate both intrafusal and extrafusal muscle fibers are referred to as *beta* axons. Beta axon collaterals provide the equivalent of alpha-gamma coactivation. Beta innervation in spindles exists in both cats and humans, although it is unquantified for most muscles.

The forced linkage of extrafusal and intrafusal contraction by the beta fusimotor system highlights the importance of the independent fusimotor system (the gamma motor neurons). Indeed, in lower vertebrates, such as amphibians, beta efferents are the only source of intrafusal innervation. Mammals have evolved a mechanism that frees muscle spindles from complete dependence on the behavior of their parent muscles. In principle, this uncoupling allows greater flexibility in controlling spindle sensitivity for different types of motor tasks.

This conclusion is supported by recordings in spindle sensory axons during a variety of natural movements in cats. The amount and type of activity in gamma motor neurons are set at steady levels, which vary according to the specific task or context. In general, activity levels in both static and dynamic gamma motor neurons (Figure 32–2B) are set at progressively higher levels as the speed and difficulty of the movement increase. Unpredictable conditions, such as when the cat is picked up or handled, lead to marked increases in activity in dynamic gamma motor neurons and thus increased spindle responsiveness when muscles are stretched. When an animal is performing a difficult task, such as walking across a narrow beam, both static and dynamic gamma activation are at high levels (Figure 32–6).

Thus, the nervous system uses the fusimotor system to fine-tune muscle spindles so that the ensemble output of the spindles provides information most appropriate for a task. The task conditions under which independent control of alpha and gamma motor neurons occurs in humans have not yet been clearly established.

The Stretch Reflex Also Involves Polysynaptic Pathways

The monosynaptic Ia pathway is not the only spinal reflex pathway activated when a muscle is stretched. Type II sensory fibers from muscle spindles are also activated. These discharge tonically depending on

Box 32–3 The Hoffmann Reflex

The characteristics of the monosynaptic connections from Ia sensory fibers to spinal motor neurons in humans can be studied using an important technique introduced in the 1950s and based on early work by Paul Hoffmann. This technique involves electrically stimulating the Ia sensory fibers in a peripheral nerve and recording the reflex electromyogram (EMG) response in the homonymous muscle. The response is known as the *Hoffmann reflex*, or H-reflex.

The H-reflex is readily measured in the soleus muscle, an ankle extensor. The Ia fibers from the soleus and its synergists are excited by an electrode placed above the tibial nerve behind the knee (Figure 32–4A). The response recorded from the soleus muscle depends on stimulus strength. At low stimulus strengths, a pure H-reflex is evoked, for the threshold for activation of the Ia fibers is lower than the threshold for motor axons. Increasing the stimulus strength excites the motor axons innervating the soleus, producing two successive responses.

The first results from direct activation of the motor axons, and the second is the H-reflex evoked by stimulation of the Ia fibers (Figure 32–4B). These two components of the evoked EMG are called the M-wave and H-wave. The H-wave occurs later because it results from signals that travel to the spinal cord, across a synapse, and back again to the muscle. The M-wave, in contrast, results from direct stimulation of the motor axon innervating the muscle.

As the stimulus strength is increased still further, the M-wave continues to become larger and the H-wave progressively declines (Figure 32–4C). The decline in the H-wave amplitude occurs because action potentials in the motor axons propagate toward the cell body (antidromic conduction) and cancel reflexively evoked action potentials in the same motor axons. At very high stimulus strengths, only the M-wave persists.

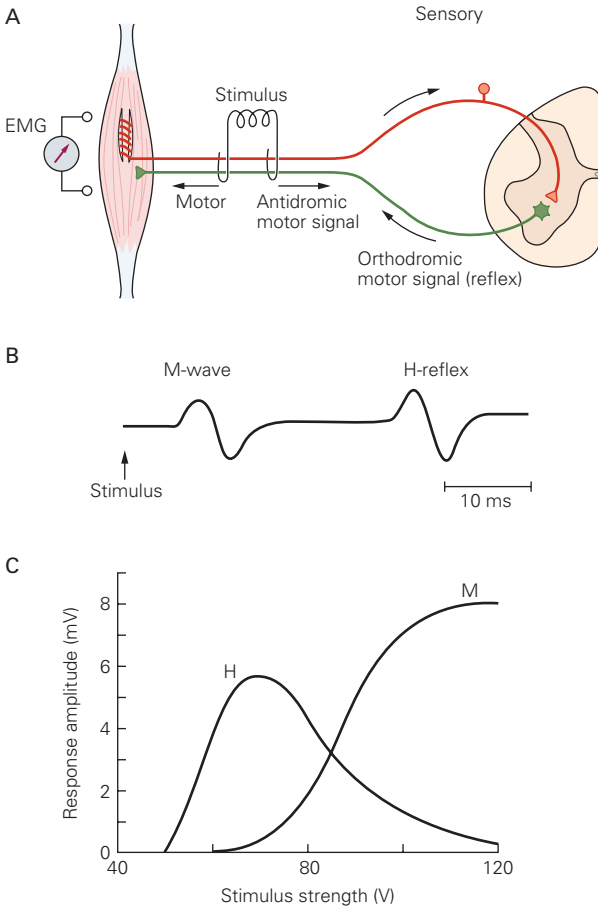

Figure 32–4 The Hoffmann reflex.

A. The Hoffmann reflex (H-reflex) is evoked by electrically stimulating Ia sensory fibers from muscle spindles. The sensory fibers excite alpha motor neurons, which in turn activate the muscle. When a mixed nerve is used, the motor neurons axons may also be activated directly.

B. At intermediate stimulus strengths, an M-wave precedes the H-wave (H-reflex) in the electromyogram (EMG).

C. As the stimulus strength increases, the orthodromic motor neuron spikes generated reflexively by the spindle sensory fibers are obliterated by antidromic spikes initiated by the electrical stimulus in the same motor axons. Figure 32–5 Activation of gamma motor neurons during active muscle contraction maintains muscle spindle sensitivity to muscle length. (Adapted, with permission, from Hunt and Kuffler 1951.)

A. Sustained tension elicits steady firing in the Ia sensory fiber from the muscle spindle (the two muscle fibers are shown separately for illustration only).

B. A characteristic pause occurs in the discharge of the Ia fiber when the alpha motor neuron is stimulated, causing a brief contraction of the muscle. The Ia fiber stops firing because the spindle is unloaded by the contraction.

C. Gamma motor neurons innervate the contractile polar regions of the intrafusal fibers of muscle spindles (see Figure 32–2A). If a gamma motor neuron is stimulated at the same time as the alpha motor neuron, the spindle is not unloaded during the contraction. As a result, the pause in discharge of the Ia sensory fiber that occurs when only the alpha motor neuron is stimulated is "filled in" by the response of the fiber to stimulation of the gamma motor neuron.

muscle length and gamma motor neuron activity (Box 32–1) and connect to different populations of excitatory and inhibitory interneurons in the spinal cord.

Some of the interneurons project directly to the spinal motor neurons, whereas others have more indirect connections. Because of the slower conduction velocity of type II sensory fibers and the signal relay through interneurons, the muscular responses elicited by group II fibers are smaller, more variable, and delayed compared to the monosynaptic stretch reflex. Some of the interneurons activated by group II fibers send axons across the midline of the spinal cord and give rise to crossed reflexes. Such connections that cross the midline are important for coordination of bilateral muscle activity in functional motor tasks.

Golgi Tendon Organs Provide Force-Sensitive Feedback to the Spinal Cord

Stimulation of Golgi tendon organs or their Ib sensory fibers in passive animals produces disynaptic inhibition of homonymous motor neurons (*autogenic*

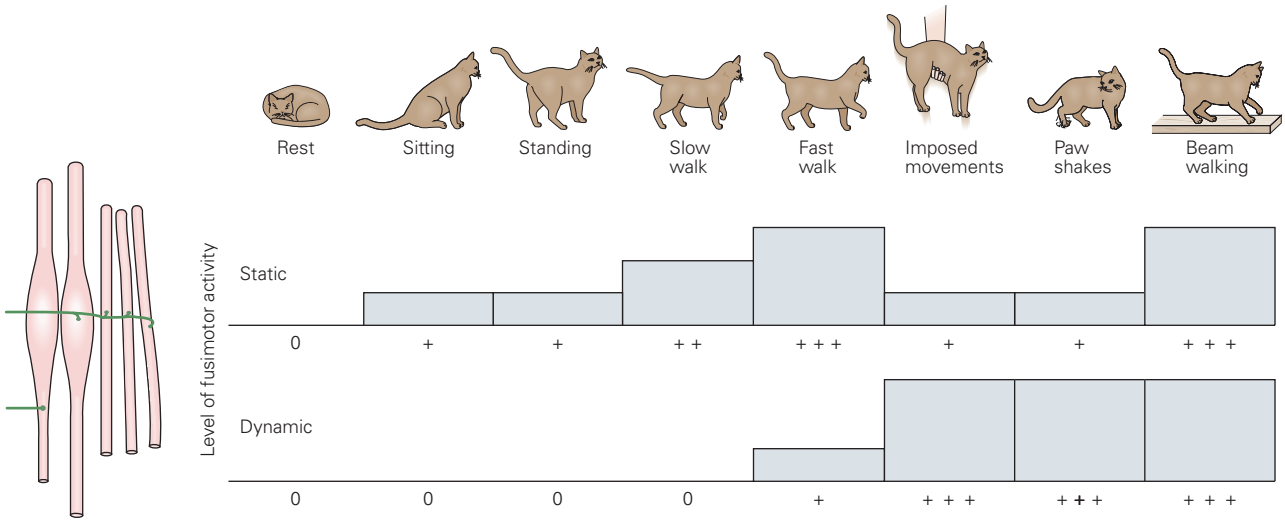

Figure 32–6 The level of activity in the fusimotor system varies with the type of behavior. Only static gamma motor neurons are active during activities in which muscle length changes slowly and predictably. Dynamic gamma motor neurons are activated during behaviors in which muscle length may change rapidly and unpredictably. (Adapted, with permission, from Prochazka et al. 1988.)

inhibition) and excitation of antagonist motor neurons (reciprocal excitation). Thus, these effects are the exact opposite of the responses evoked by muscle stretch or stimulation of Ia sensory axons.

This autogenic inhibition is mediated by *Ib inhibitory interneurons.* These inhibiting interneurons receive their principal input from Golgi tendon organs, sensory receptors that signal the tension in a muscle (Box 32–4), and they make inhibitory connections with homonymous motor neurons. However, stimulation of the Ib sensory fibers from tendon organs in active animals does not always inhibit homonymous motor neurons. Indeed, as we shall see later, stimulation of tendon organs may in certain conditions excite homonymous motor neurons.

One reason that the reflex actions of the sensory axons from tendon organs are complex in natural situations is that the Ib inhibitory interneurons also receive input from the muscle spindles, cutaneous receptors, and joint receptors (Figure 32–8A). In addition, they receive both excitatory and inhibitory input from various descending pathways.

Golgi tendon organs were first thought to have a protective function, preventing damage to muscle. It was assumed that they always inhibited homonymous motor neurons and that they fired only when tension in the muscle was high. We now know that these receptors signal minute changes in muscle tension, thus providing the nervous system with precise information about the state of a muscle's contraction.

The convergent sensory input from tendon organs, cutaneous receptors, and joint receptors to the Ib inhibitory interneurons (Figure 32–8A) may allow for precise spinal control of muscle force in activities such as grasping a delicate object. Additional input from cutaneous receptors may facilitate activity in the Ib inhibitory interneurons when the hand reaches an object, thus reducing the level of muscle contraction and permitting a soft grasp.

As is the case with the Ia fibers from muscle spindles, the Ib fibers from tendon organs form widespread connections with motor neurons that innervate muscles acting at different joints. Therefore, the connections of the sensory fibers from tendon organs with the Ib inhibitory interneurons are part of spinal networks that regulate movements of whole limbs.

Cutaneous Reflexes Produce Complex Movements That Serve Protective and Postural Functions

Most reflex pathways involve interneurons. One such reflex pathway is that of the flexion-withdrawal reflex, in which a limb is quickly withdrawn from a painful stimulus. Flexion-withdrawal is a protective reflex in which a discrete stimulus causes all the flexor muscles in that limb to contract coordinately. We know that this is a spinal reflex because it persists after complete transection of the spinal cord.

The sensory signal of the flexion-withdrawal reflex activates divergent polysynaptic reflex pathways. One

Box 32–4 Golgi Tendon Organs

Golgi tendon organs are slender encapsulated structures approximately 1 mm long and 0.1 mm in diameter located at the junction between skeletal muscle fibers and tendon. Each capsule encloses several braided collagen fibers connected in series to a group of muscle fibers.

Each tendon organ is innervated by a single Ib axon that branches into many fine endings inside the capsule; these endings become intertwined with the collagen fascicles (Figure 32–7A).

Stretching of the tendon organ straightens the collagen fibers, thus compressing the Ib nerve endings and causing them to fire. Because the nerve endings are so closely associated with the collagen fibers, even very small stretches of the tendons can compress the nerve endings.

Whereas muscle spindles are most sensitive to changes in length of a muscle, tendon organs are most sensitive to changes in muscle tension. Contraction of the muscle fibers connected to the collagen fiber bundle containing the receptor is a particularly potent stimulus to a tendon organ. The tendon organs are thus readily activated during normal movements. This has been demonstrated by recordings from single Ib axons in humans making voluntary finger movements and in cats walking normally.

Studies in anesthetized animal preparations have shown that the average level of activity in the population of tendon organs in a muscle is a good index of the total force in a contracting muscle (Figure 32–7B). This close agreement between firing frequency, and force is consistent with the view that the tendon organs continuously measure the force in a contracting muscle.

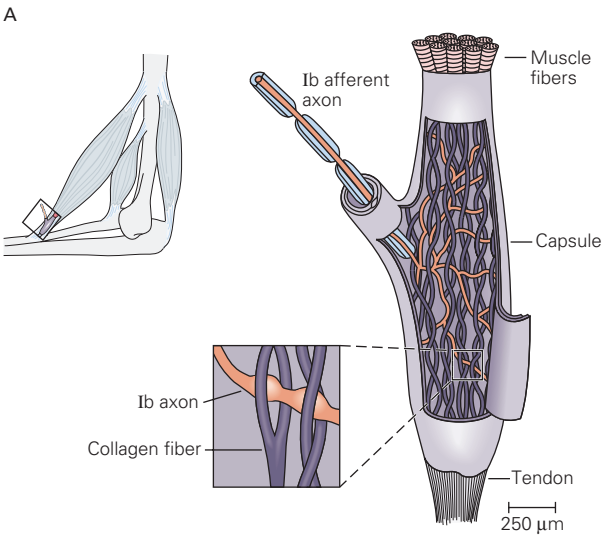

Figure 32–7A When the Golgi tendon organ is stretched (usually because of contraction of the muscle), the Ib afferent axon is compressed by collagen fibers (see enlargement) and its rate of firing increases. (Adapted, with permission, from Schmidt 1983; inset adapted, with permission, from Swett and Schoultz 1975.)

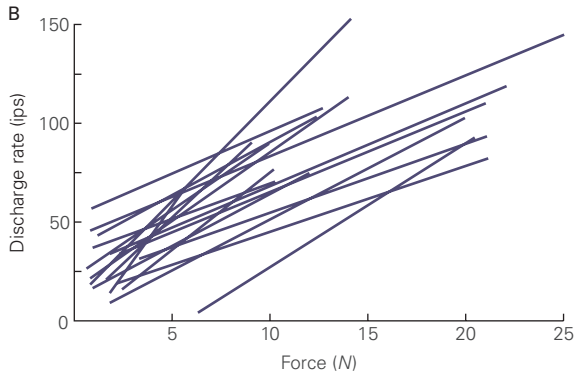

Figure 32–7B The discharge rate of a population of Golgi tendon organs signals the force in a muscle. Linear regression lines show the relationship between discharge rate and force for Golgi tendon organs of the soleus muscle of the cat. (Adapted, with permission, from Crago, Houk, and Rymer 1982.)

excites motor neurons that innervate flexor muscles of the stimulated limb, whereas another inhibits motor neurons that innervate the limb's extensor muscles (Figure 32–1B). This reflex can produce an opposite effect in the contralateral limb, that is, excitation of extensor motor neurons and inhibition of flexor motor neurons. This *crossed-extension reflex* serves to enhance postural support during withdrawal of a foot from a painful stimulus. Activation of the extensor muscles in the opposite leg counteracts the increased load caused by lifting the stimulated limb. Thus, flexion-withdrawal is a complete, albeit simple, motor act.

Although flexion reflexes are relatively stereotyped, both the spatial extent and the force of muscle contraction depend on stimulus intensity. Touching a stove that is slightly hot may produce moderately

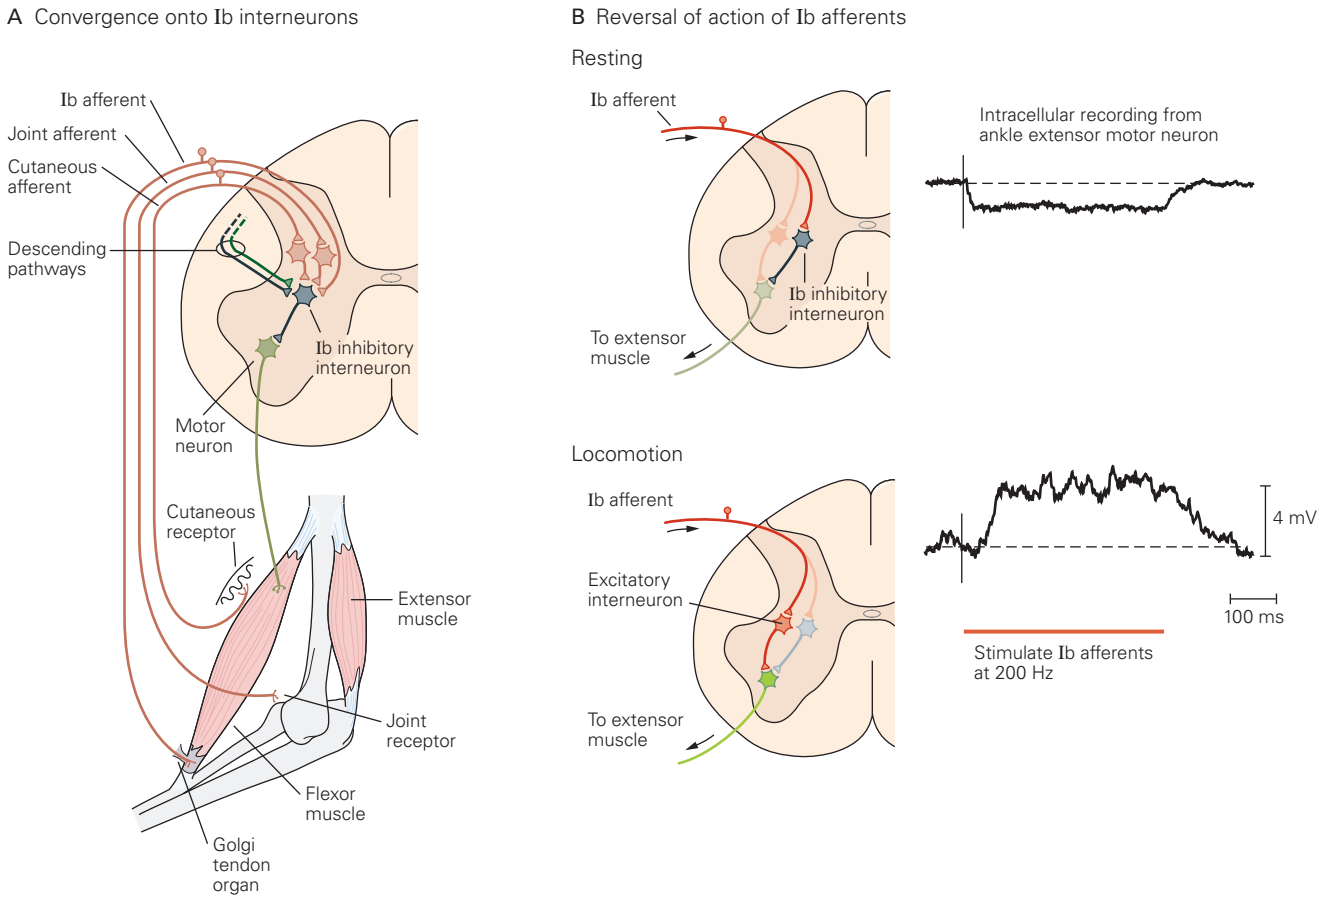

Figure 32–8 The reflex actions of Ib sensory fibers from Golgi tendon organs are modulated during locomotion.

A. The Ib inhibitory interneuron receives input from tendon organs, muscle spindles (not shown), joint and cutaneous receptors, and descending pathways.

B. The action of Ib sensory fibers on extensor motor neurons is reversed from inhibition to excitation when walking is initiated. When the animal is resting, stimulation of Ib fibers from the ankle extensor muscle inhibits ankle extensor motor neurons through Ib inhibitory interneurons, as shown by the hyperpolarization in the record. During walking, the Ib inhibitory interneurons are inhibited while excitatory interneurons that receive input from Ib sensory fibers are facilitated by the command system for walking, thus opening a Ib excitatory pathway from the Golgi tendon organs to motor neurons.

fast withdrawal only at the wrist and elbow, whereas touching a very hot stove invariably leads to a forceful contraction at all joints, leading to rapid withdrawal of the entire limb. The duration of the reflex usually increases with stimulus intensity, and the contractions produced in a flexion reflex always outlast the stimulus.

Because of the similarity of the flexion-withdrawal reflex to stepping, it was once thought that the flexion reflex is important in producing contractions of flexor muscles during walking. We now know, however, that a major component of the neural control system for walking is a set of intrinsic spinal circuits that do not require sensory stimuli (Chapter 33). Nevertheless, in mammals, the intrinsic spinal circuits that control walking share many of the interneurons involved in flexion reflexes.

Convergence of Sensory Inputs on Interneurons Increases the Flexibility of Reflex Contributions to Movement

The Ib inhibitory interneuron is not the only interneuron that receives convergent input from many different sensory modalities. An enormous diversity of sensory information converges on interneurons in the spinal cord, enabling them to integrate information from muscle, joints, and skin.

Interneurons activated by groups I and II sensory fibers have received special attention. It was thought

for some time that excitatory and inhibitory interneurons activated by group II fibers could be distinguished from those activated by group Ib afferents, but it is now believed that this distinction has to be abandoned and that groups I and II fibers converge on common populations of interneurons that integrate force and length information from the active muscle and thereby help coordinate muscle activity according to the length of the muscle, its activity level, and the external load.

Sensory Feedback and Descending Motor Commands Interact at Common Spinal Neurons to Produce Voluntary Movements

As pointed out by Michael Foster in his 1879 physiology textbook, it must be an "economy to the body" that the will should make use of the networks in the spinal cord to generate coordinated movements "rather than it should have recourse to an apparatus of its own of a similar kind." Research in the subsequent 140 years has confirmed this conjecture.

The first evidence came from intracellular recordings of synaptic potentials elicited in cat spinal motor neurons by combined and separate stimulation of sensory fibers and descending pathways. When separate stimuli are reduced in intensity to just below threshold for evoking a synaptic potential, combining the stimulations at appropriate intervals makes the synaptic potential reappear. This provides evidence of convergence of the sensory fibers and the descending pathways onto common interneurons in the reflex pathway (see Figure 13–14). Direct recordings from spinal interneurons have confirmed this, as have noninvasive Hoffmann reflex tests in human subjects (Figure 32–9).

Direct evidence that sensory feedback helps to shape voluntary motor commands through spinal reflex networks in humans comes from experiments in which sensory activity in length- and force-sensitive afferents has suddenly been reduced or abolished. This can be done by suddenly unloading or shortening a muscle during a voluntary contraction. The short latency of the consequent reduction in muscle activity can only be explained by sensory activity through a reflex pathway that directly contributes to the muscle activity.

Muscle Spindle Sensory Afferent Activity Reinforces Central Commands for Movements Through the Ia Monosynaptic Reflex Pathway

Stretch reflex pathways can contribute to the regulation of motor neurons during voluntary movements and during maintenance of posture because they form closed feedback loops. For example, stretching a muscle increases activity in spindle sensory afferents, leading to muscle contraction and consequent shortening of the muscle. Muscle shortening in turn leads to decreased activity in spindle afferents, reduction of muscle contraction, and lengthening of the muscle.

The stretch reflex loop thus acts continuously—the output of the system, a change in muscle length, becomes the input—tending to keep the muscle close to a desired or reference length. The stretch reflex pathway is a negative feedback system, or *servomechanism*, because it tends to counteract or reduce deviations from the reference value of the regulated variable.

In 1963, Ragnar Granit proposed that the reference value in voluntary movements is set by descending signals that act on both alpha and gamma motor neurons. The rate of firing of alpha motor neurons is set to produce the desired shortening of the muscle, and the rate of firing of gamma motor neurons is set to produce an equivalent shortening of the intrafusal fibers of the muscle spindle. If the shortening of the whole muscle is less than what is required by a task, as when the load is greater than anticipated, the sensory fibers increase their firing rate because the contracting intrafusal fibers are stretched (loaded) by the relatively greater length of the whole muscle. If shortening is greater than necessary, the sensory fibers decrease their firing rate because the intrafusal fibers are relatively slackened (unloaded) (Figure 32–10A).

In theory, this mechanism could permit the nervous system to produce movements of a given distance without having to know in advance the actual load or weight being moved. In practice, however, the stretch reflex pathways do not have sufficient control over motor neurons to overcome large unexpected loads. This is immediately obvious if we consider what happens when we attempt to lift a heavy suitcase that we believe to be empty. Automatic compensation for the greater-than-anticipated load does not occur. Instead, we have to pause briefly to plan a new movement with much greater muscle activation.

Strong evidence that alpha and gamma motor neurons are co-activated during voluntary human movement comes from direct measurements of the activity of the sensory fibers from muscle spindles. In the late 1960s, Åke Vallbo and Karl-Erik Hagbarth developed microneurography, a technique for recording from the largest afferent fibers in peripheral nerves. Vallbo later found that during slow movements of the fingers the large-diameter Ia fibers from spindles in the contracting muscles increase their rate of firing even when the muscle shortens as it contracts (Figure 32–10B). This occurs because the gamma motor neurons, which have

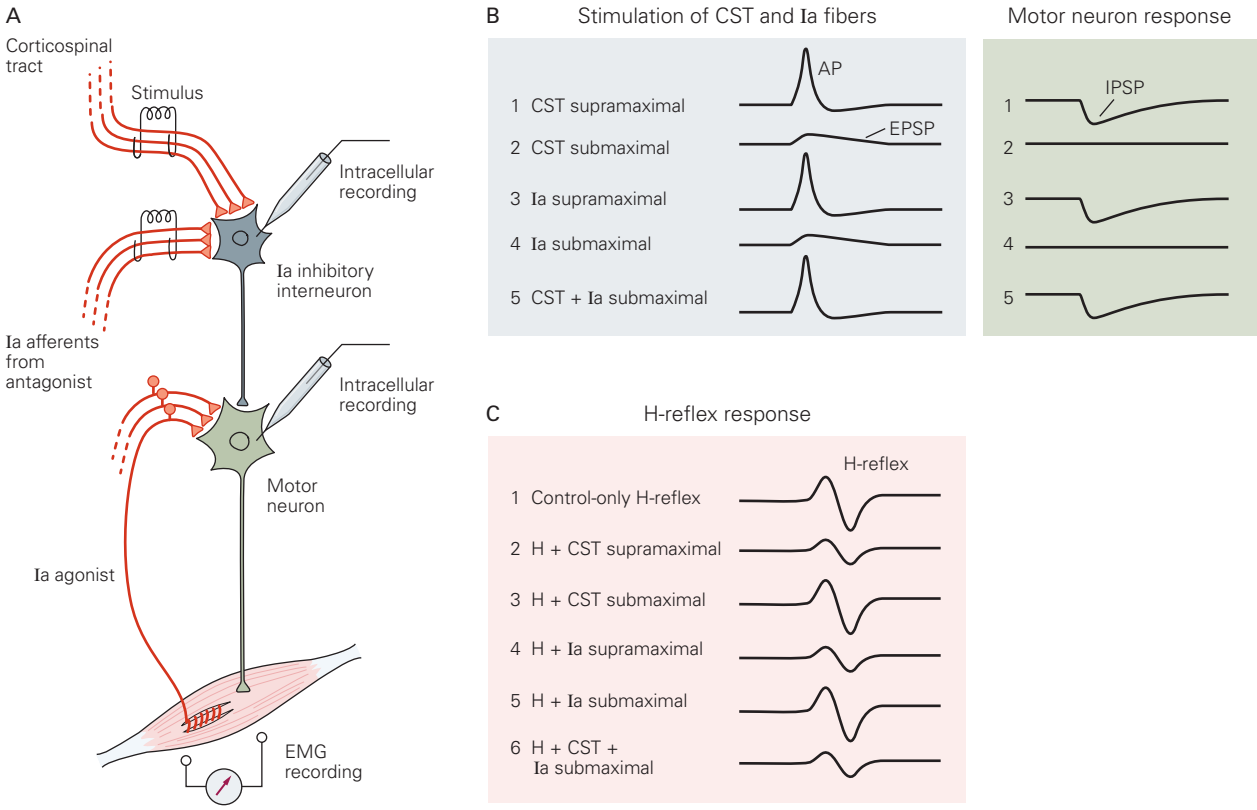

Figure 32–9 The spatial summation technique demonstrates how signals from descending inputs and spinal networks are integrated. This technique was introduced originally for investigation of spinal circuits in the cat in the 1950s, but it is also the basis of later investigations of the human spinal mechanisms of motor control. It relies on the spatial summation of synaptic inputs (see Figure 13–14), as illustrated here using the reciprocal Ia inhibitory pathway and corticospinal tract (**CST**).

A. The diagram shows the experimental setups for testing for convergence of excitatory reciprocal Ia and corticospinal pathways onto Ia inhibitory interneurons in the spinal cord.

B. In acute experiments on the cat spinal cord, supramaximal stimuli were applied separately to corticospinal fiber tracts (**1**) and Ia axons (**3**); each stimulus elicited an inhibitory postsynaptic potential (**IPSP**) in the motor neuron. Next, the intensities of the two stimuli were reduced to just submaximal levels, at which point each pathway failed to elicit an IPSP in the motor neuron (**2**, **4**). Then, when the two sets of submaximal stimuli were paired, they elicited an IPSP in the motor neuron (**5**), leading to the conclusion that the two input pathways converge on the same interneurons. This was confirmed by direct recording from a Ia inhibitory interneuron. (**AP**, action potential).

C. In humans, direct intracellular recording from interneurons and motor neurons is not possible, but recording of H-reflexes (Box 32–4, Figure 32–4) and transcutaneous stimulation of the corticospinal tract have provided indirect evidence for convergence similar to that demonstrated in cats (see part **B**). The electromyogram (**EMG**) record of the H-reflex provides a measure of the excitability of the spinal motor neurons (**1**). When the CST and antagonist Ia fibers were stimulated separately at supramaximal levels, the H-reflex amplitude was diminished due to the compound IPSPs elicited in the motor neurons (**2**, **4**). Next, the stimuli to these two excitatory pathways to the inhibitory interneurons were reduced until neither stimulus alone elicited a reduction in amplitude of the H-reflex (**3**, **5**). Then, the two submaximal stimuli were timed to produce synchronous subthreshold excitatory postsynaptic potentials (**EPSPs**) in the inhibitory interneurons (**6**). Because this protocol caused suppression of the H-reflex, one may conclude that the CST and Ia afferents converge on the same Ia inhibitory interneurons.

direct excitatory connections with spindles, are coactivated with alpha motor neurons.

Furthermore, when subjects attempt to make slow movements at a constant velocity, the firing of the Ia fibers mirrors the small deviations in velocity in the trajectory of the movements (sometimes the muscle shortens quickly and at other times more slowly). When the velocity of flexion increases transiently, the rate of firing in the fibers decreases because the muscle is shortening more rapidly and therefore exerts less tension on the intrafusal fibers. When the velocity decreases, firing increases because the muscle is

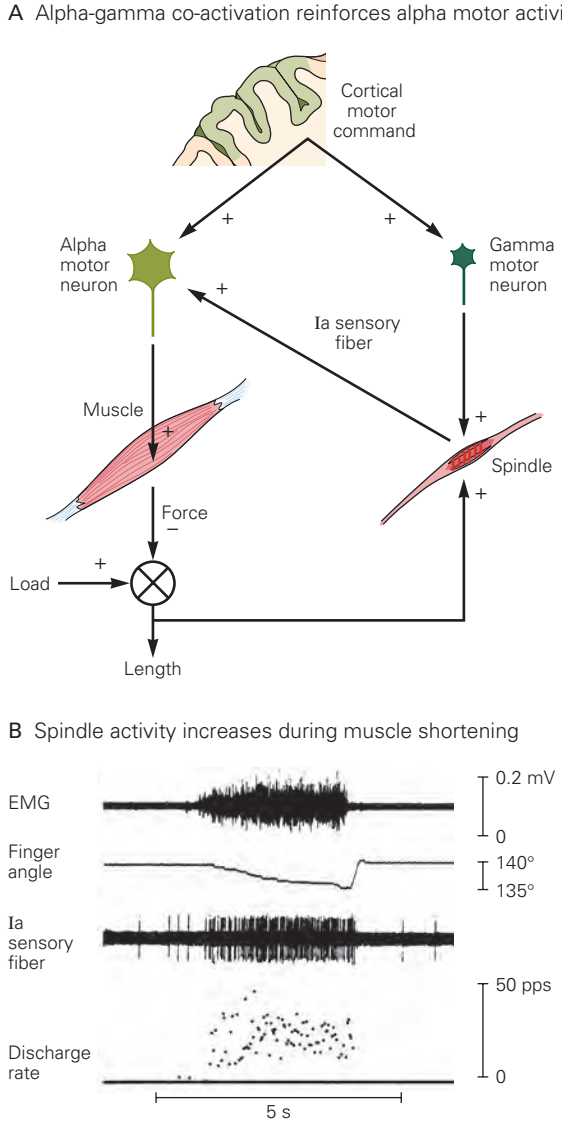

Figure 32–10 Co-activation of alpha and gamma motor neurons.

A. Co-activation of alpha and gamma motor neurons by a cortical motor command allows feedback from muscle spindles to reinforce activation in the alpha motor neurons. Any disturbance during a movement alters the length of the muscle and thus changes the activity in the sensory fibers from the spindles. The changed spindle input to the alpha motor neuron compensates for the disturbance.

B. The discharge rate in the Ia sensory fiber from a spindle increases during slow flexion of a finger. This increase depends on alpha-gamma co-activation. If the gamma motor neurons were not active, the spindle would slacken, and its discharge rate would decrease as the muscle shortened. (**EMG**, electromyogram; **PPS**, pulses/s) (Adapted, with permission, from Vallbo 1981.)

shortening more slowly, and therefore, the relative tension on the intrafusal fibers increases. This information can be used by the nervous system to compensate for irregularities in the movement trajectory by exciting the alpha motor neurons.

Modulation of Ia inhibitory Interneurons and Renshaw Cells by Descending Inputs Coordinate Muscle Activity at Joints

Reciprocal innervation is useful not only in stretch reflexes but also in voluntary movements. Relaxation of the antagonist muscle during a movement enhances speed and efficiency because the muscles that act as prime movers are not working against the contraction of opposing muscles.

The Ia inhibitory interneurons receive inputs from collaterals of the axons of neurons in the motor cortex that make direct excitatory connections with spinal motor neurons. This organizational feature simplifies the control of voluntary movements, because higher centers do not have to send separate commands to the opposing muscles.

It is sometimes advantageous to contract both the prime mover and the antagonist at the same time. Such *co-contraction* has the effect of stiffening the joint and is most useful when precision and joint stabilization are critical. An example of this phenomenon is the co-contraction of flexor and extensor muscles of the elbow immediately before catching a ball. The Ia inhibitory interneurons receive both excitatory and inhibitory signals from all of the major descending pathways (Figure 32–11A). By changing the balance of excitatory and inhibitory inputs onto these interneurons, supraspinal centers can modulate reciprocal inhibition of muscles and enable co-contraction, thus controlling the relative amount of joint stiffness to meet the requirements of the motor act.

The activity of spinal motor neurons is also regulated by another important class of inhibitory interneurons, the *Renshaw cells.* Excited by collaterals of the axons of motor neurons and receiving significant synaptic input from descending pathways, Renshaw cells make inhibitory synaptic connections with several populations of motor neurons, including the motor neurons that excite them, as well as Ia inhibitory interneurons (Figure 32–11B). The connections with motor neurons form a negative feedback system that regulates the firing rate of the motor neurons, whereas the connections with the Ia inhibitory interneurons regulate the strength of inhibition of antagonistic motor neurons, for instance in relation to co-contraction of antagonists. The distribution of projections from Renshaw

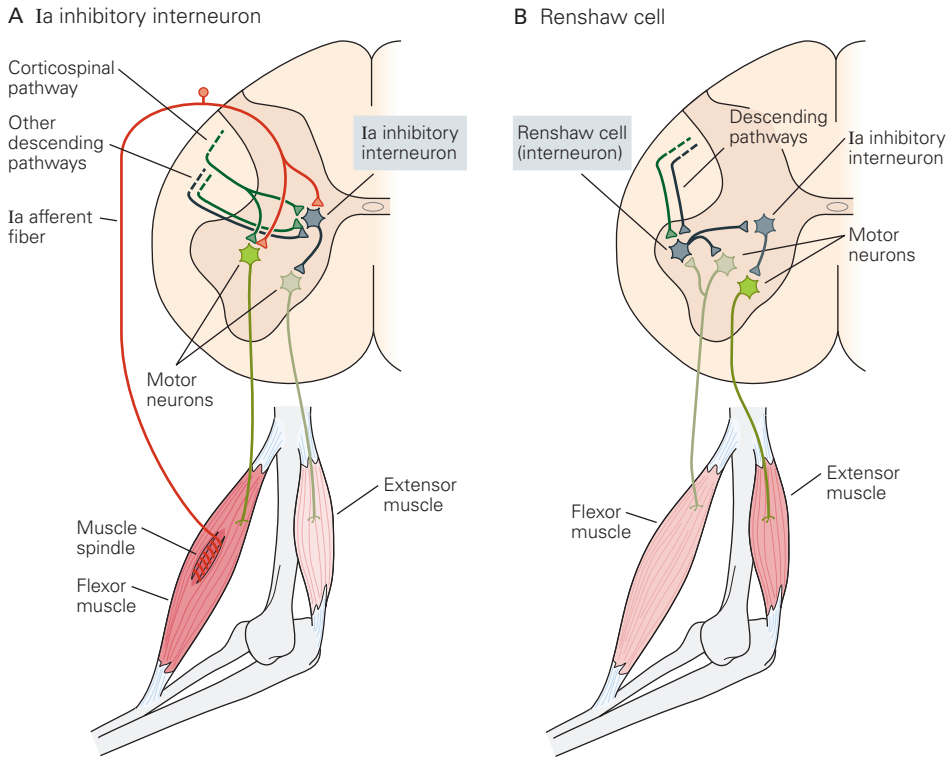

Figure 32–11 Inhibitory spinal interneurons coordinate reflex actions.

A. The Ia inhibitory interneuron regulates contraction in antagonist muscles in stretch reflex circuits through its divergent contacts with motor neurons. In addition, the interneuron receives excitatory and inhibitory inputs from corticospinal and other descending pathways. A change in the balance of these supraspinal signals allows the interneuron to coordinate co-contractions in antagonist muscles at a joint.

B. The Renshaw cell produces recurrent inhibition of motor neurons. These interneurons are excited by collaterals from motor neurons and inhibit those same motor neurons. This negative feedback system regulates motor neuron excitability and stabilizes firing rates. Renshaw cells also send collaterals to synergist motor neurons (not shown) and Ia inhibitory interneurons that synapse on antagonist motor neurons. Thus, descending inputs that modulate the excitability of the Renshaw cells adjust the excitability of all the motor neurons that control movement around a joint.

cells to different motor nuclei also facilitate that muscle activity is coordinated in functional synergies during movement.

Transmission in Reflex Pathways May Be Facilitated or Inhibited by Descending Motor Commands

As we have seen, in an animal at rest, the Ib sensory fibers from extensor muscles have an inhibitory effect on homonymous motor neurons. During locomotion, they produce an excitatory effect on those same motor neurons because transmission in the disynaptic inhibitory pathway is depressed (Figure 32–8B), while at the same time transmission through excitatory interneurons is facilitated.

This phenomenon, called *state-dependent reflex reversal*, illustrates how transmission in spinal circuit is regulated by descending motor commands to meet the changing requirements during movement. By favoring transmission through excitatory pathways from the load-sensitive Golgi tendon organs, the descending motor commands ensure that feedback from the active muscles automatically facilitates the activation of the muscles, thereby greatly simplifying the task for supraspinal centers.

State-dependent reflex reversal has also been demonstrated in humans. Stimulation of skin and muscle afferents from the foot produces facilitation of muscles that lift the foot early in the swing phase, but suppresses activity of the same muscles late in the swing phase. Both effects make good functional sense. Early in the swing phase, positive feedback from the foot will help to lift the foot over an obstacle, whereas suppression of the same muscles in late swing will help to lower the foot quickly to the ground so that the obstacle may be passed using the opposite leg first.

Descending Inputs Modulate Sensory Input to the Spinal Cord by Changing the Synaptic Efficiency of Primary Sensory Fibers

In the 1950s and early 1960s, John C. Eccles and his collaborators demonstrated that monosynaptic excitatory postsynaptic potentials (EPSPs) elicited in cat spinal motor neurons by stimulation of Ia sensory fibers become smaller when other Ia fibers are stimulated. This led to the discovery in the spinal cord of several groups of GABAergic inhibitory interneurons that exert presynaptic inhibition of primary sensory neurons (Figure 32–12). Some interneurons inhibit mainly Ia sensory axons, whereas others inhibit mainly Ib axons or sensory fibers from skin.

The principal mechanism responsible for sensory inhibition is a depolarization of the primary terminal caused by an inward Cl^- current when GABAergic receptors on the terminal are activated. This depolarization inactivates some of the Na^+ channels in the terminal, so the action potentials that reach the synapse are reduced in size. The effect of this is that release of neurotransmitter from the sensory afferent is diminished.

When tested by stimulation of peripheral afferents, presynaptic inhibition is widespread in the spinal cord and affects primary afferents from all muscles in a limb. However, similar to other interneurons, the neurons responsible for presynaptic inhibition are also controlled by descending pathways, making possible a much more focused modulation of presynaptic inhibition in relation to movement. Presynaptic inhibition at the synapse of Ia axons with motor neurons of the muscles that are activated as part of a movement is reduced at the onset of movement. In contrast, presynaptic inhibition of Ia axons on motor neurons connected to inactive muscles is increased. One example of this selective modulation is increased presynaptic inhibition of Ia axons at their synapse with antagonist motor neurons, which explains part of the reduction of stretch reflexes in antagonist muscles at the onset of agonist contraction. In this way, the nervous system takes advantage of the widespread connectivity of Ia axons, using presynaptic inhibition to shape activity in the Ia afferent network to facilitate activation of specific muscles.

Presynaptic inhibition provides a mechanism by which the nervous system can reduce sensory feedback predicted by the motor command, while allowing unexpected feedback access to the spinal motor circuit and the rest of the nervous system. In line with this function, presynaptic inhibition of Ia sensory axons from muscle spindles generally increases during

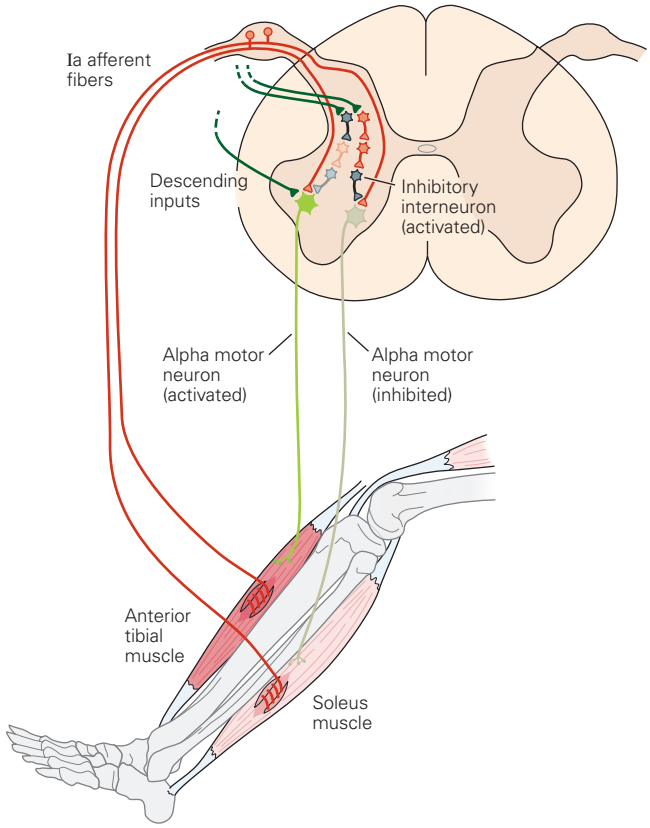

Figure 32–12 **Selective modulation of primary sensory axon terminals by descending presynaptic inhibitory inputs contributes to generation of coordinated limb movements.** Inhibitory interneurons (**blue**) activated by descending inputs can have either pre- or postsynaptic effects. Some interneurons releasing the inhibitory neurotransmitter γ-aminobutyric acid (GABA) form axo-axonic synapses with the primary sensory fibers. The principal inhibitory mechanism involves activation of GABAergic receptors on the terminals of the presynaptic Ia sensory axons, resulting in depolarization of the terminals and reduced transmitter release. Such presynaptic inhibition is widely distributed in the spinal cord. Stimulation of Ia sensory fibers from one flexor muscle may elicit presynaptic inhibition of both flexor and extensor Ia axon terminals on motor neurons innervating muscles throughout the limb. However, several different populations of interneurons mediating presynaptic inhibition exist, which allows a very specific regulation of presynaptic inhibition in relation to voluntary movements. Interaction of sensory inputs with descending motor commands in the corticospinal tract may thus *decrease* presynaptic inhibition of Ia axon terminals on agonist motor neurons (eg, anterior tibial motor neurons) and at the same time *increase* presynaptic inhibition of Ia terminals on antagonist motor neurons (eg, soleus motor neurons). Regulation of presynaptic inhibition may thus simultaneously facilitate the sensory feedback to the activation of agonist motor neurons and at the same time diminish the risk that stretch of the antagonist muscles will elicit a stretch reflex that would counteract the movement.

movements that are highly predictable, such as walking and running.

Finally, presynaptic inhibition may help stabilize the execution of movements by preventing excessive sensory feedback and associated self-reinforcing oscillatory activity.

Part of the Descending Command for Voluntary Movements Is Conveyed Through Spinal Interneurons

In cats as well as most other vertebrates, the corticospinal tract has no direct connections to spinal motor neurons; all the descending commands have to be channeled through spinal interneurons that are also part of reflex pathways. Humans and Old World monkeys are the only species in which corticospinal neurons make direct connections with the spinal motor neurons in the ventral horn of the spinal cord. Even in these species, a considerable fraction of the corticospinal tract fibers terminate in the intermediate nucleus on spinal interneurons, and the corticospinal fibers that terminate on motor neurons also have collaterals that synapse on interneurons. A considerable part of each descending command for movement in the corticospinal tract therefore has to be conveyed through spinal interneurons—and integrated with sensory activity—before reaching the motor neurons.

Propriospinal Neurons in the C3–C4 Segments Mediate Part of the Corticospinal Command for Movement of the Upper Limb

In the 1970s, Anders Lundberg and his collaborators demonstrated that a group of neurons in the C3–C4 spinal segments of the cat spinal cord send their axons to motor neurons located in more caudal cervical segments (Figure 32–13). Since the neurons in the C3–C4 segments project to motor neurons that innervate a range of forelimb muscles controlling different joints, and receive input from both skin and muscles throughout the forelimb, they are named *propriospinal neurons*. In addition to sensory input from skin and muscle afferents, the C3–C4 propriospinal neurons are activated by collaterals from the corticospinal tract and thereby relay disynaptic excitation from the motor cortex to the spinal motor neurons.

Subsequent experiments by Bror Alstermark in Sweden and Tadashi Isa in Japan have confirmed that similar propriospinal neurons also exist in the C3–C4 segments of the monkey spinal cord and are involved in mediating at least part of the motor command for reaching. Noninvasive experiments have also provided indirect evidence of the existence of C3–C4 propriospinal neurons in the human spinal cord. With the evolution of direct monosynaptic corticomotor connections in monkeys and humans, the corticospinal transmission through this disynaptic pathway may have become less important.

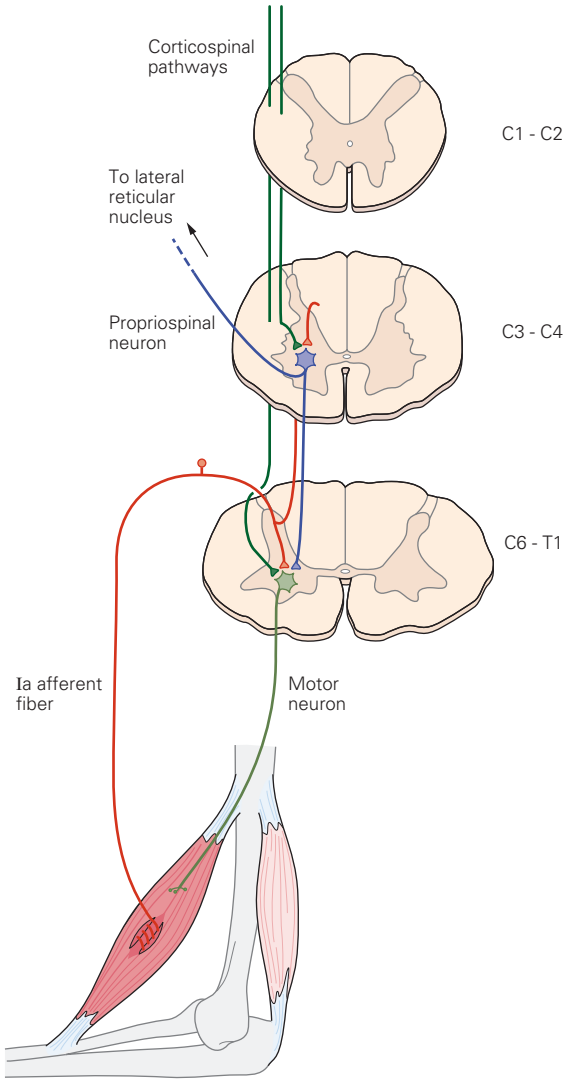

Figure 32–13 **Propriospinal neurons in spinal segments C3–C4 mediate part of the descending motor command to cervical motor neurons.** Some corticospinal fibers (**green**) send collaterals to propriospinal neurons in the C3–C4 segments (**blue**). These C3–C4 propriospinal neurons project to motor neurons located in more caudal cervical segments. They also receive excitatory input from muscle afferents and send collaterals to the lateral reticular nucleus.

Lumbar interneurons that receive input from groups I and II sensory axons from muscle also receive significant input from descending motor tracts and provide excitatory projections to spinal motor neurons. These interneurons thus convey part of the indirect motor command for voluntary movements to the spinal motor neurons that control leg muscles and may be a lumbar equivalent of the C3–C4 propriospinal neurons in the cervical spinal cord.

Neurons in Spinal Reflex Pathways Are Activated Prior to Movement

Synaptic transmission in spinal reflex pathways may change in response to the intention to move, independent of movement. Intracellular recordings from active monkeys have demonstrated that the intention to make a movement modifies activity in interneurons in the spinal cord and alters transmission in spinal reflex pathways. Similarly, in human subjects who have been prevented from contracting a muscle (by injection of lidocaine into the peripheral nerve supplying the muscle), the voluntary effort to contract the muscle still changes transmission in reflex pathways as if the movement had actually taken place.

In both humans and monkeys, spinal interneurons also change their activity well in advance of the actual movement. For example, in human subjects, Hoffmann reflexes elicited in a muscle that is about to be activated are facilitated fully 50 ms prior to the onset of contraction and remain facilitated throughout the movement. Conversely, reflexes in the antagonist muscles are suppressed. The suppression of stretch reflexes in the antagonist muscle prior to the onset of movement is an efficient way of preventing the antagonist from being reflexively activated when it is stretched at the onset of the agonist contraction.

Transmission in spinal reflex pathways can also be modified in connection with higher cognitive functions. Two examples are (1) an increase in the tendon jerk reflex in the soleus muscle of a human subject imagining pressing a foot pedal and (2) modulation of the Hoffmann reflex in arm and leg muscles while a subject observes grasping and walking movements, respectively.

Proprioceptive Reflexes Play an Important Role in Regulating Both Voluntary and Automatic Movements

All movements activate receptors in muscles, joints, and skin. Sensory signals generated by the body's own movements were termed *proprioceptive* by Sherrington, who proposed that they control important aspects of normal movements. A good example is the Hering-Breuer reflex, which regulates the amplitude of inspiration. Stretch receptors in the lungs are activated during inspiration, and the Hering-Breuer reflex eventually triggers the transition from inspiration to expiration when the lungs are expanded.

A similar situation exists in the walking systems of many animals; sensory signals generated near the end of the stance phase initiate the onset of the swing phase (Chapter 33). Proprioceptive signals can also contribute to the regulation of motor activity during voluntary movements, as shown in studies of individuals with sensory neuropathy of the arms. These patients display abnormal reaching movements and have difficulty in positioning the limb accurately because the lack of proprioception results in a failure to compensate for the complex inertial properties of the human arm.

Therefore, a primary function of proprioceptive reflexes in regulating voluntary movements is to adjust the motor output according to the changing biomechanical state of the body and limbs. This adjustment ensures a coordinated pattern of motor activity during an evolving movement and compensates for the intrinsic variability of motor output.

Spinal Reflex Pathways Undergo Long-Term Changes

Transmission in spinal reflex pathways is modulated not only to suit the immediate requirements of the movement but also to adapt the motor command to the motor experience of the individual. For example, transmission in the reciprocal Ia inhibitory pathway shows a gradual change when subjects improve their ability in coordinating agonist and antagonist contraction. Inactivity following long periods of bedrest or immobilization also results in changes in stretch reflexes and H-reflexes. Conversely, the soleus stretch reflex is low in highly trained ballet dancers and varies among different kinds of athletes.

Extensive studies of humans, monkeys, and rats by Jonathan Wolpaw and his colleagues have found that stretch reflexes can be operantly conditioned to either increase or decrease. The mechanisms underlying these changes are complex and involve alterations at multiple sites including changes in the properties of motor neurons. A general prerequisite for these changes is that corticospinal control of the spinal motor circuits must be intact.

Damage to the Central Nervous System Produces Characteristic Alterations in Reflex Responses

Stretch reflexes are routinely used in clinical examinations of patients with neurological disorders. They are typically elicited by sharply tapping the tendon of a muscle with a reflex hammer. Although the responses are often called tendon reflexes or tendon jerks, the receptor that is stimulated, the muscle spindle, actually lies in the muscle rather than the tendon. Only the primary sensory fibers in the spindle participate in the tendon reflex, for these are selectively activated by a rapid stretch of the muscle produced by the tendon tap.

Measuring alterations in the strength of the stretch reflex can assist in the diagnosis of certain conditions and in localizing injury or disease in the central nervous system. Absent or hypoactive stretch reflexes often indicate a disorder of one or more of the components of the peripheral reflex pathway: sensory or motor axons, the cell bodies of motor neurons, or the muscle itself (Chapter 57). Nevertheless, because the excitability of motor neurons is dependent on descending excitatory and inhibitory signals, absent or hypoactive stretch reflexes can also result from lesions of the central nervous system. Hyperactive stretch reflexes, conversely, always indicate that the lesion is in the central nervous system.

Interruption of Descending Pathways to the Spinal Cord Frequently Produces Spasticity

The force with which a muscle resists being lengthened depends on the muscle's intrinsic elasticity, or stiffness. Because a muscle has elastic elements in series and parallel that resist lengthening, it behaves like a spring (Chapter 31). In addition, connective tissue in and around the muscle may also contribute to its stiffness. These elastic elements may be pathologically altered following brain and spinal cord injury and thereby cause contractures and abnormal joint positions. However, there is also a neural contribution to the resistance of a muscle to stretch; the feedback loop inherent in the stretch reflex pathway acts to resist lengthening of the muscle.

Spasticity is characterized by hyperactive tendon jerks and an increase in resistance to rapid stretching of the muscle. Slow movement of a joint elicits only passive resistance, which is caused by the elastic properties of the joint, tendon, muscle, and connective tissues. As the speed of the stretch is increased, resistance to the stretch rises progressively. This phasic relation is what characterizes spasticity; an active reflex contraction occurs only during a rapid stretch, and when the muscle is held in a lengthened position, the reflex contraction subsides.

Spasticity is seen following lesion of descending motor pathways caused by stroke, injuries of the brain or spinal cord, and degenerative diseases such as multiple sclerosis. It is also seen in individuals with brain damage that occurs before, during, or shortly after birth, resulting in *cerebral palsy*.

Spasticity is not seen immediately following lesions of descending pathways, but develops over days, weeks, and even months. This parallels plastic changes at multiple sites in the stretch reflex circuitry. Sensory group Ia axons release more transmitter substance when active, and the alpha motor neurons change their intrinsic properties and their morphology (dendritic sprouting and denervation hypersensitivity) so that they become more excitable. Changes in excitatory and inhibitory interneurons that project to the motor neurons also take place and probably contribute to the increased excitability.

Whatever the precise mechanisms that produce spasticity, the effect is a strong facilitation of transmission in the monosynaptic reflex pathway. It is not the only reflex pathway affected by lesions of descending motor pathways. Pathways involving group I/II interneurons and sensory fibers from skin are also affected and exhibit the symptomatology observed in patients with central motor lesions. In the clinic, spasticity is therefore used in a broader sense and does not only relate to stretch reflex hyperexcitability. It is still debated whether reflex hyperexcitability contributes to the movement disorder following lesion of descending pathways or whether it may be a pertinent adaptation that helps to activate the muscles when descending input is diminished.

Lesion of the Spinal Cord in Humans Leads to a Period of Spinal Shock Followed by Hyperreflexia

Damage to the spinal cord can cause large changes in the strength of spinal reflexes. Each year, approximately 11,000 Americans sustain spinal cord injuries, and many more suffer from strokes. More than half of these injuries produce permanent disability, including impairment of motor and sensory functions and loss of voluntary bowel and bladder control. Approximately 250,000 people in the United States today have some permanent disability from spinal cord injury.

When the spinal cord is completely transected, there is usually a period immediately after the injury when all spinal reflexes below the level of the

transection are reduced or completely suppressed, a condition known as *spinal shock*. During the course of weeks and months, spinal reflexes gradually return, often greatly exaggerated. For example, a light touch to the skin of the foot may elicit strong flexion withdrawal of the leg.

Highlights

1. Reflexes are coordinated, involuntary motor responses initiated by a stimulus applied to peripheral receptors.
2. Many groups of interneurons in spinal reflex pathways are also involved in producing complex movements such as walking and transmitting voluntary commands from the brain.
3. Some components of reflex responses, particularly those involving the limbs, are mediated by supraspinal centers, such as brain stem nuclei, the cerebellum, and the motor cortex.
4. Reflexes are smoothly integrated into centrally generated motor commands because of the convergence of sensory signals onto spinal and supraspinal interneuronal systems involved in initiating movements. Establishing the details of these integrative events is one of the major challenges of contemporary research on sensory-motor integration in the spinal cord.
5. Because of the role of supraspinal centers in spinal reflex pathways, injury to or disease of the central nervous system often results in significant alterations in the strength of spinal reflexes. The pattern of changes provides an important aid to diagnosis of patients with neurological disorders.

Locomotion

Locomotion is one of the most fundamental of animal behaviors and is common to all members of the animal kingdom. As one might expect of such an essential behavior, the neural mechanisms responsible for the basic alternating rhythmicity that underlies locomotion are highly conserved throughout the animal kingdom, from invertebrates to vertebrates, and from the early vertebrates to primates. However, while the basic locomotor-generating circuits have been conserved, the evolution of limbs, and then of ever more complex patterns of behavior, has resulted in the development of progressively more complex spinal and supraspinal circuits (Figure 33–1).

Scientists have been intrigued with the neural mechanisms of locomotion since the beginning of the 20th century, when pioneering work by Charles Sherrington and Thomas Graham Brown showed that the isolated spinal cord of the cat is able to generate the basic aspects of locomotor activity and subsequently that this capacity was intrinsic to the spinal cord. Throughout the 20th century, major advances were made in detailing both the rhythm- and pattern-producing capacities of the spinal cord, leading ultimately to the groundbreaking concept of a central pattern generator for locomotion in the spinal cord. This single concept, more than any other, has driven research into the mechanisms underlying locomotor control since the 1970s, allowing a detailed electrophysiological examination of the neuronal mechanisms involved in the control of locomotion that is not possible for most other motor acts.

Most research throughout the 20th century on the spinal mechanisms mediating locomotion was performed on the cat, which remains an important model

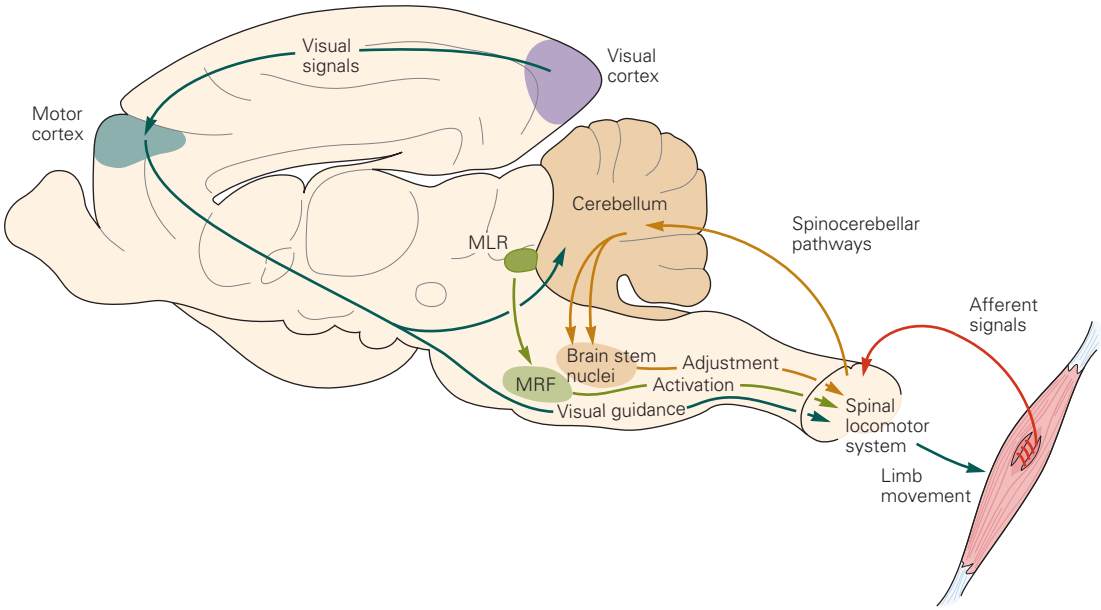

Figure 33–1 The locomotor system. Multiple regions of the central nervous system interact to initiate and regulate locomotion. Locomotor networks in the spinal cord—the central pattern generators (CPGs)—generate the precise timing and patterning of locomotion. Proprioceptive sensory feedback modulates the activity of the locomotor CPG. The initiation of locomotion is mediated by neurons in the mesencephalic locomotor region (**MLR**) that project to neurons in the medial reticular formation (**MRF**) in the lower brain stem, which in turn project to the spinal cord. Descending fibers from the vestibular nuclei, pontomedullary reticular formation, and the red nucleus (**brain stem nuclei**) maintain equilibrium and modulate the ongoing locomotor activity. Cortical activity from the posterior parietal cortex (not illustrated) and the motor cortex is involved in the planning and execution of visually guided locomotion, while the basal ganglia (not illustrated) and cerebellum are important for the selection and coordination of locomotor activity.

for studying many aspects of locomotor control. However, the complexity of the spinal circuits in mammals led to the search for simpler preparations that would allow a better understanding of the synaptic connectivity and neuronal properties responsible for the generation of locomotion. This search led to the development of the lamprey and the tadpole models (Box 33–1; Figures 33–2 and 33–3). Experiments using these species have led to a detailed understanding of the neuronal circuits responsible for generating swimming. Influential work on understanding the processes underlying locomotion has also come from other experimental models, including mouse, rat, turtle, salamander, and zebrafish.

More recently, the development of molecular-genetic techniques has provided a powerful tool to probe the spinal circuits responsible for locomotion in preparations as diverse as zebrafish and mouse. These techniques have allowed researchers to explore more thoroughly both the neuronal circuits in the mammalian spinal cord responsible for rhythmic, alternating patterns of activity that define over-ground locomotion and those responsible for swimming.

The rhythmic pattern of activity is only one element of the complex locomotor behavior observed in most vertebrates, especially mammals, which have evolved to allow them to move quickly and elegantly. This flexibility is provided via feedback and feedforward modification of the locomotor patterns generated by spinal networks.

Feedback information from the body and limbs in the form of cutaneous and proprioceptive inputs is important for regulating aspects of the locomotor cycle, including bending of the body, stride length, and the force produced during propulsion. This information is equally critical in assuring that animals can rapidly and efficiently react to unexpected perturbations in the environment, such as when hitting a branch during walking or stepping on an unstable surface.

Feedforward information from supraspinal systems modifies activity according to the goals of the animal and the environment in which it moves. Information from defined structures in the brain stem is important for both the initiation of locomotion and for regulating general aspects of locomotor activity, including the speed of locomotion, level of muscle activity, and interlimb coupling in animals with limbs. Information from cortical structures

Box 33–1 Preparations Used to Study the Neuronal Control of Locomotion

The neuronal control of locomotion is studied experimentally in diverse vertebrate species that produce swimming or over-ground locomotion, or both. The prevailing experimental models used for studying swimming are the lamprey, the tadpole, and the zebrafish; for over-ground locomotion, the cat, rat, or mouse; and for both swimming and locomotion, the turtle, salamander, and frog.

Semi-intact preparations—in which influences from parts of the brain, all supraspinal inputs, and/or afferent inputs to the spinal cord have been removed—are also commonly used in studies of the neuronal control of locomotion in vertebrates (Figure 33–2A). Finally, in vitro preparations of the spinal cord or of the brain stem and spinal cord from young animals or adult and anoxia-resistant animals are extensively used for circuit analysis (Figure 33–2C).

Intact Preparations Are Used to Study the Behavioral Output

In intact preparations, locomotion is studied either during walking over ground or on a motorized treadmill. Chronic electromyographic (EMG) recordings of limb muscles, coupled with video recordings of the movement, reveal details of the rhythm of locomotion, the pattern of muscle or joint activation, and interlimb coordination (Figure 33–2B). Such studies allow researchers to understand how normal locomotion behavior is expressed.

These behavioral studies are often combined with experimental manipulations that modify the supraspinal or afferent control of locomotion. Such experiments may use electrical stimulation or surgical ablation of circumscribed areas in the central nervous system, genetic inactivation or activation of defined populations of nerve cells, or perturbation of the afferent input to the spinal cord using genetic techniques or electrical stimulation. Finally, single-cell activity in the brain can be recorded from identified populations of neurons and correlated with specific aspects of the locomotor behavior (eg, speed, postural adjustments, gait modifications, flexor-extensor muscle activity). Cells are identified by their anatomical location, their projection pattern, transmitter content, and molecular markers.

Semi-intact Preparations Are Commonly Used to Study the Central Control of Locomotion in the Absence of Cortical Influence or Sensory Feedback

Decerebrate Preparations

In the decerebrate preparation, the brain stem is completely transected at the level of the midbrain (Figure 33–2A), disconnecting rostral brain centers, including the cortex, basal ganglia, and thalamus, from locomotor-initiating centers in the brain stem and spinal cord. These preparations allow investigation of the role of cerebellum and brain stem structures in controlling locomotion in the absence of influence from higher brain centers.

Locomotion is generally evoked by electrical stimulation of locomotor regions in the brain stem, as described in the text. To increase recording stability, the animals are often paralyzed by blocking transmission at the neuromuscular junction. When locomotion is initiated in such an immobilized preparation, often referred to as *fictive locomotion*, the motor nerves to flexors and extensor muscles discharge (recorded as an electroneurogram), but no movement takes place.

Spinal Preparations

In spinal preparations, the spinal cord is completely transected, generally at the lower thoracic level, thus isolating the spinal segments that control the hindlimb musculature from the rest of the central nervous system (Figure 33–2A). This procedure allows investigations of the spinal locomotor circuits without any influence from supraspinal structures.

Two types of spinal preparation are used: acute spinal preparations, in which studies are performed immediately after the spinalization, and chronic spinal preparations, in which the animals are allowed to recover from the surgery and are then studied over a period of time.

In acute spinal preparations, locomotion is frequently induced chemically, either by intravenous administration of drugs that stimulate monoaminergic and/or serotonergic receptors or by local application of glutamatergic receptor agonists. These drugs increase the excitability in the spinal locomotor circuits,

(continued)

contributes primarily to the planning and execution of locomotion in situations in which vision is used to make anticipatory modifications of gait. Finally, two structures with no direct spinal connections, the basal ganglia and the cerebellum, contribute to the selection of locomotor activity and to its coordination (Figure 33–1).

The way in which all of these structures interact and permit diverse modes of locomotion is the subject of this chapter.

Box 33–1 Preparations Used to Study the Neuronal Control of Locomotion (continued)

mimicking the locomotor-initiating drive from the brain stem. Alternatively, locomotion is induced electrically, by stimulation of the dorsal roots or dorsal columns. Acute spinal preparations are often paralyzed in order to increase recording stability from motor neurons and interneurons in the spinal cord, as well as to discriminate between central and peripheral effects.

In chronic spinal preparations, animals are studied for weeks or months after transection, often with the aim of finding better ways to improve the locomotor capability after spinal cord injury. In both young and adult cats and in young rodents, the hindlimb locomotor capability can often return following training but with no further treatment. In all animals, the locomotor capability is improved dramatically by drug treatments that activate the spinal central pattern generator. Electromyographic activity, together with behavioral measures, can be recorded before and after transection (Figure 33–2B).

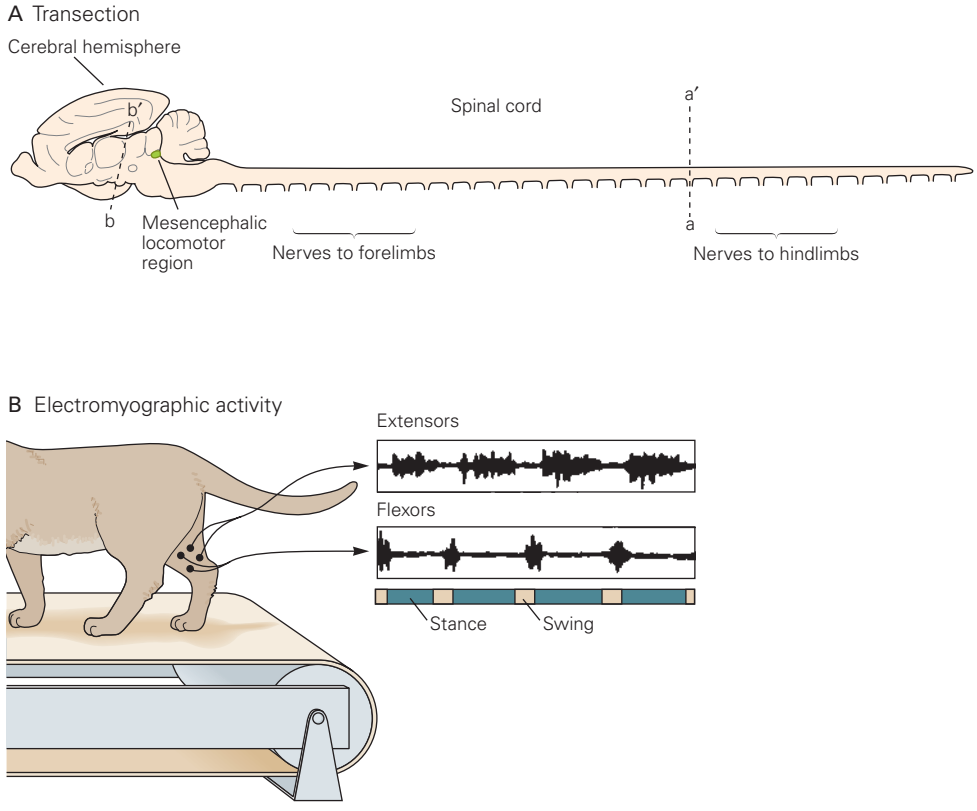

Figure 33–2 Selected animal models used to study locomotor control systems.

A. Schematic of the cat cerebral hemispheres, brain stem, and spinal cord showing the level of transection for spinalization (a′-a) and decerebration (b′-b). Decerebration isolates the brain stem and spinal cord from the cerebral hemispheres. Transection at a′-a isolates the lumbar spinal cord from all descending inputs.

B. The electromyogram can be used to record locomotor activity during actual movement in intact, decerebrate, or spinal animals.

Locomotion Requires the Production of a Precise and Coordinated Pattern of Muscle Activation

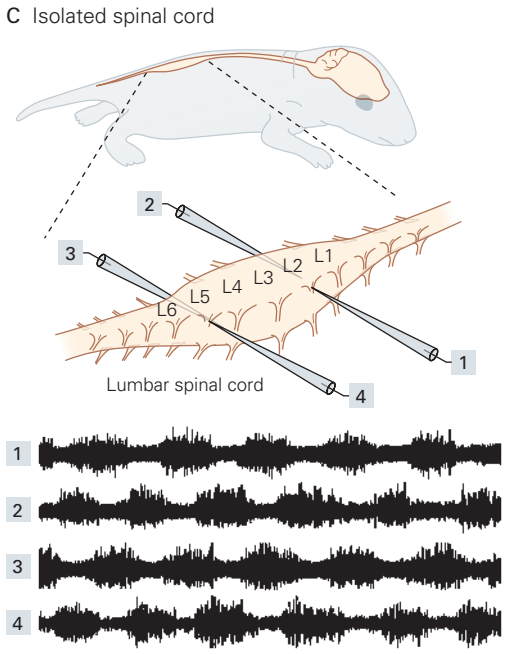
Locomotion requires the production of activity in many muscles that need to be coordinated in a precise rhythm and pattern. The rhythm defines the frequency of the cyclic activity, whereas the pattern defines the spatiotemporal activation of muscle groups within a cycle. In swimming animals, such as the lamprey or the tadpole, locomotion is expressed as a traveling

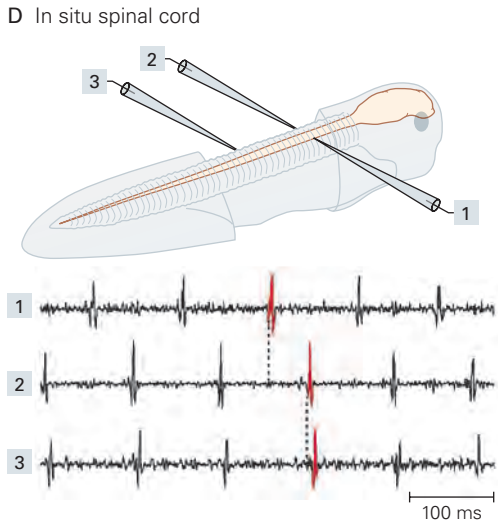
In Vitro Preparations Are Used to Study Central Organization of Networks

With in vitro preparations, the spinal cord or brain stem is removed from the animal and placed in a bath that is perfused with artificial cerebrospinal fluid (rodent, lamprey, and turtle) (Figure 33–2C). Alternatively, the brain stem and spinal cord are left in situ in the animal that is paralyzed or immobilized and kept in vitro (tadpole and zebrafish) (Figure 33–2D).

In all cases, no rhythmic afferent inputs occur in the cord, and motor activity is recorded in peripheral nerves or, more often, in the ventral roots where the motor neurons have their axons leaving the spinal cord.

Locomotion is induced chemically, either by application of glutamatergic or serotonergic receptor agonists or a combination of both, or electrically by stimulating the brain stem or peripheral afferents. Rhythm and pattern generation, circuit connectivity, cellular properties of interneurons and motor neurons, and circuit neuromodulation are studied with conventional electrophysiological methods, imaging, and anatomical tracing, or with molecular genetic methods that allow manipulation and recording of identified populations of neurons.





C. The isolated lumbar (L1–L6) spinal cord from a newborn rat or mouse. Motor activity is recorded in flexor-related L2 ventral roots and extensor-related L5 ventral roots on either side of the cord. Locomotor-like activity is induced by application of *N*-methyl-D-aspartate (NMDA) and serotonin (5-hydroxytryptamine, 5-HT) to the bathing solution. Flexor-extensor alternation is seen as out-of-phase activity between L2 and L5 ventral roots on the same side of the cord (**1** and **4**; **2** and **3**), and left–right alternations are seen as out-of-phase activity between L2–L2 and L5–L5 ventral roots on either side of the cord (**1** and **2**; **3** and **4**). (Adapted, with permission, from Kiehn et al. 1999; data from O Kiehn.)

D. In vitro tadpole preparation, in which the spinal cord remains in situ, showing ventral root recordings on the right side (**1**) and on the left side (**2** and **3**). side of the spinal cord. The swimming rhythm in the nervous system of the paralyzed animal was induced by a brief stimulation of the skin on the head. (Data from L Picton and KT Silar.)

wave of activity (Figure 33–3A) that propagates from rostral to caudal body segments during forward progression. This pattern can be recorded as an electromyogram (EMG) during locomotion in the intact animal (Figure 33–3B) and as an electroneurogram in the isolated spinal cord (Figure 33–3C). Activity in more caudal roots occurs later than that in more rostral roots, and the activity on each side of the body is reciprocal.

In limbed animals, the pattern of muscle activity is more complex and serves to support the body as well

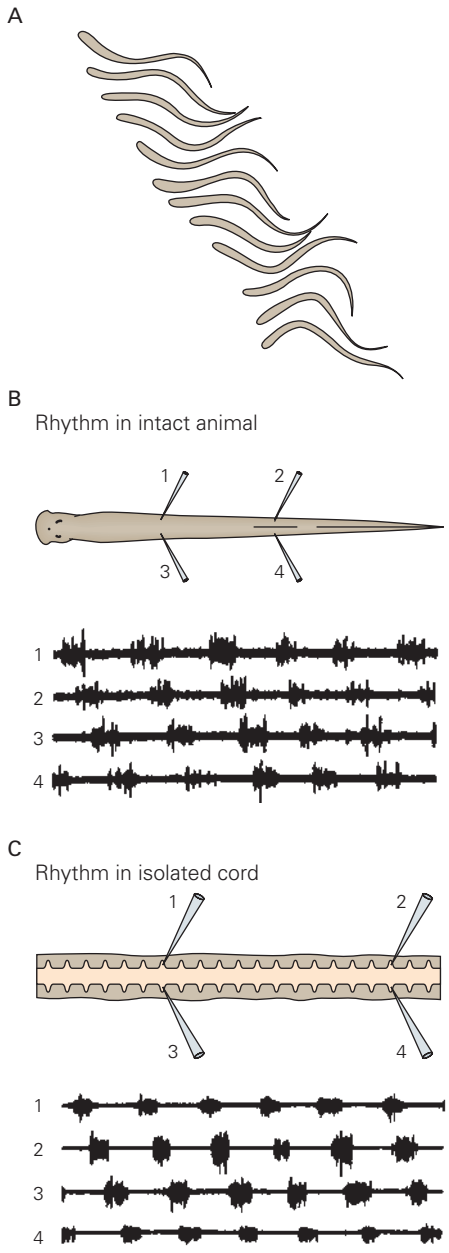


Figure 33–3 Lamprey swimming. The lamprey swims by means of a wave of muscle contractions traveling down one side of the body 180° out of phase with a similar traveling wave on the opposite side (**A**). This pattern is evident in electromyogram recordings from four locations along the animal during normal swimming (**B**). A similar pattern is recorded from four ventral roots in an isolated cord (**C**). (Data from S Grillner.)

as to transport it forward. The general unit of measure of locomotion in limbed vertebrates is the *step cycle*, which is defined as the time between any two successive events (eg, foot or paw contact of a given limb). The step cycle is divided into a *swing* phase, when the foot is off the ground and being transferred forward, and a *stance* phase, when the foot is in contact with the ground and propelling the body forward. Based on measures of changes in joint angle, each of these phases can be further divided into a period of flexion (F) followed by an initial period of extension (E_1) during swing and two additional periods of extension (E_2 and E_3) during stance (Figure 33–4A; see below).

Muscles within a single limb must be activated and coordinated in a precise spatiotemporal pattern (Figure 33–4B) so that the relative time of activation of different muscles, the duration of their activity, and the magnitude of that activity are coordinated to meet the demands of the environment (*intralimb coordination*).

In the hindlimb, swing is initiated by flexion of the knee produced by activation of muscles such as the semitendinosus, followed shortly by activation of hip and ankle flexors (the F phase). The hip flexors continue to contract throughout swing, but the activity in the knee and ankle flexors is arrested as the leg extends in preparation for contact with the support surface (the E_1 phase). Activity in most extensor muscles begins at this stage, before the foot contacts the ground. This preparatory prestance phase signifies that the extensor muscle activity is centrally programmed and not simply the result of afferent feedback arising from contact of the foot with the ground.

Stance begins with contact of the foot or paw with the ground. During early stance (the E_2 phase), the knee and ankle joints flex due to the acceptance of the weight of the body, causing extensor muscles to lengthen at the same time they are contracting strongly (eccentric contraction). The spring-like yielding of these muscles as weight is accepted allows the body to move smoothly over the foot and is essential for establishing an efficient gait. During late stance (the E_3 phase), the hip, knee, and ankle all extend as the extensor muscles provide a propulsive force to move the body forward.

There is also a requirement for *interlimb coordination*, the precise coupling between different limbs. The coupling between the four legs in quadrupeds, for example, can vary quite substantially, dependent on both the speed of locomotion and the adopted gait (a walk, pace, trot, gallop, or bound). This is particularly true of the pattern of coupling between muscles of limbs of the same side (homolateral limbs) and for the diagonal limbs. The relation between limbs can be characterized by the phase difference, with 0 reflecting limbs that move together in phase and 0.5 limbs that move fully out of phase (ie, in opposite directions). During walking, activity between the homolateral limbs varies by a phase value of 0.25, and three legs are always in contact

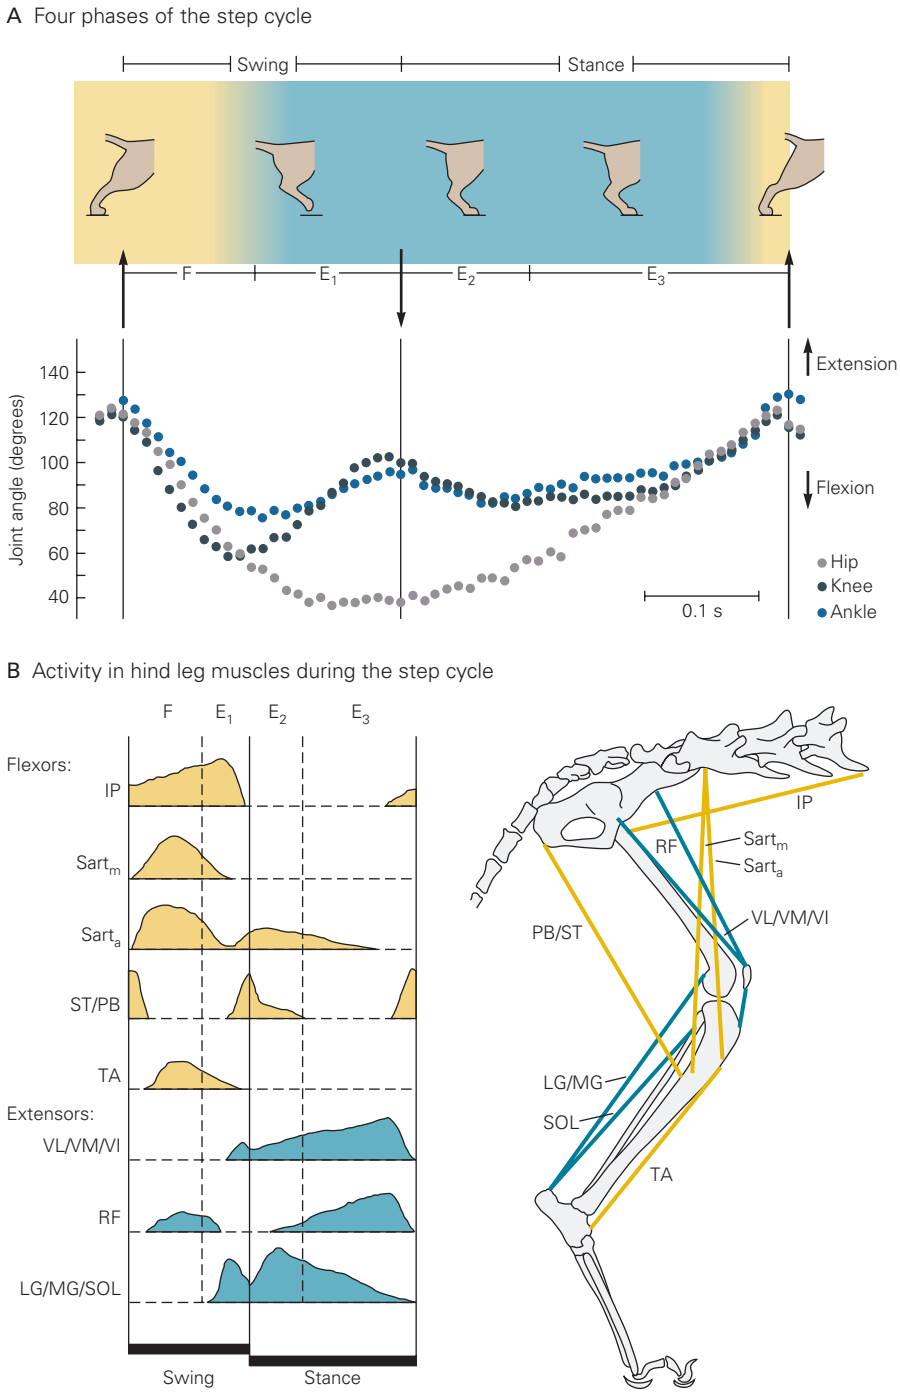

Figure 33–4 Stepping is produced by complex patterns of contractions in leg muscles.

A. The step cycle is divided into four phases. The flexion (**F**) and first extension (E_1) phases occur during the swing phase, when the foot is off the ground, whereas second extension (E_2) and third extension (E_3) occur during the stance phase, when the foot contacts the ground. E_2 is characterized by flexion at the knee and ankle as the leg begins to bear the animal's weight. The contracting knee and ankle extensor muscles lengthen during this phase. (Adapted, with permission, from Engberg and Lundberg 1969.)

B. Profiles of electrical activity in some of the hind leg flexor (**yellow**) and extensor (**blue**) muscles in the cat during stepping. Although flexor and extensor muscles are generally active during the swing and stance phases, respectively, the overall pattern of activity is complex in both timing and amplitude. (Muscles: **IP**, iliopsoas; **LG** and **MG**, lateral and medial gastrocnemius; **PB**, posterior biceps; **RF**, rectus femoris; **$Sart_m$** and **$Sart_a$**, medial and anterior sartorius; **SOL**, soleus; **ST**, semitendinosus; **TA**, tibialis anterior; **VL**, **VM**, and **VI**, vastus lateralis, medialis, and intermedius.)

with the ground. During a trot, the diagonal limbs (eg, the left hindlimb and the right forelimb) are in phase, and the phase difference between homolateral limbs is 0.5. Phase relationships between limbs of the same girdle (ie, the forelimbs or hindlimbs) are more stable during gaits produced by activation of alternating limbs, such as a walk or trot (generally out of phase by 0.5 cycle), compared to synchronous locomotion like a gallop or bound (generally in-phase).

The appropriate generation of the intra- and interlimb coordination of activity and the adaptation of these patterns of activity according to circumstance is one of the major functions of the central nervous system during locomotion.

The Motor Pattern of Stepping Is Organized at the Spinal Level

While the entire nervous system is necessary for an animal to produce a rich behavioral repertory, the spinal cord is sufficient to generate both the rhythm underlying locomotion as well as much of the specific pattern of muscle activity required for intra- and interlimb coordination.

At the beginning of the 20th century, Graham Brown showed that the isolated spinal cord had the intrinsic capacity to generate a rudimentary alternating locomotor pattern around the ankle joint in the absence of sensory inputs to the spinal cord (Figure 33–5). He proposed that locomotor networks controlling flexor and extensor activity in the spinal cord were organized as half-centers such that when half of the circuit was active it would inhibit the other half. The center would be released from inhibition through some sort of synaptic or neuronal fatigue.

This ground-breaking observation was mostly ignored until the mid-1960s and early 1970s, when there began a period of intense study of the mechanisms by which the spinal cord could generate a rhythmical pattern of activity. Initial studies showed that stimulation of sensory fibers in spinal cats treated with L-DOPA (a precursor of the monoamine transmitters dopamine and norepinephrine) and nialamide (a drug that prolongs the action of L-DOPA) could produce short sequences of rhythmic activity in flexor and extensor motor neurons. It was further found that groups of interneurons in the spinal cord were activated in a reciprocal flexor and extensor pattern. This organizational feature was consistent with Graham Brown's theory that mutually inhibiting half-centers produced the alternating burst activity in flexor and extensor motor neurons.

In the half-center model, the spinal cord produces only the locomotor rhythm, while the pattern is sculpted by afferent feedback caused by the movement. However, this view was changed by experiments that demonstrated that a well-organized locomotor pattern could be observed in decerebrate and spinal cats walking on a treadmill after section of the dorsal roots, thus removing the afferent feedback (Figure 33–6A,B). Later experiments in chronic spinal cats in which rhythmic afferent feedback was abolished by preventing movement (Figure 33–6C) showed that spinal circuits were not only able to intrinsically produce a locomotor rhythm but could also produce some of

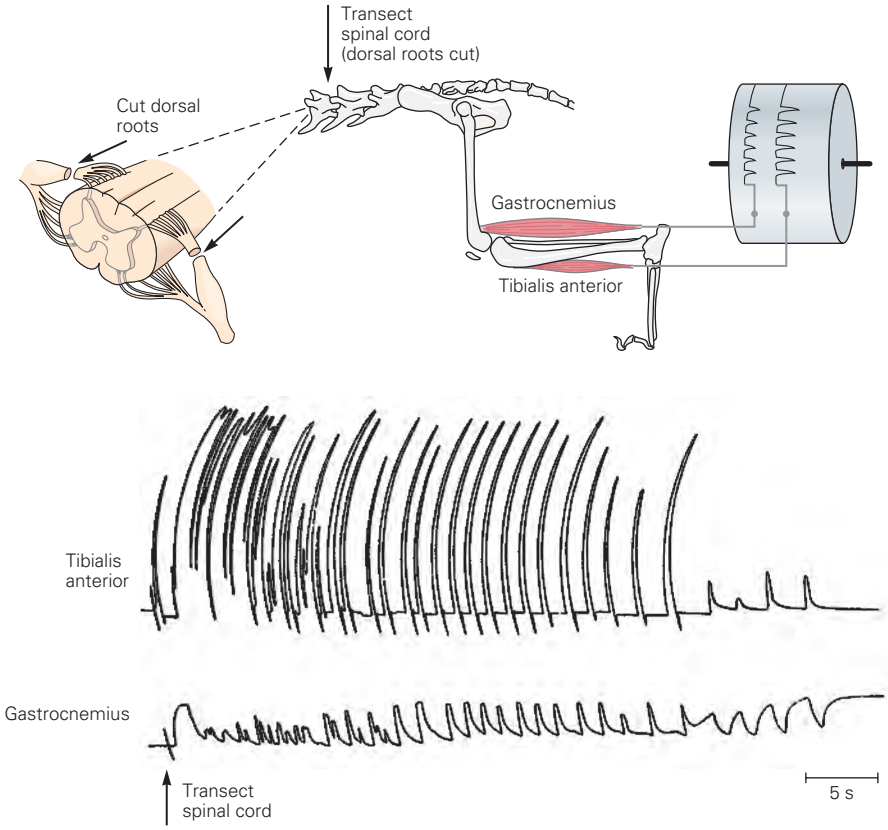

Figure 33–5 Rhythmic stepping is generated by spinal networks. The existence of intrinsic spinal networks was first demonstrated in 1911 by Thomas Graham Brown who developed an experimental preparation in which the dorsal roots were cut so that sensory information from the limb could not reach the spinal cord. The lower figure shows an original record from Graham Brown's study. Rhythmic alternating contractions of an ankle flexor (tibialis anterior) and an ankle extensor (gastrocnemius) are generated by the isolated spinal cord and persist for some time after the transection.

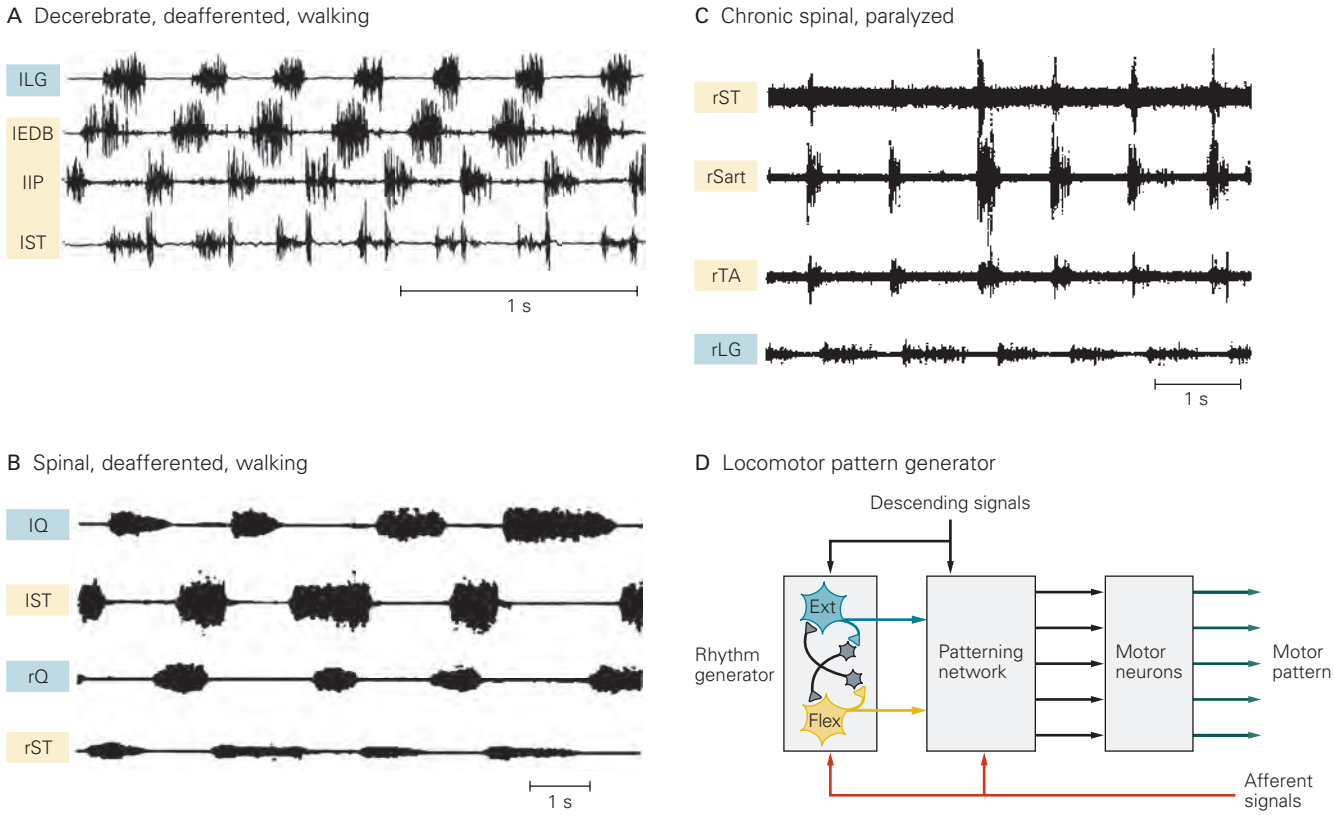

Figure 33–6 Spinal circuits generate both a rhythm and a pattern.

A. Even after removal of all sensory input to the spinal cord by cutting the dorsal roots, a decerebrate cat walking on a treadmill exhibits a complex motor pattern that is not just a simple alternation of flexor and extensor activity. (Abbreviations: **I**, left; **EDB**, extensor digitorum brevis; **LG**, lateral gastrocnemius; **IP**, iliopsoas; **ST**, semitendinosus.) (Adapted, with permission, from Grillner and Zangger 1984.)

B. Intravenous injection of L-DOPA and nialamide produces a well-organized locomotor pattern in an acute spinal cat with the dorsal roots cut. (Abbreviation: **I**, left; **Q**, quadriceps; **r**, right.) (Adapted with permission from Grillner and Zangger 1979. Copyright © 1979 Springer Nature.)

C. Fictive locomotion in a chronic spinal paralyzed cat, demonstrating the typical pattern of activity in the semitendinosus, tibialis anterior (**TA**), lateral gastrocnemius (**LG**), and sartorius (**Sart**) muscles in intact cats. (**l**, left; **r**, right.) (Adapted from Pearson and Rossignol 1991.)

D. Conceptual model of a spinal locomotor central pattern generator (CPG) based on studies in decerebrate cats. The CPG model is formed of separate rhythm- and pattern-generating layers. Each of these layers can be modified by descending inputs and peripheral afferent information. (Adapted from Rybak et al. 2006.)

the spatiotemporal details of the pattern of activity observed in the intact cat (Figure 33–6C).

These observations led to the important concept of a *central pattern generator* (CPG) that can generate both the rhythm and the pattern, independent of sensory inputs. Subsequent experiments led to the idea that separate components of the CPG are responsible for generating the underlying rhythm of locomotion within a limb and the spatiotemporal pattern of muscle action in the limb (Figure 33–6D). This notion was based on the observation that changes in rhythm and pattern can be influenced independently. Other studies have led to the concept that the CPG is modular, allowing independent control of activity around different joints.

Experiments in a variety of species have suggested that there are probably separate CPGs for each limb. For example, experiments using split belts, in which either the fore- and hindlimbs or the left and right limbs walk on separate treadmill belts, show that animals can independently modify step cycle duration in each pair of limbs. This organization would allow relatively simple descending commands to modify the coupling between each CPG and so to alter the pattern of the gait.

CPGs have now been identified and analyzed in many rhythmic motor systems, including those

controlling over-ground locomotion, swimming, flying, respiration, and swallowing, in both invertebrates and vertebrates. In all vertebrates except higher primates and humans, a prominent locomotor pattern can be observed immediately after spinal transection when the spinal cord below the transection is activated with neuroactive drugs that function as a substitute for the descending drive that normally activates the spinal locomotor networks (Box 33–1).

The Spinal Circuits Responsible for Locomotion Can Be Modified by Experience

Lesion of the spinal cord in otherwise intact adult mammals leads to paralysis. In the absence of any further intervention, such animals will regain only minimal locomotion. However, when quadrupedal animals with complete lesions of the thoracic spinal cord are trained daily, they regain a remarkable ability to use their hindlimbs to walk on a treadmill.

A similar improvement in locomotion can also be obtained from the application of noradrenergic agonists. Indeed, recordings of hindlimb joint angles and EMG activity from these animals show that the spinal cord isolated from all descending systems can generate most of the coordinating features in the hindlimb that are observed in intact animals. This training effect is believed to occur because of an activity-dependent reorganization of both internal spinal circuits and the modification of synaptic inputs from peripheral afferents that is specific to the training regimen. Indeed, cats can be trained specifically to either support their weight or to walk, without a transfer of motor skills between the two behaviors.

Spinal Locomotor Networks Are Organized Into Rhythm- and Pattern-Generation Circuits

The question of how the spinal cord generates the complex activity underlying locomotion has been one of intense study that has followed three complementary paths. The earliest experiments directed at this issue were performed in the cat and provided important information on the functional characteristics of different interneuronal populations. However, the complex nature of the mammalian spinal cord led researchers to identify models with fewer neurons in the spinal cord, such as the turtle and two aquatic preparations, the tadpole and the lamprey (Box 33–1). These latter two models have provided an excellent window into the organization of the spinal circuits involved in swimming and a foundation for studying rhythm and pattern generation in limbed animals. Last, the development of important molecular-genetic models in the mouse and the zebrafish has provided additional insights not available by more traditional methods.

The Swimming Central Pattern Generator

The lamprey—a jawless fish—swims like an eel with a wave of left–right bending traveling from front to back (Figure 33–3A). The spinal cord is made up of about 100 spinal segments, each containing neurons that can generate the rhythm and produce alternation between the two sides of the body. The rhythm is generated by interconnected glutamatergic excitatory neurons endowed with active membrane properties supporting rhythm generation. These glutamatergic neurons, which are the kernel in the swimming network, excite commissural inhibitory neurons, local inhibitory neurons, and motor neurons on the same side of the cord (Figure 33–7A).

The commissural interneurons, whose axons cross the midline, inhibit the contralateral interneurons involved in generating the alternating rhythm as well as contralateral motor neurons (Figure 33–7A). Cellular mechanisms contribute to phase switching in the network (Box 33–2). For example, Ca^{2+} entry triggered by bursting in glutamatergic neurons activates their calcium-activated K^+ channels. The opening of these channels hyperpolarizes the cells and enables termination of the burst. The termination of bursting on one side activates the other side by the commissural interneurons, thus allowing the contralateral rhythm-generating interneurons and motor neurons to become active. To enable coordination along the body, the segmental networks are connected through long-distance descending projections of excitatory and inhibitory neurons. This basic organization of interconnected excitatory neurons, inhibitory commissural neurons, and a rostrocaudal connectivity gradient for intersegmental coordination is also found in the tadpole and is possibly common to other swimming species.

Molecular and genetic approaches have expanded our understanding of the functional organization of CPGs in fish and identified two groups of glutamatergic interneurons—a group of commissural neurons and a group of ipsilaterally projecting neurons—that are involved in rhythm generation but at different speeds of locomotion. In adult zebrafish, the rhythm-generating circuit is composed of three functional classes of excitatory neurons that drive slow, intermediate, and fast pools of motor neurons that are selectively recruited as the speed of swimming increases.

The Quadrupedal Central Pattern Generator

The CPG controlling quadrupedal locomotion has added organizational complexity compared to the swimming CPG since it must generate both the rhythm and the pattern that involves the sequential flexor-extensor alternation of muscles around different joints within a limb (Figure 33–4B), as well as left–right coordination and coordination between the forelimbs and hindlimbs. Circuits controlling the forelimb are located in the cervical enlargement, whereas circuits controlling the hindlimb are located in the lower thoracic and lumbar spinal cord.

As in the CPG that generates rhythmical swimming activity, glutamatergic excitatory interneurons are involved in quadrupedal rhythm generation. Using advanced mouse genetics together with a molecular code that builds on expression of gene-regulating transcription factors that differentiate spinal neurons into classes with specific projection and transmitter phenotypes (Box 33–3), it has now been shown that the core of the rhythm-generating circuits in rodents includes two nonoverlapping groups of molecularly distinct glutamatergic neurons (Shox2^{ON} and Hb9; Figure 33–7B1).

The flexor (f) and extensor (e) rhythm-generating (R) circuits, which are connected by reciprocal inhibition (Figure 33–7B), drive other neurons in the locomotor network into rhythmicity and provide the rhythmic excitation for motor neurons (Figure 33–7B). As has been observed in the swimming CPG, ionic channels are also likely to contribute to rhythm generation and phase switching in the quadrupedal CPG.

The Flexor and Extensor Coordination Circuit

Flexor and extensor activity must be coordinated around joints (eg, hip-knee-ankle-toe in the hindlimb) to control the limb movement in a precise manner. Accordingly, the flexor-extensor alternation around the different joints is not simultaneous but has a sequential pattern, which suggests that multiple flexor-extensor alternating circuits are needed to time muscle actions in a limb. The basic flexor-extensor alternation circuits are organized in flexor and extensor modules composed of inhibitory and excitatory interneurons that are one synapse away from the flexor and extensor motor neurons they control (Figure 33–7B,B1).

Inhibitory and excitatory neurons in the module provide alternating inhibition and excitation of motor neurons. The reciprocally connected inhibitory Ia interneurons (Chapter 32) are part of the flexor and extensor modules providing the direct motor neuron inhibition in a reciprocal fashion (rIa in Figure 33–7B1). The rIas belong to the molecularly defined inhibitory V1 and V2b neurons (Figure 33–7B1). The excitatory neurons that directly excite motor neurons during locomotion are likely to belong to multiple classes of neurons in the spinal cord, including V2a-Shox2^{ON} and the dI3 neurons (Figure 33–7B1).

In this basic scheme, the flexor-extensor modules are driven by flexor (fR in Figure 33–7B1) and extensor rhythm-generating circuits (eR in Figure 33–7B1), which themselves are reciprocally connected via inhibitory neurons (Figure 33–7B), resulting in their out-of-phase activity.

Left–Right Coordination

Left–right alternation, for both swimming and overground locomotion, depends on crossed inhibition produced in two ways: directly by inhibitory commissural neurons or indirectly by excitatory commissural neurons, each of which acts on premotor inhibitory neurons (Figure 33–7B2). This dual inhibitory system has a counterpart in one specific neuronal population, the V0 commissural neurons (Figure 33–7B2). Ablation of V0 neurons results in loss of left–right alternation at all speeds of locomotion. The inhibitory dorsal class of V0 neurons ($V0_D$), which makes up about half of the V0 population, controls alternating locomotion during walking, whereas the excitatory ventral class of V0 neurons ($V0_V$), which makes up the remaining half of V0 neurons, controls alternating locomotion during trot. The dual system thus serves a speed-dependent role in coordinating alternating gaits (walk and trot). Separate excitatory non-V0 commissural neurons—possibly the ventral V3 neurons (Box 33–3)—are responsible for synchrony in gaits such as bound and gallop (Figure 33–7B2).

The dual-mode left–right alternating pathways are driven directly by the rhythm-generating neurons or indirectly by other non–rhythm-generating excitatory neurons, including the V2a-Shox2^{Off} neurons that are recruited at high speeds of locomotion and synaptically connect to the $V0_V$ neurons. The left–right synchronous pathways are active at higher speeds of locomotion when the alternating system is suppressed or less active.

The speed-dependent changes in the left–right alternation circuits in the rodent are an example of functional reorganization of the vertebrate locomotor network needed to produce diverse motor outputs. Similar dynamic circuit reorganization has also been demonstrated in zebrafish and in studies of rhythmic networks in invertebrates, such as the stomatogastric ganglion controlling gut movements in crustaceans, where different functional networks emerge from a common CPG network.

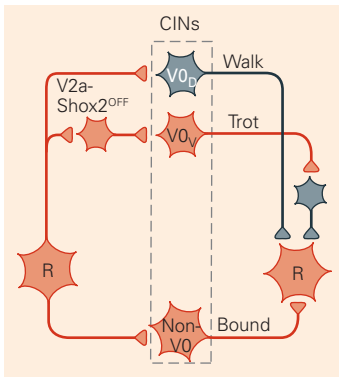
2 Left–right coordination



Interlimb Coordination

The organization of the networks that couple fore- and hindlimbs is not known in detail, but experiments using both lesion and genetic ablation suggest that these pathways involve both inhibitory and excitatory intersegmental connections.

Somatosensory Inputs From Moving Limbs Modulate Locomotion

Even though the CPG can produce the precise timing and phasing of the muscle activity needed to walk, this central pattern is normally modulated by sensory signals from the moving limbs. Two types of sensory input modulate the CPG activity: proprioceptive information generated by the active movement of the limb and tactile information generated when the moving limb meets an obstacle in the surrounding environment.

Proprioception Regulates the Timing and Amplitude of Stepping

One of the clearest indications that somatosensory signals from moving limbs regulate the locomotor cycle is that the rate of locomotion in spinal and decerebrate cats matches the speed of the motorized treadmill belt on which they walk. As the stepping rate increases, the stance phase becomes shorter while the swing phase remains relatively constant.

This observation suggests that some form of sensory input from the moving limb signals the end of the stance phase and thus leads to the initiation of the swing phase. The sensory information from the moving limb is generated by proprioceptors in the muscles and joints. These proprioceptors include stretch-sensitive muscle spindles in the hip and force-sensitive Golgi tendon organs in the ankle that are particularly important for facilitating locomotor phase transition.

The influence from the hip was noticed already by Sherrington, who showed that rapid extension at the hip joint leads to contractions in the hip flexor muscles of chronic spinal cats and dogs. More recent studies have found that preventing hip extension in a limb suppresses stepping in that limb, whereas rhythmically moving the hip in an immobilized cat can entrain the locomotor rhythm; that is, the stretching of the hip muscles causes the timing of the motor output to match the rhythm of the externally imposed movements (Figure 33–8A). The stretching also activates flexor muscle spindles and mimics the lengthening that occurs at the end of the stance phase, thus inhibiting extensor activity and facilitating activation of the flexor rhythm-generating circuits in the spinal cord (Figure 33–8B).

Activation of sensory fibers from Golgi tendon organs and muscle spindles in ankle extensor muscles prolongs the stance phase, often delaying the onset of

Figure 33–7 (Opposite) Spinal locomotor networks are organized into rhythm- and pattern-generation circuits with distinct cellular identities.

A. Circuit diagram of swimming central pattern generator (**CPG**) in the lamprey. Rhythm-generating circuits include excitatory interneurons (**EN**) that drive motor neurons (**MN**), inhibitory commissural interneurons (**CIN**) whose axons project to the other half of the cord, and local inhibitory interneurons (**IN**) with axons projecting on the same side of the cord. A single neuron in the diagram represents multiple neurons in the animal. **Gray neurons**, inhibitory; **red neurons**, excitatory. The vertical **dashed line** indicates the midline. (Data from Grillner 2006.)

B. General circuit diagram for limbed locomotion. Rhythm-generating circuits (**fR** and **eR**) composed of excitatory neurons on either side of the spinal cord drive flexor and extensor muscles on the same side through a pattern-generating layer (empty box). Rhythm-generating flexor (**fR**) and extensor (**eR**) neurons are reciprocally connected via inhibitory neurons and are connected across the midline via commissural interneurons (not shown) that mediate left–right coordination. The diagram shows one spinal segment. (Abbreviation: **MN**, motor neurons.) (Data from Kiehn 2016.)

B1. Flexor and extensor alternation is controlled at multiple levels in the locomotor network. One synapse away from flexor (**f**) and extensor (**e**) motor neurons (**MN**) are Ia-inhibitory interneurons, which reciprocally innervate antagonist motor neurons and each other (Chapter 32). The rIa neurons belong to two major groups of molecularly defined inhibitory neurons, V1 and V2b, in the ventral spinal cord. Excitatory neurons with different molecular markers (including V2a-Shox2^{ON}) provide premotor rhythmic excitation of motor neurons. Rhythm-generating Shox2^{ON} or Hb9 neurons (**fR** and **eR**) drive both inhibitory and excitatory premotor neurons. (Data from Kiehn 2016.)

B2. Rhythm-generating circuits drive left–right coordinating circuits composed of a dual inhibitory pathway involved in alternation and a single excitatory pathway involved in synchrony. The dual inhibitory pathway is composed of inhibitory $V0_D$ commissural neurons that directly inhibit rhythm generation on the other side and excitatory $V0_V$ commissural neurons that indirectly inhibit locomotor networks on the other side. The inhibitory $V0_D$ commissural neuron pathway controls the alternating gait walk. A population of V2a excitatory neurons is part of the left–right alternating circuit and connects to $V0_V$ commissural neurons. This pathway controls the alternating gait trot. Rhythm-generation circuits also drive a left–right synchronizing circuit possibly involved in bound, composed of non-V0 neurons. Only the projections from the left to the right side are shown. (Data from Kiehn 2016.)

Box 33–2 Neuronal Ion Channels Contribute to Central Pattern Generator Function

Neuronal membrane properties make an important contribution to the function of the central pattern generator (CPG). Neurons have a variety of K^+, Na^+, and Ca^{2+} channels that determine their activity and response to synaptic inputs. Studies of CPGs in diverse experimental models have shown that ion channels may be important for promoting rhythmicity, through bursting properties, or patterning, through ion channels that affect phase transitions or the rate of neuronal discharge.

Bursting and Plateau Properties Amplify Cellular Responses

Membrane properties that produce bursting allow cells to produce sustained oscillations in the absence of synaptic inputs. These properties are either intrinsic, as in cells in the sinusoidal node in the heart, or conditional, dependent on the presence of certain neurotransmitters. In some small motor CPGs (such as the pyloric network in the stomatogastric ganglion, which controls rhythmic movements in the gut of crustaceans), intrinsic bursting properties are essential for generating the rhythm.

Conditional bursting triggered by glutaminergic activation of *N*-methyl-D-aspartate (NMDA) receptors has been described in spinal cord interneurons and motor neurons in lamprey, rodents, and amphibians. In the lamprey, bursting due to NMDA receptor activation plays a role in generating swimming. In mammals, it is as yet uncertain whether NMDA receptor–induced bursting is essential for rhythm generation, although it may facilitate excitatory synaptic inputs in the circuit.

Plateau potential is another membrane property that may cause a neuron's membrane potential to jump to a depolarized state that will support action potential firing without further increase in the excitatory drive. Plateau properties amplify and prolong the effect of synaptic excitatory inputs and may promote rhythm generation and motor output. Plateau properties are generated by activation of slowly inactivating L-type Ca^{2+} channels or slowly inactivating Na^+ channels. These channels have been found in vertebrate interneurons and motor neurons. The expression of plateau properties mediated by L-type Ca^{2+} channels in motor neurons is controlled by neuromodulatory neurotransmitters, such as serotonin and norepinephrine. The slowly inactivating Na^+ channels are generally not regulated by neurotransmitters. Blockage of these channels decreases rhythm generation.

Phase Transitions May Be Regulated by Voltage-Gated Ion Channel Activation

Reciprocal inhibition between neurons is a common design in locomotor circuits; ion channels activated in the subthreshold spike range may enhance or delay phase transitions by such inhibition. Three types of voltage-gated channels are involved: a transient low threshold Ca^{2+} channel, cation-nonselective permeable hyperpolarization-activated cyclic nucleotide-gated (HCN) channels, and transient K^+ channels.

The transient low-threshold Ca^{2+} channels are inactivated at membrane potentials around rest. Transient inhibitory synaptic inputs remove the inactivation. When released from synaptic inhibition, activation of low-threshold Ca^{2+} channels will cause a short-lasting rebound excitation before the channels inactivate again. In the lamprey, spinal cord activation of metabotropic $GABA_B$ receptors depresses low-threshold Ca^{2+} channels involved in producing the swimming motor pattern. The suppression leads to a longer hyperpolarized phase and therefore to a slower alternation between antagonistic muscles, a possible mechanism for the slowing of swimming seen following $GABA_B$ receptor activation.

HCN channels are found in many CPG neurons and motor neurons and may help neurons escape from inhibition. They are activated by hyperpolarization, such as occurs during synaptic inhibition. Their activation depolarizes the cell, counteracting the hyperpolarization. Finally, the kinetics of their activation and deactivation are slow, so they stay open for some time after the hyperpolarization is released. The channel kinetics affect the integrative properties of the cell in two important ways. First, the depolarization caused by the channel opening limits the effect of sustained inhibitory inputs and helps the cell escape from inhibition. Second, the slow closing following synaptic inhibition leads to a rebound excitation promoting the next burst.

Voltage-gated A-type transient K^+ channels are usually inactivated at resting membrane potential. Hyperpolarization removes the resting inactivation, and subsequent depolarization will cause a transient activation of the channel. Their activation will therefore delay the onset of the next burst.

Regulation of Spiking Controls How Much Cells Are Activated

A number of different ion channels play a role in regulating the firing rate of a cell. Activation and inactivation kinetics of Na^+ channels are factors. Other important channels are sodium- and calcium-activated K^+ channels. The effect of activation of these K^+ channels is often seen as a slow after-hyperpolarization following an action potential or a train of action potentials. Activation of these channels therefore causes spike train adaptation and postactivation inhibition, which contribute to burst termination.

Box 33–3 Molecular-Genetics Combined With Anatomical, Electrophysiological, and Behavioral Analyses Are Used to Unravel the Locomotor Network Organization

To unravel the functional organization of the large neuronal networks in the spinal cord, researchers have used molecular-genetic–driven network analysis to take advantage of a molecular code that determines the spatial layout of the spinal locomotor networks.

It has been well documented that motor neurons develop and differentiate according to a genetic code expressed in the embryonic spinal cord (Chapter 45). This feature extends also to the development of spinal interneurons, which can be identified by different transcription factors (Table 33–1). The cardinal classes of interneuronal types belong to dorsally located interneurons (dI1–dI6) and ventrally located interneurons (V0–V3), with further subdivision within these categories (eg, $V0_D$ and $V0_V$, V2a-Shox2^{Off}, V2a-Shox^{On}) where a combination of transcription factors defines these subtypes (Table 33–1). Each group of interneurons has specific transmitter content and characteristic axonal projection patterns.

The ability to manipulate these specific interneuron types gives an unparalleled opportunity to examine the functional contribution of specific subsets of interneurons in the mouse or zebrafish that is not possible in species such as the cat. The molecular code of the spinal cord neurons is used to mark cells with a marker protein such as green fluorescent protein or for the expression of proteins that allow for cell type-specific ablation or activation/inactivation of cells types. Such studies have ascribed specific locomotor functions to the dI3, V0–V3, and Hb9 cells, all molecularly differentiated classes of neurons (Table 33–1).

Table 33–1 Developmental Molecular Codes Specify the Identity of Spinal Neurons in the Spinal Cord

Postmitotic transcription factors	Neuron type	Transmitters
Islt1/Tlx3	dI3	Glutamate
Pax2/7	$V0_D$	GABA/glycine
Evx1	$V0_V$	Glutamate
Evx1/Pitx2	$V0_C$	Acetylcholine
Evx1/Pitx2	$V0_D$	Glutamate
En1	V1	GABA/glycine
Chx10	V2a-Shox2^{Off}	Glutamate
Chx10/Shox2	V2a-Shox2^{ON}	Glutamate
GATA2/3	V2b	GABA/glycine
Sox1	V2c	GABA/glycine
Shox2	V2d	Glutamate
Hb9/Islt1-2	MN	Acetylcholine
Hb9	Hb9	Glutamate
Sim1	$V3_D$	Glutamate
Sim1	$V3_V$	Glutamate

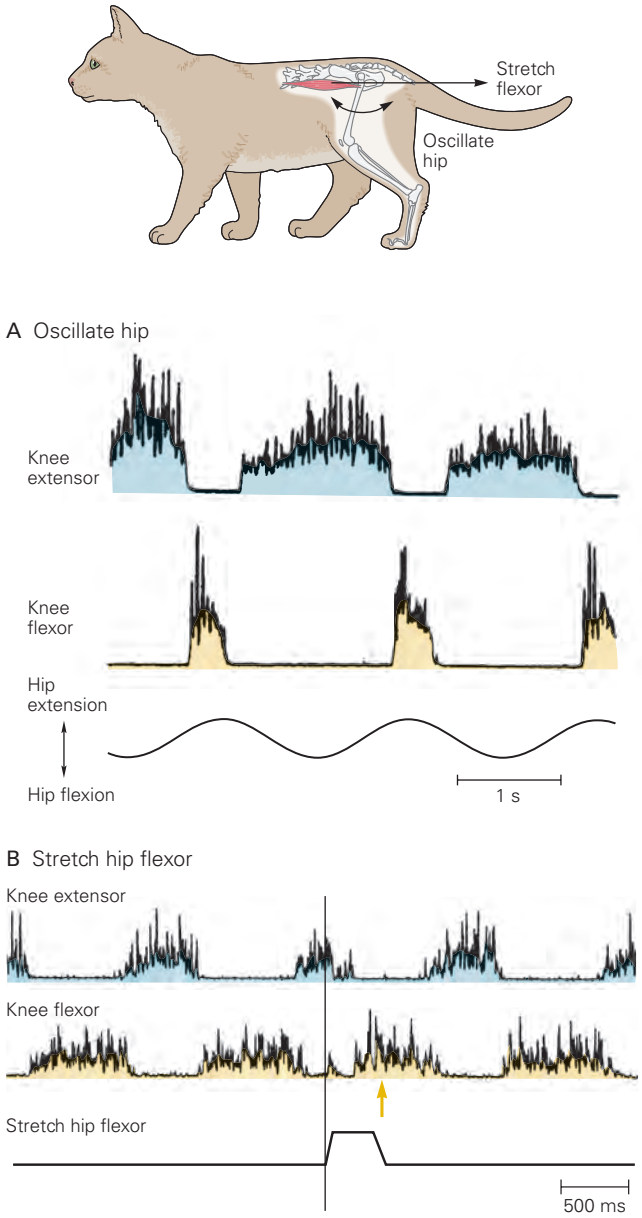

Figure 33–8 Hip extension initiates the transition from stance to swing phase of walking.

A. In an immobilized decerebrate cat, passive oscillating movement around the hip joint initiates and entrains the fictive locomotor pattern in knee extensor and flexor motor neurons. The flexor electromyogram (EMG) bursts correspond to the swing phase and are generated when the hip is extended. (Adapted, with permission, from Kriellaars et al. 1994.)

B. In a walking decerebrate cat, stretching of the hip flexor muscle (iliopsoas) inhibits knee extensor EMG activity, allowing knee flexor activity to begin earlier. The **arrow** in the knee flexor record indicates when activity in the muscle would have begun had the hip flexor muscle not been stretched. Activation of sensory fibers from muscle spindles in the hip flexor muscle is responsible for this effect. (Adapted, with permission, from Hiebert et al. 1996.)

the swing phase until the stimulus has ended (Figure 33–9A). Sensory fibers from both types of receptors are active during stance, with the intensity of the signal from the Golgi tendon organs being strongly related to the load carried by the leg. Golgi tendon organs have inhibitory actions on ankle extensor motor neurons when the body is at rest (Chapter 32) but an excitatory action during walking. This reversal of the sign of the reflex is caused by inhibition of inhibitory interneuron pathways together with a release of excitatory pathways during locomotion. The functional consequence of this reflex reversal during locomotion is that the swing phase is not initiated until the extensor muscles are unloaded and the forces exerted by these muscles are low, as signaled by a decrease in activity from the Golgi tendon organs near the end of stance.

In sum, proprioceptive signals from the ankle extensor muscles and hip flexor muscles work synergistically to facilitate the stance-to-swing phase transition. In the late stance phase, when the limb is unloaded, as inhibitory signals from Golgi tendon organs wane, their effects on extensor rhythm generation declines, while at the same time the activity in muscle afferents around the hip joint is increased, facilitating activity in flexor rhythm generation.

At least three excitatory pathways transmit sensory information from extensor muscles to extensor motor neurons during walking: a monosynaptic pathway from primary muscle spindles (group Ia afferents), a disynaptic pathway from primary muscle spindles and Golgi tendon organs (group Ia and Ib afferents), and a polysynaptic pathway from primary muscle spindles and Golgi tendon organs that includes interneurons in the extensor rhythm generator (Figure 33–9B). These pathways all contribute to phase transition from stance to swing when the ankle is unloaded and maintain extensors in stance phase when the ankle is loaded.

In addition to regulating the transition from stance to swing, proprioceptive information from muscle spindles and Golgi tendon organs contributes significantly to the generation of burst activity in extensor motor neurons. Reducing this sensory input in cats diminishes the level of extensor activity by more than half; in humans, it has been estimated that up to 30% of the activity of ankle extensor motor neurons is caused by feedback from the extensor muscles.

Mechanoreceptors in the Skin Allow Stepping to Adjust to Unexpected Obstacles

Mechanoreceptors in the skin, including some nociceptors, have a powerful influence on the CPG for

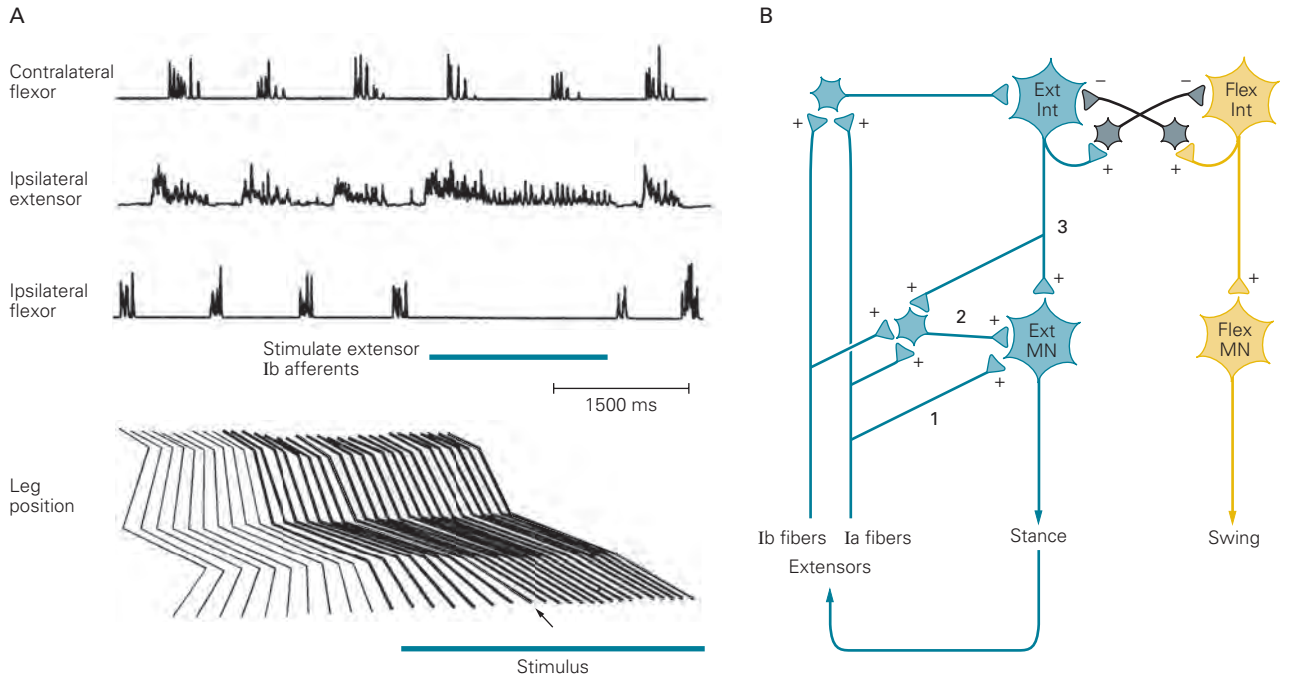

Figure 33–9 The swing phase of walking is initiated by sensory feedback from extensor muscles.

A. In a decerebrate cat, electrical stimulation of group I sensory fibers from ankle extensor muscles inhibits the electromyogram burst in ipsilateral flexors and prolongs the burst in the ipsilateral extensors during walking. The timing of contralateral flexor activity is not altered. Stimulating group I fibers from ankle extensors prevents initiation of the swing phase, as can be seen in the position of the leg during the time the fibers were stimulated. The **arrow** shows the point at which the swing phase would normally have occurred had the ankle extensor afferents not been stimulated. (Adapted, with permission, from Whelan, Hiebert, and Pearson 1995. Copyright © Springer-Verlag 1995.)

B. Mutually inhibiting groups of extensor (**Ext**) and flexor (**Flex**) interneurons (**Int**) constitute a rhythm generator in the afferent pathway regulating the stance phase. Feedback from extensor muscles increases the level of activity in extensor motor neurons (**MN**) during the stance phase and maintains extensor activity when the extensor muscles are loaded. The feedback is relayed through three excitatory (**+**) pathways: (**1**) monosynaptic connections from Ia fibers to extensor motor neurons; (**2**) disynaptic connections from Ia and Ib fibers to extensor motor neurons; and (**3**) polysynaptic excitatory pathways that act through the extensor rhythm generator to maintain the extensor motor neurons active in stance phase.

walking. One important function of these receptors is to detect obstacles and adjust stepping movements to avoid them. A well-studied example is the corrective reaction to stumbling in cats.

A mild mechanical stimulus applied to the dorsal part of the paw during the swing phase produces excitation of flexor motor neurons and inhibition of extensor motor neurons, leading to rapid flexion of the paw away from the stimulus and elevation of the leg in an attempt to step over the object. Because this corrective response is readily observed in spinal cats, it must be produced to a large extent by circuits entirely contained within the spinal cord.

One of the interesting features of the corrective reaction is that corrective flexion movements are produced only if the paw is stimulated during the swing phase. An identical stimulus applied during the stance phase produces the opposite response—excitation of extensor muscles that reinforces the ongoing extensor activity. This extensor action is appropriate; if a flexion reflex were produced during the stance phase, the animal might collapse because it is being supported by the limb. This is an example of a phase-dependent reflex reversal. The same stimulus can excite one group of motor neurons during one phase of locomotion while activating the antagonist motor neurons during another phase.

Supraspinal Structures Are Responsible for Initiation and Adaptive Control of Stepping

Although the basic motor patterns for locomotion are generated in the spinal cord, the initiation, selection, and planning of locomotion require activation

of supraspinal structures, including the brain stem, the basal ganglia, cerebellum, and cerebral cortex. Supraspinal regulation of stepping provides a number of behavioral modifications that cannot be mediated by spinal circuits alone. These include the voluntary initiation of locomotion and the regulation of speed; postural regulation, including weight support, balance, and interlimb coordination; and the planning and execution of anticipatory modifications of gait, particularly visually guided modifications.

Midbrain Nuclei Initiate and Maintain Locomotion and Control Speed

The locomotor networks in the spinal cord require a command or start signal from supraspinal regions to initiate and maintain their activity. The major neuronal structure involved in the initiation in vertebrates is a region in the midbrain called the mesencephalic locomotor region (MLR). The MLR was first identified in cats as a unitary region localized in or around the cuneiform nucleus, just below the inferior colliculus. Tonic electrical stimulation in this area in the resting animal increased postural tonus so that the animal stood up and then started to walk. As the intensity of stimulation rose, the speed of locomotion increased and alternating gaits switched to synchronous gaits such as gallop or bound (Figure 33–10).

Later studies with electrical stimulation confirmed the presence of the MLR in all vertebrates, suggesting that the MLR is evolutionarily conserved from the oldest vertebrates to humans. These studies have pointed to two midbrain structures as part of the MLR (Figure 33–11A): the cuneiform nucleus (CNF) and the more ventrally located pedunculopontine nucleus (PPN) (Figure 33–11A). These two nuclei differ in the types of neurons they contain.

Long-range projection neurons in the CNF are excitatory and use glutamate as their neurotransmitter, whereas those in the PPN are both glutamatergic and cholinergic. In both nuclei, the excitatory neurons are intermingled with local GABAergic interneurons. Electrical stimulation has, however, been unable to determine which nucleus or which types of neurons are involved in the initiation of locomotion and speed control. However, the use of selective activation and inactivation of neurotransmitter-specific CNF and PPN neurons suggests that the two nuclei play specific roles in speed control and gait selection of locomotion (Figure 33–11B). Glutamatergic neurons in both PPN and CNF are sufficient for supporting alternating locomotion at slower speeds, such as walking and trot, while glutamatergic neurons in the CNF are necessary for high-speed locomotion, such as gallop and bound, characteristic of escape locomotion. Expression of these gaits is dependent on the stimulation frequency, possibly reflecting the effect of firing frequency in the intact animal.

The role of cholinergic PPN neurons for locomotion is less well understood. In mammals, they do not seem to have a strong role in maintaining locomotion.

These roles of glutamatergic CNF and PPN neurons in locomotor control may also be reflected in the different inputs. PPN neurons receive strong input from the basal ganglia, specifically the substantia nigra pars reticulata, globus pallidus pars interna, and subthalamic nucleus, as well as from sensorimotor and frontal cortex. Additionally, the PPN receives sensorimotor information from many nuclei in the midbrain and brain stem. The nucleus may therefore serve as a hub for integrating information from many brain structures, possibly leading to the release of slower exploratory locomotion. In contrast, the input to neurons in CNF is much more restricted and arises principally from structures that may be involved in escape responses. The MLR is therefore composed of two regions that act together to select context-dependent locomotor behavior.

Another brain area that evokes locomotion when stimulated is the subthalamic (or diencephalic) locomotor region (to be distinguished from the subthalamic nucleus). This region includes nuclei in the dorsal and lateral hypothalamus involved in various homeostatic features such as regulating feeding. Neurons in these areas project to neurons in the reticular formation and bypass the PPN and CNF, suggesting a parallel pathway for initiating locomotion, possibly driven by the need to find food.

Midbrain Nuclei That Initiate Locomotion Project to Brain Stem Neurons

The excitatory signals from CNF and PPN are relayed indirectly to the spinal cord by way of neurons in the brain stem reticular formation, which provide the final command signal to the locomotor networks in the spinal cord. The identity of these neurons is only partly known. In general terms, two transmitter-defined pathways are involved: glutamatergic and serotonergic.

The glutamatergic locomotor pathways probably have multiple origins in the brain stem reticular formation, forming parallel descending pathways. They project directly or indirectly via a chain of intersegmental (propriospinal) glutamatergic interneurons to locomotor neurons in the spinal cord (Figure 33–10A). Reticulospinal neurons also participate in regulating

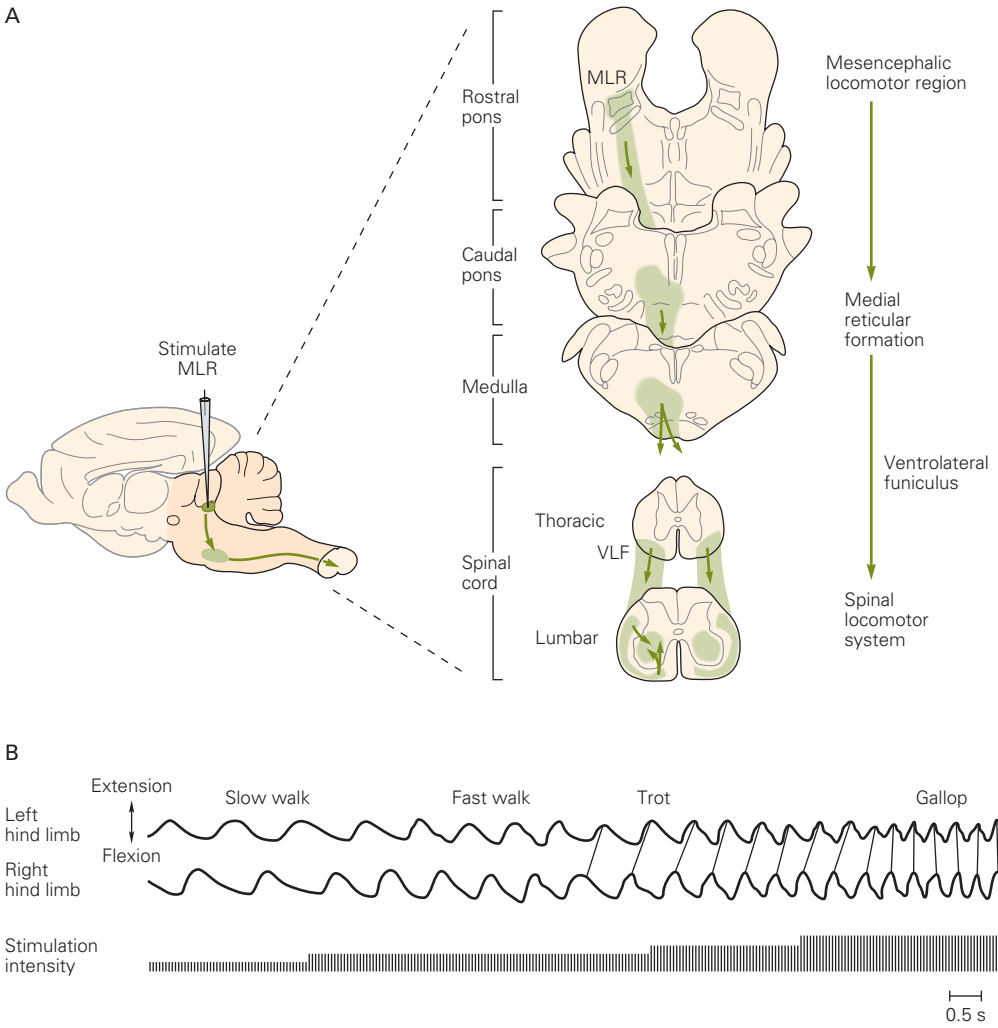

Figure 33–10 The mesencephalic locomotor region initiates locomotion.

A. Electrical stimulation of the mesencephalic locomotor region (MLR) in the cat initiates locomotion by activating neurons in the medial reticular formation whose axons descend in the ventrolateral funiculus (VLF) to the spinal locomotor system.

B. When the strength of electrical stimulation of the MLR in a decerebrate cat walking on a treadmill is gradually increased, the gait and rate of stepping change from slow walking to trotting and finally to galloping. As the cat progresses from trotting to galloping, the hind limbs shift from alternating to in-phase activity. (Adapted from Shik et al. 1966.)

the postural activity that is needed for the animal to locomote (see later discussion).

Evidence for the existence of a serotonergic locomotor pathway in mammals is restricted to experiments in rats that have shown the involvement of serotonergic neurons in the caudal brain stem. The mechanisms by which the final command signals from the brain stem to the spinal cord activate the spinal locomotor networks, maintain their activity, and allow the expression of different gaits are unknown.

The episodic nature of locomotion indicates that the initiating signals may be complemented by stop commands to allow for sudden locomotor arrest. Such signals have been found in *Xenopus* tadpole, in which head contact with obstacles activates GABAergic descending pathways that immediately terminate swimming. Likewise, in decerebrate cats, tonic electrical stimulation of the medullary and caudal pontine reticular formation leads to a general motor inhibition. Studies in mice have identified a restricted contingent of V2a neurons in the reticular formation that mediate an immediate arrest of ongoing locomotor activity. Such "V2a stop neurons" send a behaviorally relevant stop signal via descending projections to inhibitory

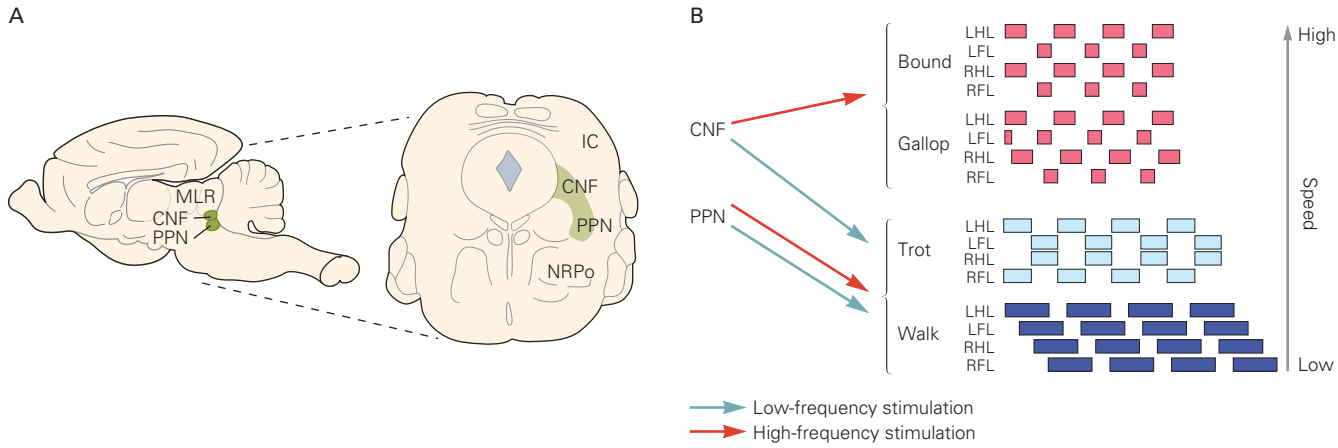

Figure 33–11 The mesencephalic locomotor region is composed of dual midbrain glutamatergic nuclei that control initiation of locomotion, speed and gait regulation, and context-dependent selection of locomotion.

A. *Left*: The site of the localization of mesencephalic locomotor region (**MLR**) in the midbrain of the mouse. *Right:* Transverse section shows that the MLR is composed of the cuneiform nucleus (**CNF**) and the pedunculopontine nucleus (**PPN**) in the midbrain, lateral to the cerebral aqueduct, and dorsal to the nucleus reticularis pontis oralis (**NRPo**). Glutamatergic, GABAergic, and cholinergic neurons are intermingled in the CNF and PPN. (Abbreviation: **IC**, inferior colliculus).

B. Effect in mice of optical stimulation of glutamatergic cells in the CNF or PPN that have been transfected with the light-sensitive channel, channelrhodopsin 2. Stimulation at low and high frequencies in the PPN leads only to alternating gaits—walking and trotting. Low-frequency simulation in the CNF likewise results only in slow, exploratory locomotion, while high-frequency stimulation evokes the synchronous gaits gallop and bound corresponding to escape locomotion.

The different types of gaits are shown as idealized diagrams from low to high speeds of locomotion. Filled boxes represent the stance phase; open spaces the swing phase. Walk is characterized by periods of support by three or four feet simultaneously. Trot is characterized by simultaneous activity in the diagonal fore and hindlimbs. Gallop is characterized by the forelimbs moving slightly out of phase and hind limbs being almost in phase. Bound is characterized by hind limbs and forelimbs moving simultaneously and forelimb and hindlimb out of phase. (Abbreviations: **LFL**, left forelimb; **LHL**, left hindlimb; **RFL**, right forelimb; **RHL**, right hindlimb.) (Adapted from data in Caggiano et al. 2018.)

interneurons in the ventral lumbar spinal cord that inhibits rhythm generation. A similar stop signal arrests swimming in the lamprey.

The Brain Stem Nuclei Regulate Posture During Locomotion

An important aspect of locomotor control is the regulation of posture. This general term encompasses several types of behavior, including the production of the postural support on which locomotion is superimposed, the control of balance, the regulation of interlimb coordination in quadrupeds, and the modification of muscle tonus required to adapt to locomotion on slopes or during turning. In addition, anticipatory changes in posture precede changes in voluntary gait modifications, and compensatory changes in posture follow unexpected perturbations. These functions are largely subserved by two descending systems originating from the brain stem: the vestibulospinal tract (VST), originating in the lateral vestibular nucleus (LVN), and the reticulospinal tract (RST), originating in the pontomedullary reticular formation (PMRF). Both pathways are phylogenetically old and found in all vertebrates.

Lesions of the LVN, the PMRF, or their descending axons in the spinal cord lead to a loss of weight support and the control of equilibrium, expressed as a crouched gait and swaying of the hindquarters to one side or the other. Lesions of these nuclei are also followed by large changes in the interlimb coordination between the fore- and hindlimbs. Likewise, tonic electrical or chemical stimulation of the pons and the medulla modulates the level of muscle tonus in the limbs and can either facilitate or suppress locomotion depending on the exact site stimulated (Figure 33–12).

Activity in the VST and RST, together with activity in the rubrospinal tract, which originates from the red nucleus, also phasically modifies the level of muscle tonus during each step. Weak electrical stimulation of any of these three structures produces phase-dependent modulation of locomotor activity. Brief activation of these pathways with short trains of stimuli produces

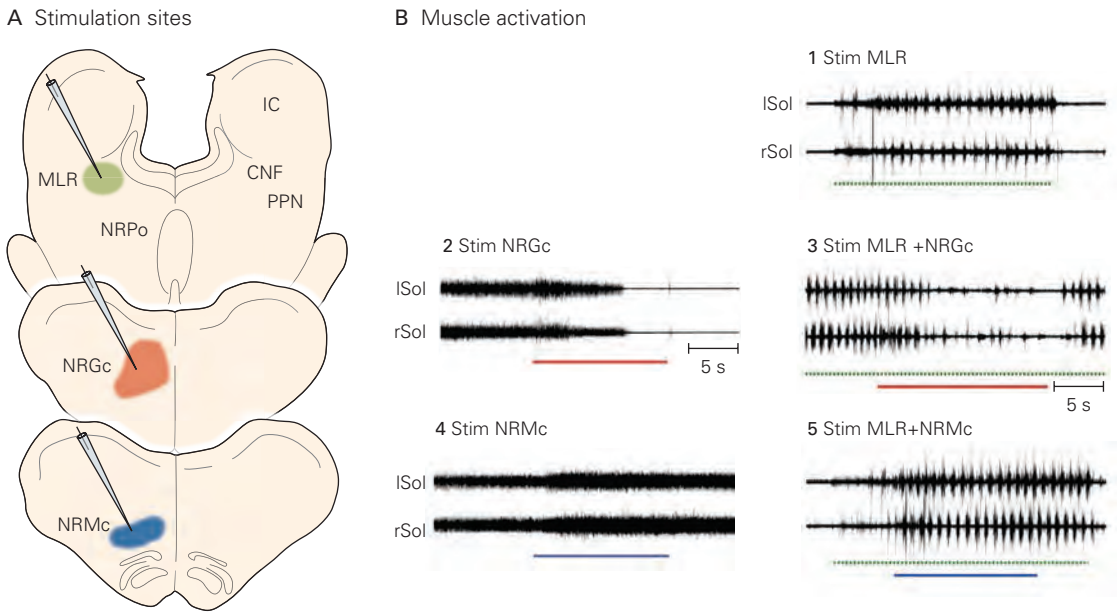

Figure 33–12 Locomotor activity is modified by the level of postural tone. (Adapted, with permission, from Takakusaki et al. 2016.)

A. Transverse sections of the brain stem of the cat at three different rostrocaudal levels. Colored areas indicate the regions stimulated during the trials shown in part **B**. (Abbreviations: **CNF**, cuneiform nucleus; **IC**, inferior colliculus; **MLR**, mesencephalic locomotor region; **NRPo**, nucleus reticularis pontis oralis; **NRGc**, nucleus reticularis gigantocellularis; **NRMc**, nucleus reticularis magnocellularis; **PPN**, pedunculopontine nucleus.)

B. Effects of stimulating the different regions of the brain stem indicated in part **A** in the decerebrate cat.

1. Stimulation of the MLR (CNF/PPN) (**green bar**) produces rhythmic activation in the left and right hindlimb extensor soleus muscles (**Sol**).

2. Tonic stimulation of the NRGc (**red bar**) in the medulla results in a loss of muscle tone in the extensor muscles.

3. Stimulation of the NRGc during CNF-induced locomotion reduces muscle tone and thereby inhibits locomotion.

4. Tonic stimulation of the NRMc (**blue bar**) in the ventral medulla produces an increase in muscle tone.

5. Stimulation of the NRMc during MLR stimulation results in increased vigor of locomotion.

transient changes in the amplitude of the muscle bursts but rarely produces any changes in the timing of the step cycle. Activation of the LVN primarily enhances responses in ipsilateral extensor muscles during their natural period of activity in the stance phase. In contrast, stimulation of the red nucleus generally produces transient increases in activity in contralateral flexor muscles, again during their natural period of activity in the swing phase.

Stimulation of the PMRF produces more complex and widespread responses that may modify activity in flexor muscles during the swing phase and in extensor muscles during the stance phase across all four limbs in a coordinated pattern (Figure 33–13). In flexor muscles, activity is generally facilitated by PMRF stimulation, but in extensor muscles, it may be facilitated or suppressed depending on the exact site stimulated. This phase-dependent nature of the responses is thought to be mediated by activation of interneurons in the spinal CPG. Stimulation of these three structures at higher strengths, or with longer trains, may produce changes in the timing of the step cycle as well as in the magnitude of EMG activity.

During locomotion, neurons within the LVN, PMRF, and red nucleus are phasically modulated at the frequency of the step cycle. Neurons in the LVN are generally activated in phase with ipsilateral extensor muscles, whereas neurons in the red nucleus are generally active during the contralateral swing phase. Neurons in the PMRF have more complicated periods of activity and may discharge in relation to ipsilateral or contralateral flexor or extensor muscles.

Brain stem structures also contribute to more complex activities during locomotion. For example, the red nucleus contributes to the complex modifications in muscle activity required for precise modifications of

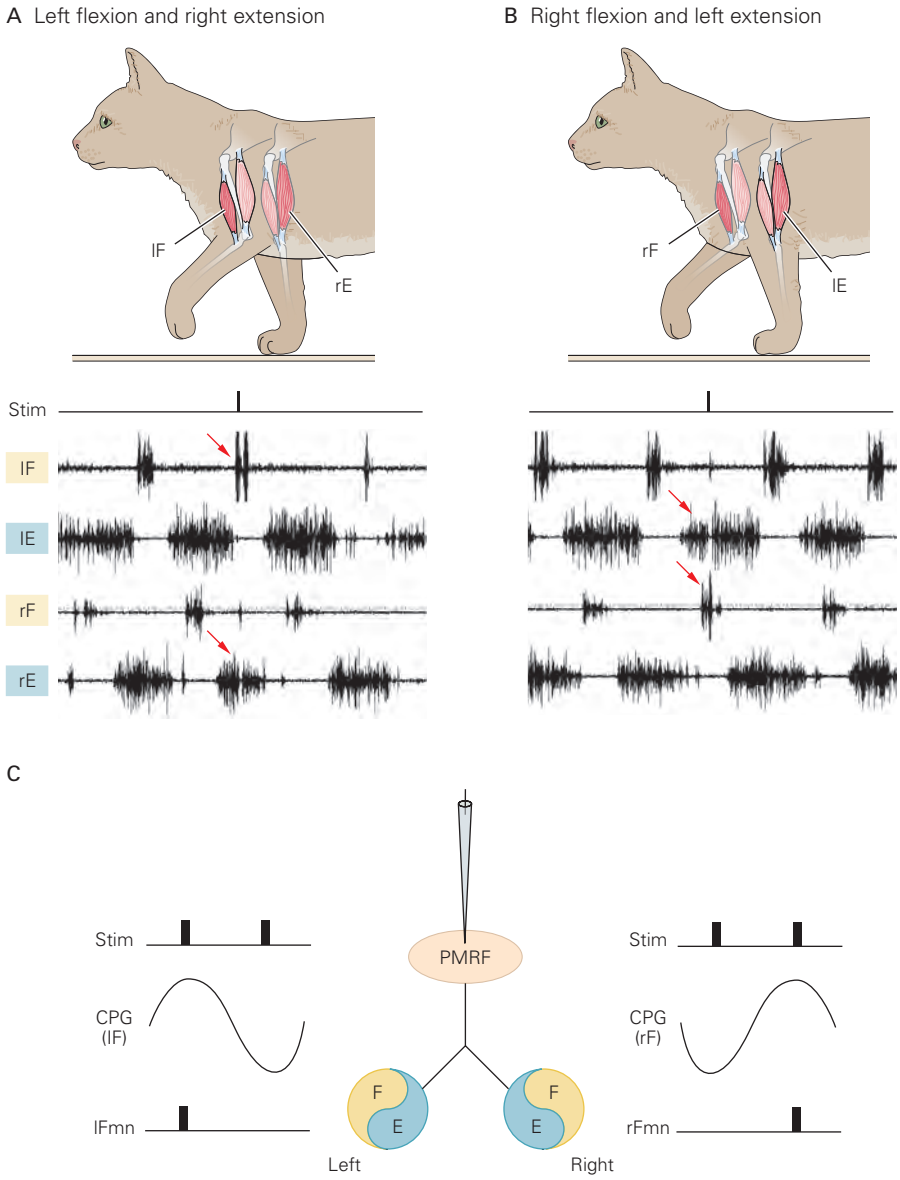

Figure 33–13 Microstimulation of the pontomedullary reticular formation (PMRF) produces phase-dependent responses in flexor and extensor muscles. (Data from T. Drew.)

A. Stimulation of the left PMRF during the swing phase of the left limb produces a transient increase in the electromyogram activity of the left flexor muscles (**IF**) and a simultaneous decrease in activity in the right extensor muscles (**rE**) (**red arrows**). There is little stimulus-evoked activity in the left extensor (**lE**) or right flexor (**rF**) muscles, which are inactive at this phase of the step cycle.

B. Stimulation at the same location in the PMRF during the swing phase of the right limb produces the inverse responses.

C. The phase-dependent nature of the responses is likely determined by the cyclical nature of the level of excitability in interneurons that are part of the locomotor central pattern generator (**CPG**). Responses are gated by activity in the flexor (**F**) and extensor (**E**) parts of the locomotor CPG. When the first stimulation arrives, flexor interneurons in the left CPG (**lF**) are active, whereas those in the right CPG (**rF**) are inactive. The stimulation therefore produces a response only in the left flexor motor neurons (**lFmn**). When the second stimulation arrives, flexor interneurons in the right CPG (**rF**) are active, whereas those on the left side are inactive, and therefore, the stimulation elicits a response only in the flexor motor neurons on the right (**rFmn**).

gait (see below). In a complementary manner, the widespread effects of the PMRF on multiple limbs allow it to produce the coordinated changes in postural activity that accompany gait modifications. The coordination between gait modifications and postural activity is assured by the strong connections from the motor cortex to the PMRF in the same manner as for discrete voluntary movements (Chapter 34). The PMRF also contributes to the compensatory changes in posture that occur as a consequence of perturbations. In this situation, it forms part of a spino-bulbo-spinal reflex that contributes to the widespread postural responses that follow the immediate spinal reflexes activated by a sudden perturbation.

Visually Guided Locomotion Involves the Motor Cortex

Walking is most often guided by vision, and the motor cortex is largely essential for visually guided movement, especially when gait must be modified to ensure precise control over limb trajectory and foot placement. In mammals, lesions of the motor cortex do not

prevent animals from walking on a smooth floor, but they severely impair "precision locomotion," which requires a high degree of visuomotor coordination, such as walking on the rungs of a horizontal ladder, stepping over a series of barriers, and stepping over single objects placed on a treadmill belt.

Experiments in intact cats trained to step over obstacles attached to a moving treadmill belt show that precision locomotion is associated with considerable modulation of the activity of numerous neurons in the motor cortex (Figure 33–14). Other neurons in the motor cortex show a more discrete pattern of activity and are activated sequentially during different parts of the swing phase. The activity of these cortical neurons correlates with the periods of modified muscle activity required to produce the gait modifications in a similar manner to what occurs during reaching (see Figure 34–21). Such subpopulations of neurons may serve to modify the activity of the groups of synergistic muscles required to produce flexible changes in limb trajectory.

Many of these cortical neurons project directly to the spinal cord (corticospinal neurons) and thus may regulate the activity of spinal interneurons, including those within the CPG, thereby adapting the timing and magnitude of motor activity to a specific locomotor task. Brief trains of electrical stimulation applied to either the motor cortex or the corticospinal tract in normal walking cats produce transient responses in the contralateral limb in a phase-dependent manner, similar to that produced by activity in various brain stem structures. However, in contrast to the situation

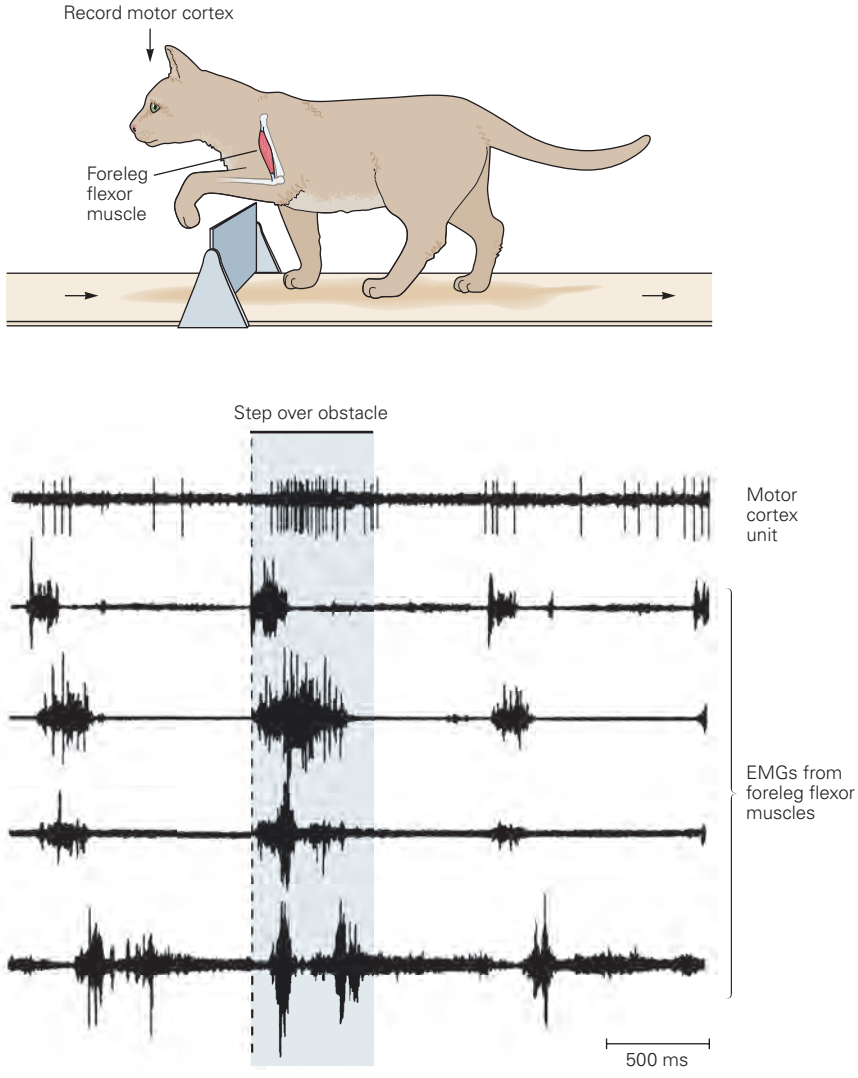

Figure 33–14 Stepping movements are adapted by the motor cortex in response to visual inputs. When a cat steps over a visible object fixed to a treadmill, neurons in the motor cortex increase in activity. This increase in cortical activity is associated with enhanced activity in foreleg muscles, as seen in the electromyograms (**EMG**). (Adapted, with permission, from Drew 1988.)

observed with brain stem structures, increasing the duration of the stimulation train applied to the motor cortex frequently results in a reset of the locomotor rhythm, characterized as an interruption of the ongoing step cycle and the initiation of a new step cycle. This suggests that in mammals the corticospinal tract has privileged access to the rhythm generator of the CPG.

Planning of Locomotion Involves the Posterior Parietal Cortex

When humans and animals approach an obstacle in their pathway, they must adjust their walking pattern to move around the obstacle or step over it. Planning of these adjustments begins two or three steps before the obstacle is reached. Recent experiments suggest that the posterior parietal cortex (PPC) is particularly involved in planning gait modifications. Lesions in this region cause walking cats to misplace the positioning of their paws as they approach an obstacle and increase the probability that one or more legs contact the obstacle as they step over it.

In contrast to what is observed in the motor cortex, recordings in PPC show that many neurons increase their activity in advance of the step over the obstacle. Moreover, many cells in the PPC discharge similarly regardless of which leg is first to step over the obstacle (Figure 33–15A,B). Such cells may provide an estimation of the position of the body with respect to objects in the environment (Figure 33–15B), allowing animals to modify gait as they approach the obstacle. The manner in which the PPC interacts with other cortical and subcortical structures generally considered to be involved in motor planning is unknown. However, recent work shows that the premotor cortex also makes an important contribution to planning visually guided gait modifications (Figure 33–15C) and may be implicated in the transformation of a global signal providing information concerning obstacle location to the muscle-based signal necessary for the execution of the step over the obstacle.

Visual information about the size and location of an obstacle is also stored in working memory, a form of short-term memory (Chapter 52). This information is used to ensure that gait modifications in the hindlimb are coordinated with those of the forelimb and is necessary because the obstacle is no longer within the visual field by the time the hindlimbs are stepping over it. The neurobiological mechanisms underlying this form of working memory remain to be established, but the persistence of the memory appears to depend, at least in part, on neuronal systems in the PPC. With bilateral lesions or cooling of the medial PPC, the memory is completely abolished (Figure 33–16A). Complementing this observation is the finding that the activity of some neurons in the PPC is elevated during a step over an obstacle, as well as throughout the time the animal straddles the obstacle (Figure 33–16B). This activity could represent the working memory of key features of the obstacle such as height.

The Cerebellum Regulates the Timing and Intensity of Descending Signals

Damage to the cerebellum results in marked abnormalities in locomotor movements, including the need for a widened base of support, impaired coordination of joints, and abnormal coupling between limbs during stepping. These symptoms, which are characteristic of *ataxia* (Chapter 37), indicate that the cerebellum contributes importantly to the regulation of locomotion.

A major function of the cerebellum is to correct movement based on a comparison of the motor signals sent to the spinal cord and the movement produced by that motor command (Chapter 37). In the context of locomotion, the motor signal is generated by neurons in the motor cortex and brain stem nuclei. Information about the movement comes from the ascending spinocerebellar pathways. For the hind legs of the cat, these are the dorsal and ventral spinocerebellar tracts. Neurons in the dorsal spinocerebellar tract (DSCT neurons) are strongly activated by numerous leg proprioceptors and thus provide the cerebellum with detailed information about the mechanical state of the hind legs. In contrast, neurons in the ventral tract (VSCT neurons) are activated primarily by interneurons in the CPG, thus providing the cerebellum with information about the state of the spinal locomotor network.

During locomotion, the motor command (the central efference copy), the movement (the afference copy, via the DSCT), and the state of the spinal networks (the spinal efference copy, via the VSCT) are integrated within the cerebellum and expressed as changes in the pattern of rhythmical discharge of Purkinje cells in the cerebellar cortex and neurons in the deep cerebellar nuclei. These signals from the deep cerebellar nuclei are then sent to the motor cortex and the various brain stem nuclei where they modulate descending signals to the spinal cord to correct any motor errors.

Behavioral experiments show that the cerebellum also plays an important role in the adaptation of gait. For example, when subjects walk on a split treadmill,

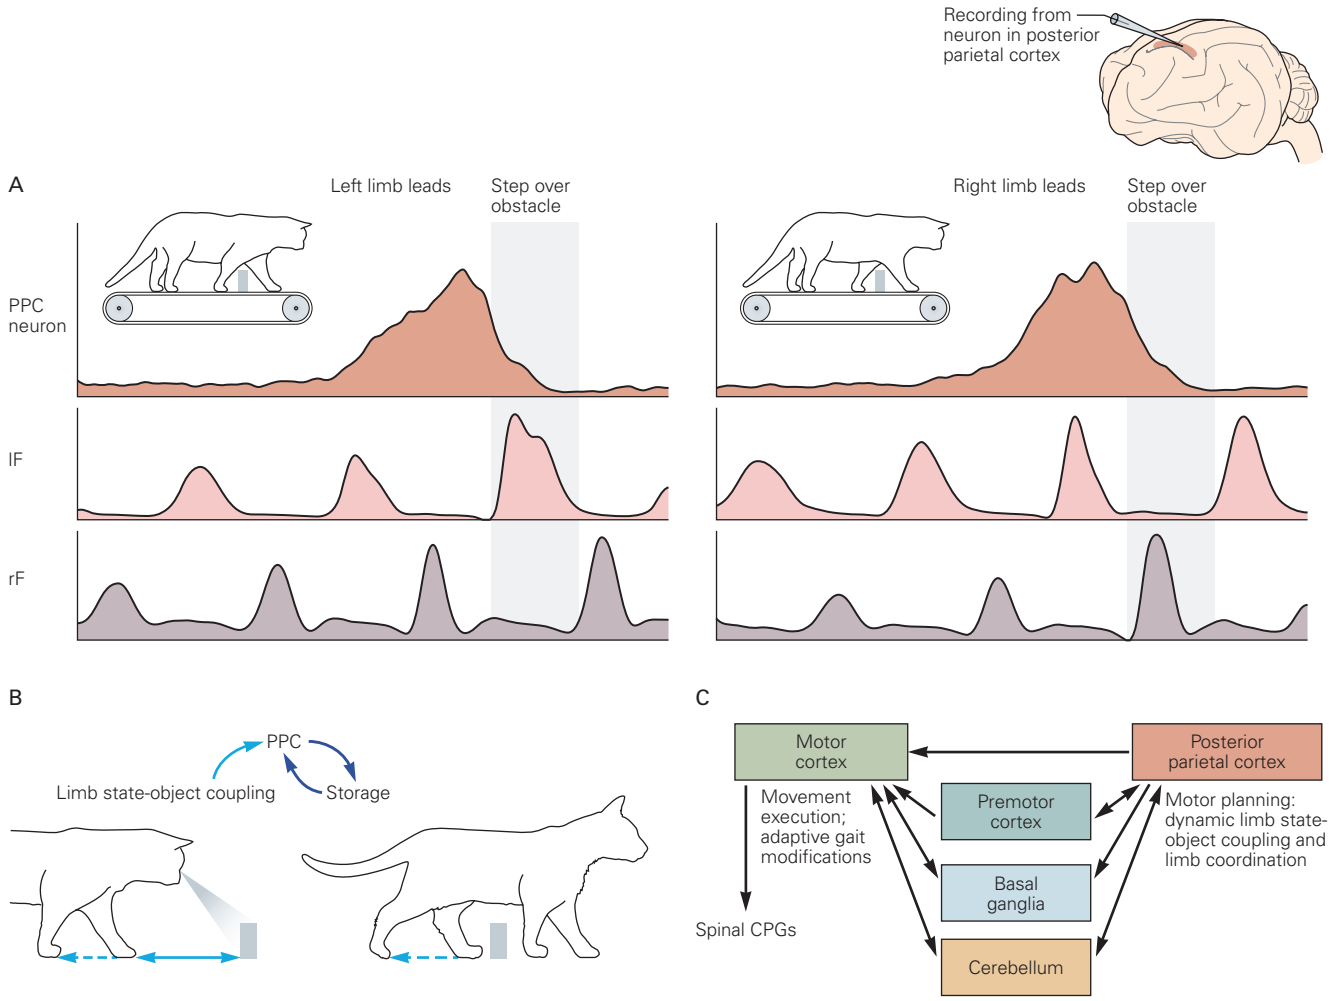

Figure 33–15 Neurons in the posterior parietal cortex (PPC) are involved in planning voluntary gait modifications.

A. Activity of a PPC neuron in the right cortex during a step over the obstacle when the left or right forelimb is the first to step over the obstacle. In each situation, the cell in the PPC discharges two to three steps in advance of the step over the obstacle.

B. The observation that PPC neurons discharge independent of which limb is the first to step over the obstacle suggests a global function of PPC in the planning of locomotion. In a general scheme, the PPC neurons are involved in the estimation of the relative location of an object with respect to the body (limb state–object coupling [**double arrow**]) and storage information in the PPC for later retrieval.

C. The PPC does not act alone in planning gait modifications. It is part of a cortical and subcortical network that includes, among other structures, the premotor cortex, the basal ganglia, and the cerebellum. Connections exist between each of these structures as well as between each of them and the motor cortex, which is responsible for the execution of the gait modification. (Abbreviation: **CPG**, central pattern generator.) (Adapted, with permission, from Drew and Marigold 2015.)

so that each leg walks at a different speed, they initially show a very asymmetric gait before adapting over time to a more asymmetric one. When the two treadmill belts are reset to the same speed, they again show an asymmetric gait, demonstrating that the experimental condition had produced adaptation (see Figure 30–13). Patients with damage to the cerebellum are not able to adapt to this condition.

The Basal Ganglia Modify Cortical and Brain Stem Circuits

The basal ganglia are found in all vertebrates from the oldest vertebrates to primates and probably contribute to the selection of different motor patterns. The importance of the basal ganglia to the control of locomotion is clearly demonstrated by the deficits in

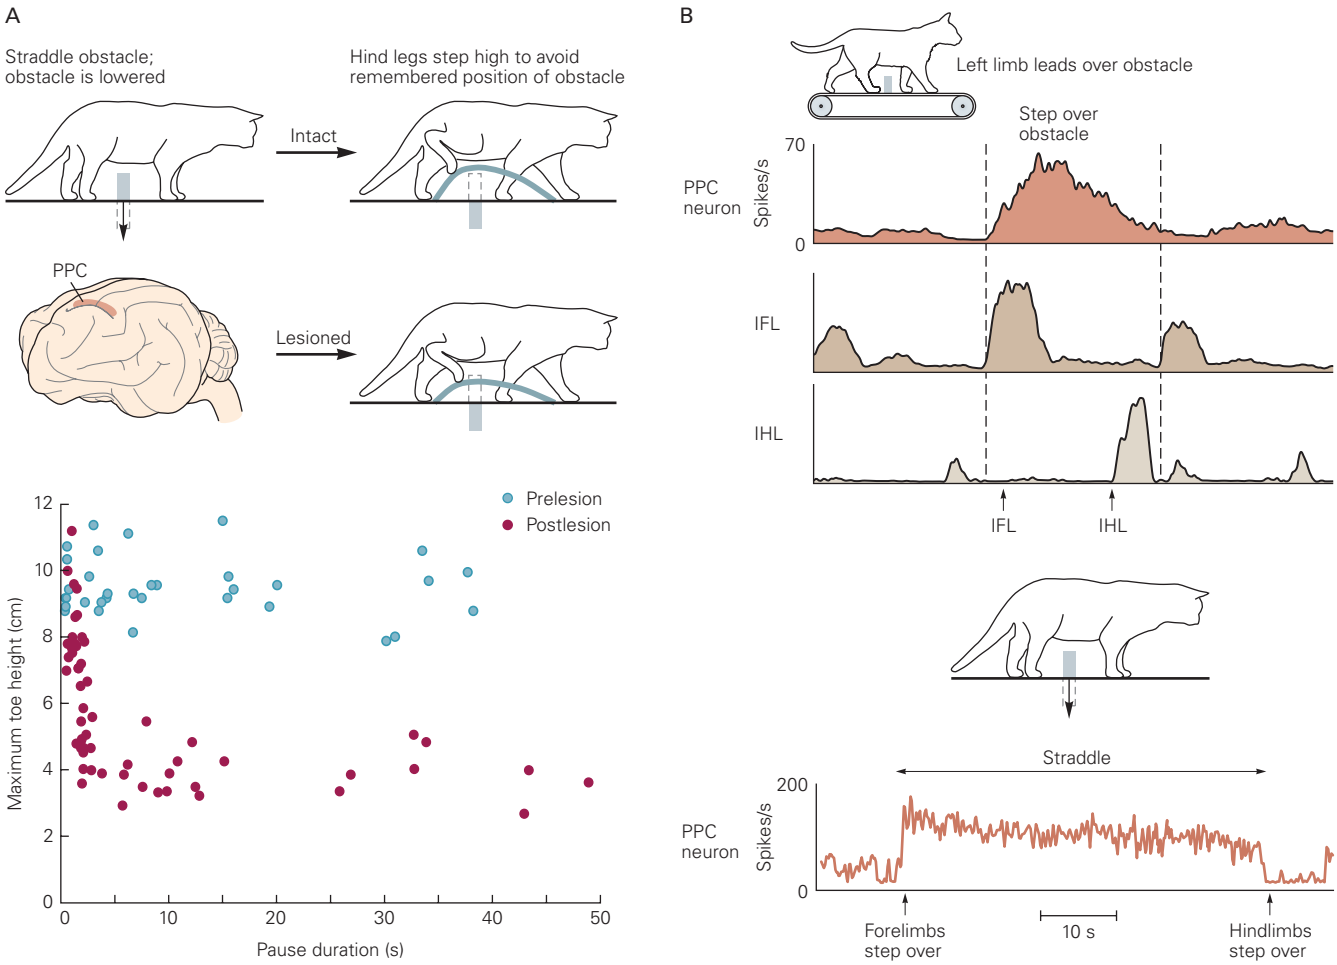

Figure 33–16 The posterior parietal cortex (PPC) is involved in maintaining an estimate of an obstacle in working memory during locomotion.

A. **Upper figure:** Normal animals were trained to walk forward, step over an obstacle, and then pause. While the animal paused, the obstacle was removed. When walking resumed, the hind legs stepped high to avoid the remembered obstacle. This memory lasted for more than 30 seconds. The trajectory of the hindlimbs was scaled appropriately for the height of the obstacle and for the relative position of the hind paws. Bilateral lesions of the PPC led to an impairment in the memory, making it impossible for the animal to pass the obstacle without hitting it. **Lower figure:** Following the lesion, animals stored the memory for only 1 to 2 seconds, and the maximum height of the toe was insufficient to clear the obstacle and was significantly lower than in the prelesion condition. (Adapted from McVea and Pearson 2009.)

B. **Upper figure:** Neurons recorded in an intact animal in the PPC on the right side discharged in the period between the passage of the left forelimb (**IFL**) and hindlimb (**IHL**) over an obstacle (represented by electromyogram activity from representative flexor muscles in each limb). This discharge may be used to coordinate the movement of the hindlimb with that of the forelimb during the visually guided gait modification. **Lower figure:** When the cat steps over an obstacle and pauses, as in part **A**, cells in the PPC show a maintained discharge that could provide the neural representation of the working memory. (Adapted, with permission, from Lajoie et al. 2010.)

locomotion observed in patients with Parkinson disease, which disrupts the normal functioning of the basal ganglia due to degradation of their dopaminergic inputs from the substantia nigra (Chapter 38).

Such patients show a characteristic slow, shuffling gait and, in later stages of the disease, can also show "freezing" of gait. Patients with Parkinson disease also show problems with balance during locomotion and with the anticipatory postural adjustments that occur at the initiation of a gait pattern. These deficits suggest that the basal ganglia contribute to the initiation, regulation, and modification of gait patterns. This regulation is mediated by the two major projections of the basal ganglia to the brain stem pathways and cortical structures.

The basal ganglia influence brain stem activity through their projections to the PPN. The PPN receives

inhibitory inputs from GABAergic inhibitory neurons in the substantia nigra pars reticulata (SNr) as well as from the globus pallidus pars interna (GPi); it also receives glutamatergic input from neurons in the subthalamic nucleus (STN). Decreased inhibitory input and increased glutamatergic input to PPN from the basal ganglia are thought to promote activity in PPN and favor exploratory locomotion. The STN and GPi are major targets of deep brain stimulation for improvement of motor symptoms such as rigidity and reduced mobility in patients with Parkinson disease.

The basal ganglia influence cortical activity by means of its connections via the thalamus to different parts of the frontal cortex, including the supplementary motor regions. These connections allow the basal ganglia to exert a modulatory effect on visually guided locomotion, possibly by selecting the appropriate motor patterns required in different behavioral situations.

Computational Neuroscience Provides Insights Into Locomotor Circuits

While functional studies have revealed much about the organization of the locomotor networks, their overall complexity makes it difficult to capture the integrative function of synaptic and cellular properties of the circuit. Computational network modeling, however, allows one to simulate the circuit activity and to investigate the dynamic interactions between the circuit elements. Computational models can be developed at many levels: to study the ionic basis of neural activity within a given circuit, to study the connectivity between different groups of neurons in a particular circuit, or to better understand the interactions between different structures in the locomotor network. Computational models at each of these levels have been developed to study rhythm and pattern generation in both invertebrates and vertebrates and in the latter, ranging from the lamprey to mammals. As in other domains, approaches combining experimental manipulation and computational modeling are likely to increase in the coming years and have the potential to advance our understanding of the complex systems and interconnections between structures that are required to produce the full locomotor repertoire.

Neuronal Control of Human Locomotion Is Similar to That of Quadrupeds

By necessity, most of our understanding of the neural mechanisms underlying the control of locomotion comes from experiments on quadrupedal animals. Nonetheless, the available evidence suggests that all the major principles concerning the origin and regulation of walking in quadrupeds also pertain to locomotion in humans. Although the issue of whether CPGs exist in humans remains contentious, several observations are compatible with the view that CPGs are important for human locomotion.

For example, observations of some patients with spinal cord injury parallel the findings from studies of spinal cats. Striking cases of patients with nearly complete transection of the spinal cord have shown uncontrollable, spontaneous, rhythmic movements of the legs when the hips were extended. This behavior closely parallels the rhythmic stepping movements in chronic spinal cats. Moreover, tonic electrical stimulation of the spinal cord below the injury can evoke locomotor-like activity, as in other mammals.

Parallels between human and quadrupedal walking have also been found in patients trained after spinal cord injury. Daily training combined with drug treatments restores stepping in spinal cats and improves stepping in patients with chronic spinal injuries. People with severe spinal cord injury who have been exposed to both treadmill-induced stepping and drug treatments similar to those that have been shown to activate the CPG in cats have demonstrated dramatic improvements in the ability to produce locomotion (Box 33–4). These results suggest that CPGs are present in humans and share functional similarities with CPGs found in other vertebrates.

Compelling evidence for the existence of spinal CPGs in humans also comes from studies in human infants who make rhythmic stepping movements immediately after birth if held upright and moved over a horizontal surface. This strongly suggests that some of the basic neuronal circuits for locomotion are innate and present at birth when descending control systems are not well developed. Because stepping can also occur in infants who lack cerebral hemispheres (*anencephaly*), these circuits must be located at or below the brain stem, perhaps entirely within the spinal cord.

During the first year of life, as automatic stepping is transformed into functional walking, these basic circuits are thought to be brought under supraspinal control. In particular, the stepping pattern gradually develops from a more primitive flexion-extension pattern that generates little effective forward movement to the mature pattern of complex movements. It is plausible, based on studies of cats, that this adaptation reflects maturation of descending systems that originate in the motor cortex and brain stem nuclei and are modulated by the cerebellum.

Box 33–4 Rehabilitative Training Improves Walking After Spinal Cord Injury in Humans

According to the World Health Organization, between 250,000 and 500,000 people worldwide incur spinal cords injuries annually. For many, this results in permanent loss of sensation, movement, and autonomic function. The devastating loss of functional abilities, together with the enormous cost of treatment and care, creates an urgent need for effective methods to repair the injured spinal cord and to facilitate functional recovery.

Over the past decades, progress has been made in animal research aimed at preventing secondary damage after injury, repairing the axons of lesioned neurons in the spinal cord, and promoting the regeneration of severed axons through and beyond the site of injury. In many instances, the regeneration of axons has been associated with modest recovery of locomotor function. However, none of the regeneration strategies has reached the point where they can be confidently used in humans with spinal cord injury.

Thus, rehabilitative training is the preferred treatment for people with spinal cord injury. One especially successful technique for enhancing walking in patients with partial damage to the spinal cord is repetitive, weight-supported stepping on a treadmill (Figure 33–17). This technique is based on the observation that spinal cats and rodents can be trained to step with their hind legs on a moving treadmill.

For humans, partial support of the body weight through a harness system is critical to the success of training; presumably, it facilitates the training of spinal cord circuits by reducing the requirements for supraspinal control of posture and balance.

Although the neural basis for the improvement in locomotor function with treadmill training has not been established, it is thought to depend on synaptic plasticity in local spinal circuits as well as successful transmission of at least some command signals from the brain through preserved descending pathways if the spinal cord injury is only partial.

Locomotor training is sometimes combined with other treatments. These include different types of medication designed to reduce spasticity, seen as involuntary muscle contractions, and facilitation of activity in spinal circuits by electrical transcutaneous activation of spinal circuits and/or activation of corticospinal pathways by transcranial magnetic stimulation.

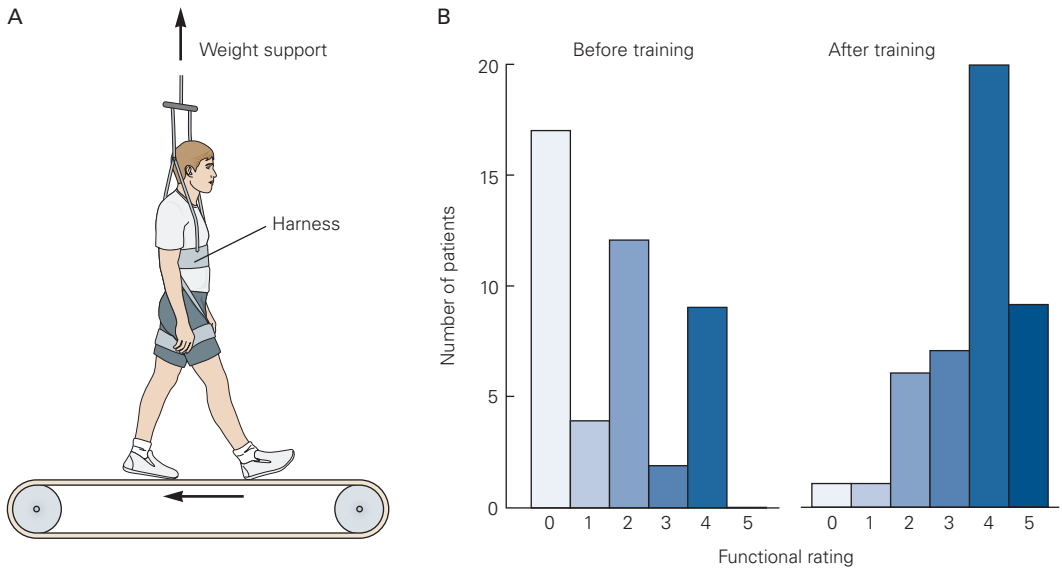

Figure 33–17 Treadmill training improves locomotor function in patients with partial spinal cord injury.

A. The patient is partially supported on a moving treadmill by a harness, and stepping movements are assisted by therapists.

B. Locomotor function improvement in 44 patients with chronic spinal cord injury after daily training lasting from 3 to 20 weeks. The functional rating ranges from 0 (unable to stand or walk) to 5 (walking without devices for more than five steps). (Adapted, with permission, from Wernig et al. 1995. Copyright © 2006, John Wiley and Sons.)

At the cortical level, stroke involving the motor cortex or damage to the corticospinal tracts leads to deficits in locomotion, as in cats. However, the deficits in humans are much stronger than in cats or even nonhuman primates, suggesting that the motor cortex in humans plays a more important role in locomotion than in other mammals. Studies using transcranial magnetic stimulation (TMS) to modulate motor cortical activity also show that the motor cortex contributes importantly to the control of human locomotion. TMS parameters that result in cortical inactivation, for example, produce a decrease in the level of muscle activity during locomotion. In contrast, TMS parameters that activate the motor cortex improve the recovery of locomotion following incomplete spinal cord injury.

Imaging studies, together with high-resolution electroencephalogram recordings, show changes in the activity of several cortical regions, including the motor cortex, premotor cortex, and PPC, during locomotion and particularly during imagined locomotion over obstacles. Imaging studies have also shown increased activity during locomotion in those parts of the midbrain shown to be important for the initiation and speed control of locomotion in animals. Similarly, neurons in the pedunculopontine nucleus can be affected in Parkinson disease, contributing to the severe gait disturbances seen in the late phase of the disease.

Highlights

1. Locomotion is a highly conserved behavior that is essential for the survival of the species. Our understanding of the neuronal mechanisms involved in the generation and control of locomotion came initially from the study of phylogenetically older animals, such as the lamprey and the tadpole. More recently, in mammals, with their more complex nervous systems, the organization of the different neural pathways involved in the generation and regulation of locomotion has also been determined in significant detail.
2. The spinal cord, in isolation from descending and rhythmical peripheral afferent inputs, can generate a complex locomotor pattern that contains elements of the rhythms and patterns observed in intact animals. The circuits responsible for producing this activity are referred to as central pattern generators (CPGs). Activity in spinal circuits can be modified by experience.
3. The basic components of CPGs controlling swimming are excitatory rhythm-generating neurons together with commissural inhibitory neurons responsible for left–right alternation. This organizational principle is also found in CPGs controlling limbed movements with the addition of flexor-extensor pattern-generating circuits and additional commissural neuronal networks. The circuits in the locomotor networks have a modular organization with distinct transmitter and molecular codes for the constituent neurons. Descending command signals act on these circuit elements to produce the diverse aspects of locomotor behavior.
4. Ionic membrane properties in interneurons and motor neurons contribute to rhythm and pattern generation. Cell-specific manipulation of these properties will enable a precise understanding of their relative contributions to locomotor production.
5. Peripheral afferent inputs modulate the function of spinal locomotor circuits. Proprioceptive sensors are used to stabilize phase transitions between stance and swing (and vice versa), whereas input from exteroceptors is used to modify limb activity in response to unexpected perturbations.
6. Circuits that are involved in initiating locomotion, controlling speed of locomotion, and selecting gaits are localized in the midbrain and encompass excitatory neurons in the pedunculopontine and cuneiform nuclei. These excitatory nuclei serve diverse roles in controlling either slow explorative locomotion or the full range of speeds and gaits including fast escape locomotion. Molecular-genetically driven cell-specific approaches allow unparalleled access to the organization of these pathways in the brain stem and how they integrate with spinal locomotor networks.
7. Activity in the three main structures in the brain stem with axons that descend to the spinal cord (the pontomedullary reticular formation, the lateral vestibular nucleus, and the red nucleus) contributes to the control of posture and interlimb coordination. Signals from these structures modify the level of muscle activity in a structure-specific manner.
8. The motor cortex provides precise control of muscle activity patterns to allow animals to make visually guided anticipatory adjustments of their gait. The signal from the motor cortex is integrated into the ongoing rhythm.
9. The posterior parietal cortex (PPC) is part of a network that contributes to the advanced planning

of gait based on visual information. PPC neurons estimate the relative location of objects with respect to the body and retain information in working memory to facilitate coordination of the limbs. The contribution of other cortical and subcortical areas to locomotor planning remains little studied.

10. Inputs from the cerebellum and the basal ganglia are used to correct motor errors and select the appropriate patterns of motor activity. The contribution of the basal ganglia to the control of locomotion is complex and is only now being determined.
11. The available evidence suggests that the neural control mechanisms determined from experiments in animals are also used to control locomotion in humans, including the existence of a CPG. Major advances remain to be made in understanding the mechanisms of spinal and supraspinal influences on human locomotor control.
12. Recent technological advances now give us an unparalleled opportunity to investigate the control mechanisms underlying locomotion. Molecular and genetic advances provide the ability to manipulate behavior at both the cellular and systems level and allow detailed study of the contributions of brain stem and spinal circuits to the initiation and regulation of locomotion. Advances in multineuronal recording techniques in animals, as well as the development of high-resolution recordings of human brain activity, will facilitate our understanding of the contribution of cortical structures to the control of locomotion.

Voluntary Movement: Motor Cortices

In this chapter, we describe how the cerebral cortex uses sensory information from the external world to guide motor actions that allow the individual to interact with the surrounding environment. We begin with a general description of what we mean by the term voluntary movement and some theoretical frameworks for understanding its control, followed by the basic anatomy of the cortical circuits involved in voluntary motor behavior. We then consider how information related to the body, external space, and behavioral goals is combined and processed in parietal cortical regions. This is followed by a discussion of the

role of premotor cortical regions in selecting and planning motor actions. Finally, we examine the role played by the primary motor cortex in motor execution.

Voluntary Movement Is the Physical Manifestation of an Intention to Act

Animals, including humans, have a nervous system not just so that they can sense their world or think about it, but primarily to interact with it to survive and reproduce. Understanding how purposeful actions are achieved is one of the great challenges in neuroscience. We focus here on the cerebral cortical control of voluntary motor behavior, in particular voluntary arm and hand movements in primates.

In contrast to stereotypical fixed-latency reflexive responses that are automatically triggered by incoming sensory stimuli (Chapter 32), voluntary movements are purposeful, intentional, and context-dependent, and are typically accompanied, at least in humans, by a sense of "ownership" of the actions, the sense that the actions have been willfully caused by the individual. Decisions to act are often made without an external trigger stimulus. Moreover, the continuous flux of events and conditions in the world presents changing opportunities for action, and thus voluntary action involves choices between alternatives, including the choice not to act. Finally, the same object or event can evoke different actions at different times, depending on the current context.

Throughout evolution, these features of voluntary behavior have become increasingly prominent in higher primates, especially in humans, indicating that the neural circuits controlling voluntary behavior in primates are adaptive. In particular, evolution has resulted in an increasing degree of dissociation of the physical properties of sensory inputs from their behavioral salience to the individual. Adaptation of the control circuits also enhances the repertoire of voluntary motor actions available to a species by allowing individuals to remember and learn from prior experience, to predict the future outcomes of different action choices, and to adopt new strategies and find new solutions to attain their desired goals. Volitional self-control over how, when, and even whether to act endows primate voluntary behavior with much of its richness and flexibility and prevents behavior from becoming impulsive, compulsive, or even harmful.

Voluntary behavior is the physical manifestation of an individual's intention to act on the environment, usually to achieve a goal immediately or at some point in the future. This may require single nonstereotypical movements or sequences of actions tailored to current conditions and to the longer-term objectives of the individual. The ability to use fingers, hands, and arms independent of locomotion further helps primates, and especially humans, exploit their environment. Most animals must search their environment for food when hungry. In contrast, humans can "forage" by using their hands to cook a meal or simply enter a few numbers on a cellphone to order food for delivery. Because large areas of the cerebral cortex are implicated in various aspects of voluntary motor control, the study of the cortical control of voluntary movement provides important insights into the purposive functional organization of the cerebral cortex as a whole.

Theoretical Frameworks Help Interpret Behavior and the Neural Basis of Voluntary Control

The neural processes by which individuals acquire information about their environment and the relationship of their body to it, decide how to interact with the environment to achieve short- or long-term goals, and organize and execute the voluntary movement(s) that will fulfill their goals are traditionally partitioned into three analytic components: Perceptual mechanisms generate an internal representation of the external world and the individual within it, cognitive processes use this internal model of the world to select a course of action to interact with its environment, and the chosen plan of action is then relayed to the motor systems for implementation. This serial view of the brain's overall functional organization has long dominated neuroscience; this textbook, for example, has separate sections dedicated to perception, cognition, and movement.

The brain must transform a goal into motor commands that realize the goal. For example, taking a sip of coffee requires the brain to convert visual information about the coffee cup and somatic information about the current posture and motion of your arm and hand into a pattern of muscle contractions that moves your hand to the cup, grasps it, and then lifts it to your mouth. Many behavioral and modeling studies suggest that this could be accomplished by a series of transformations of sensorimotor coordinates that convert the retinal image of the cup into motor commands (Figure 34–1A).

Variants of this sensorimotor transformation model have guided the design and interpretation of many studies on the control of voluntary arm movements. Neural recording studies, including many that will be described here, have found possible neural correlates of the motor parameters and sensorimotor transformations presumed to underlie movement

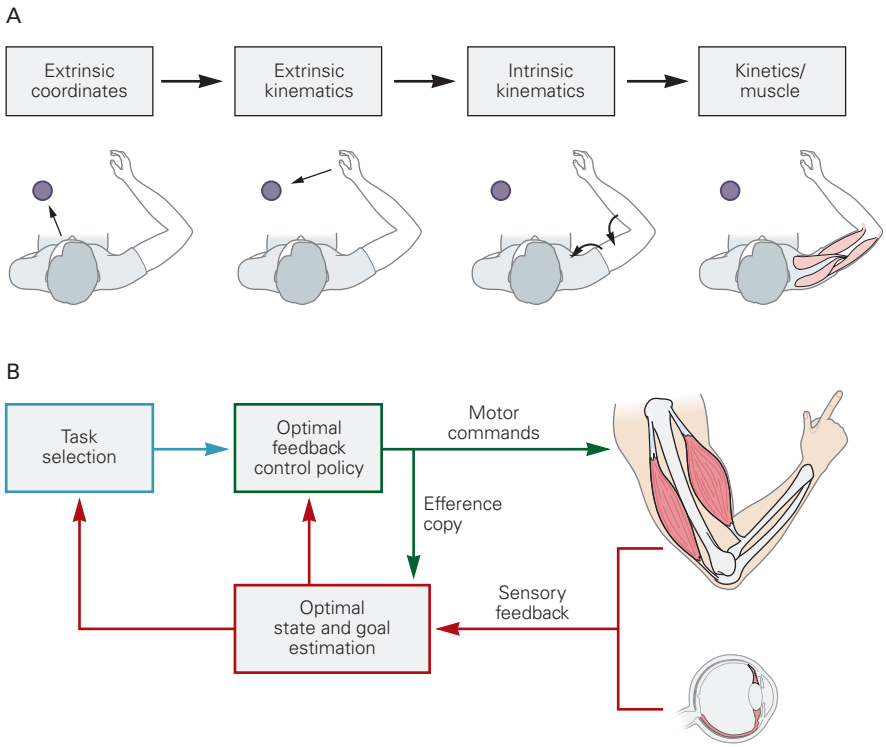

Figure 34–1 Theoretical frameworks for interpreting neural processing during voluntary motor actions.

A. The concept of sensorimotor transformations addresses the basic problem that tasks such as reaching to a visual target require the brain and spinal cord to convert sensory information about the spatial location of the target, initially represented in retinal coordinates, into patterns of muscle activity to move the limb to the target object. It is assumed that this sensorimotor transformation involves the use of intermediary representations—representation of the location of the target object relative to the body, the spatiotemporal trajectory of the hand (extrinsic kinematics), and motion of the joints (intrinsic kinematics) necessary to reach and grasp the object—before generating the patterns of neural activity that specify the causal forces (kinetics) or muscle activity.

B. Optimal feedback control recognizes three key processes for control. Optimal state and goal estimation (**red box**) integrates sensory feedback from various modalities along with an efference copy of motor commands to estimate the present position and motion of the body and objects in the world. Task selection (**blue box**) involves processes that identify behavioral goals based on internal desires and information about the state of the body and the world. Control policy (**green box**) determines the feedback gains, operations, and processes necessary to generate motor commands to control movement.

planning and execution. This conceptual framework is an example of a *representational model* of brain function. Just as the activity of neurons in primary sensory areas appears to encode specific physical properties of stimuli, the sensorimotor transformation model assumes that the activity of neurons in the motor system explicitly encodes or represents specific properties and parameters of the intended movement.

However, the sensorimotor transformation model has important limitations. Among them, the parameters and coordinate systems typically used in such models were imported from physics and engineering, rather than derived from the physiological properties of biological sensors and effectors. Furthermore, the model places all emphasis on strictly serial feedforward computations and relegates feedback circuits primarily to the detection and correction of performance errors after they are committed. The model also requires that every temporal detail of a movement be explicitly calculated before the motor system can generate any motor commands. Another limitation is its rigidity; it assumes that the same sequence of computations controls every movement in every context. Finally, this approach has not addressed how the proposed sensorimotor transformations could be implemented by neurons.

In recent years, theoretical studies of the motor system have been moving away from strictly representational models to more dynamical causal models. This approach begins with the premise that the functional architecture of motor control circuits evolved to generate movements, not to represent their parameters.

These circuit properties were acquired by evolutionary changes in neural circuitry and by experience-dependent adaptive processes during postnatal development that produce the patterns of synaptic connectivity within the neural circuits that are necessary to generate the desired movements. Spinal and supraspinal motor circuits ensure that spinal motor neurons generate the appropriate muscle contraction signals across task conditions without relying on computational formalisms such as coordinate transformations.

One such theoretical framework is optimal feedback control (Figure 34–1B; and see Chapter 30). There are many different forms of optimal control, and each captures important aspects of control. Optimal feedback control, as the name implies, emphasizes the importance of feedback signals for the planning and control of movements. It is optimal in the sense that it emphasizes the importance of the behavioral goal and the current context in determining how best to plan and control movements. This flexibility can explain how human motor performance can be both highly variable and yet successful.

The optimal feedback control framework also divides the control of voluntary movements into three key processes: state estimation, task selection, and control policy (Figure 34–1B). State estimation involves forward internal models that use efference copies of motor commands and external sensory feedback to provide the best estimate of the present state of the body and the environment (Chapter 30). Task selection involves the neural processes by which the brain chooses a behavioral goal in the current context and what motor action(s) might best attain that goal. This selection can be based on the sensory evidence supporting alternative actions and alternate options to attain the goal, and on other factors that influence the optimal response such as motivational state, task urgency, preferences, relative benefits versus risks, the mechanical properties of the body and environment, and even the biomechanical costs of different action choices. Finally, the control policy provides the set of rules and computations that establish how to generate the motor commands to attain the behavioral goal given the present state of the body and the environment. Importantly, the control policy process in optimal feedback control is not a series of pure feedforward computations to calculate every instantaneous detail of a desired movement trajectory and associated muscle activity patterns before movement onset. Instead, it involves context- and time-dependent adjustments to feedback circuit gains that allow the spatiotemporal form of muscle activity to emerge dynamically in real time as part of the control process underlying movement generation.

The sensorimotor transformation and optimal feedback control models are not mutually incompatible hypotheses. Optimal feedback control explains certain features of motor behavior but is largely agnostic as to the neural implementation for control. It assumes that motor circuits are dynamical systems that attain desired goals under varying task constraints. As a result, a given neuron may contribute to sensorimotor control in different task conditions, but its activity may not correspond to a specific movement parameter in a definable coordinate framework. In contrast, sensorimotor transformation models do not fully explain how real-time movement control is implemented by motor circuits, but emphasize the need to convert information from sensory signals to motor commands.

Even if the neural control system is dynamical, the system it controls—the musculoskeletal plant—is a physical object that must obey the universal physical laws of motion. Thus, neural activity should show correlations with those physical parameters and laws that will help to infer how those neurons are contributing to voluntary motor control, even if they are not attempting to encode those terms. Indeed, experimental tasks that dissociate different types of movement-related information have revealed important differences in how neural activity in different cortical motor regions correlates with different movement properties and different aspects of movement planning and execution. Finally, we can impose arbitrary volitional control on how we move. For example, we can choose to make an unobstructed reaching movement efficiently along a straight path to the target or whimsically along a complex curved path even though there is no obstacle to avoid and the movement is energetically costly. The experimental challenge is to reveal how the brain can implement this willful control with neurons and neural circuits.

Many Frontal and Parietal Cortical Regions Are Involved in Voluntary Control

Here we describe the regions of frontal and parietal cortex that convert sensory inputs into motor commands to produce voluntary movement. We then examine the neural circuits involved in the voluntary control of arm and hand movements that are prominent components of the motor repertory of primates. We focus on studies in the rhesus monkey (*Macaca mulatta*), as much of our knowledge of the cortical control of the arm and hand comes from this species and the neural circuity underlying human voluntary control appears to have a similar organization. Many other neural structures, including the prefrontal cortex, the basal ganglia, and

cerebellum, also play critical roles in the global organization of goal-directed voluntary behavior (Chapters 37 and 38).

Several different nomenclatures have been used in partitioning the precentral, postcentral, and parietal cortex, based on regional differences in cytoarchitectonic and myeloarchitectonic details, cortico-cortical connectivity, the distribution of different marker molecules, and regional differences in neural response properties. Here we will use some of the more widely accepted terminology without describing approximate homologies among the various nomenclatures.

Based on the pioneering cytoarchitectonic studies of humans by Brodmann, the different lobes of the monkey's cerebral cortex were divided into smaller regions, including two in precentral cortex (areas 4 and 6), four in the postcentral cortex (areas 1, 2, 3a, and 3b), and at least two in the superior and inferior parietal cortex (areas 5 and 7). While these cytoarchitectonic divisions persist in the literature, subsequent anatomical and functional studies have radically changed the view of how the precentral and parietal cortices are organized (Figure 34–2).

Current maps usually place the *primary motor cortex* (M1), the cortical region most directly involved in motor execution in primates, in Brodmann's area 4. Brodmann's area 6 is now typically divided into five or six functional areas that are principally involved in different aspects of the planning and control of motor actions of different parts of the body. Arm-control regions include the *dorsal premotor cortex* (PMd) and *predorsal premotor cortex* (pre-PMd), in the caudal and rostral parts of the dorsal convexity of lateral area 6, respectively. Hand-control regions include the *ventral premotor cortex* (PMv), found on the ventral convexity of area 6, which has been further divided into two or three smaller subregions. A variety of functions related to motor selection, sequencing, and initiation have been found in medial premotor cortical regions. These include a region on the medial surface of the cortical hemisphere that was originally called the secondary motor cortex by Woolsey and colleagues, who discovered it, but is now called the *supplementary motor area*. This region is in turn split into two regions, a *supplementary motor area proper* (SMA) in the caudal part and a *presupplementary motor area* (pre-SMA) in the rostral part. Outside of Brodmann's area 6, three additional motor areas, the dorsal, ventral, and rostral cingulate motor areas (CMAd, CMAv, and CMAr, respectively), are also involved in motor selection but have not been as well studied as more lateral premotor areas.

The *primary somatosensory cortex* (S-I; including areas 1, 2, 3a, and 3b) is located in the anterior postcentral gyrus. It processes cutaneous and muscle mechanoreceptor signals from the periphery and transmits that information to other parietal and precentral cortical regions (Chapter 19). Like area 6, Brodmann's parietal areas 5 and 7 are now divided into several regions within and adjacent to the intraparietal sulcus (IPS), each of which integrates various types of sensory information about the body or spatial goals for voluntary motor control. These include parietal lobe areas PE and PEc on the rostral or superior bank, and PF, PFG, PG, and OPT on the caudal, inferior bank. Areas inside the IPS include the anterior, lateral, medial, and ventral intraparietal areas (AIP, LIP, MIP, and VIP, respectively) as well as intraparietal area PEip and higher visual area V6A.

These precentral, postcentral, and parietal cortical regions are interconnected by complex patterns of reciprocal, convergent, and divergent projections. The SMA, PMd, and PMv have somatotopically organized reciprocal connections not only with M1 but also with each other. Both the SMA and M1 receive somatotopically organized input from S-I and the dorsorostral parietal cortex, whereas PMd and PMv are reciprocally connected with progressively more caudal, medial, and lateral parts of the parietal cortex. These somatosensory and parietal inputs provide the primary motor and caudal premotor regions with sensory information related to behavioral goals, target objects, and the position and motion of the body that is used to plan and guide motor acts.

In contrast, pre-SMA and pre-PMd project to SMA and PMd but do not project to M1 and are only weakly connected with the parietal lobe. They instead have reciprocal connections with prefrontal cortex and so may impose more arbitrary context-dependent control over voluntary behavior. Prefrontal cortex is also connected with other premotor cortical regions.

The control of hand and arm motor actions is implemented by partially segregated parallel circuits distributed across several parietal and precentral motor areas. Hand motor function is generally supported by frontoparietal circuits that are located more laterally, notably AIP and PMv. In contrast, proximal arm motor function is supported by circuits that are more medial, notably parietal areas PE and MIP and precentral areas PMd, SMA, and pre-SMA.

Descending Motor Commands Are Principally Transmitted by the Corticospinal Tract

Older textbooks often referred to the primary motor cortex (M1) as the "final common path." Other

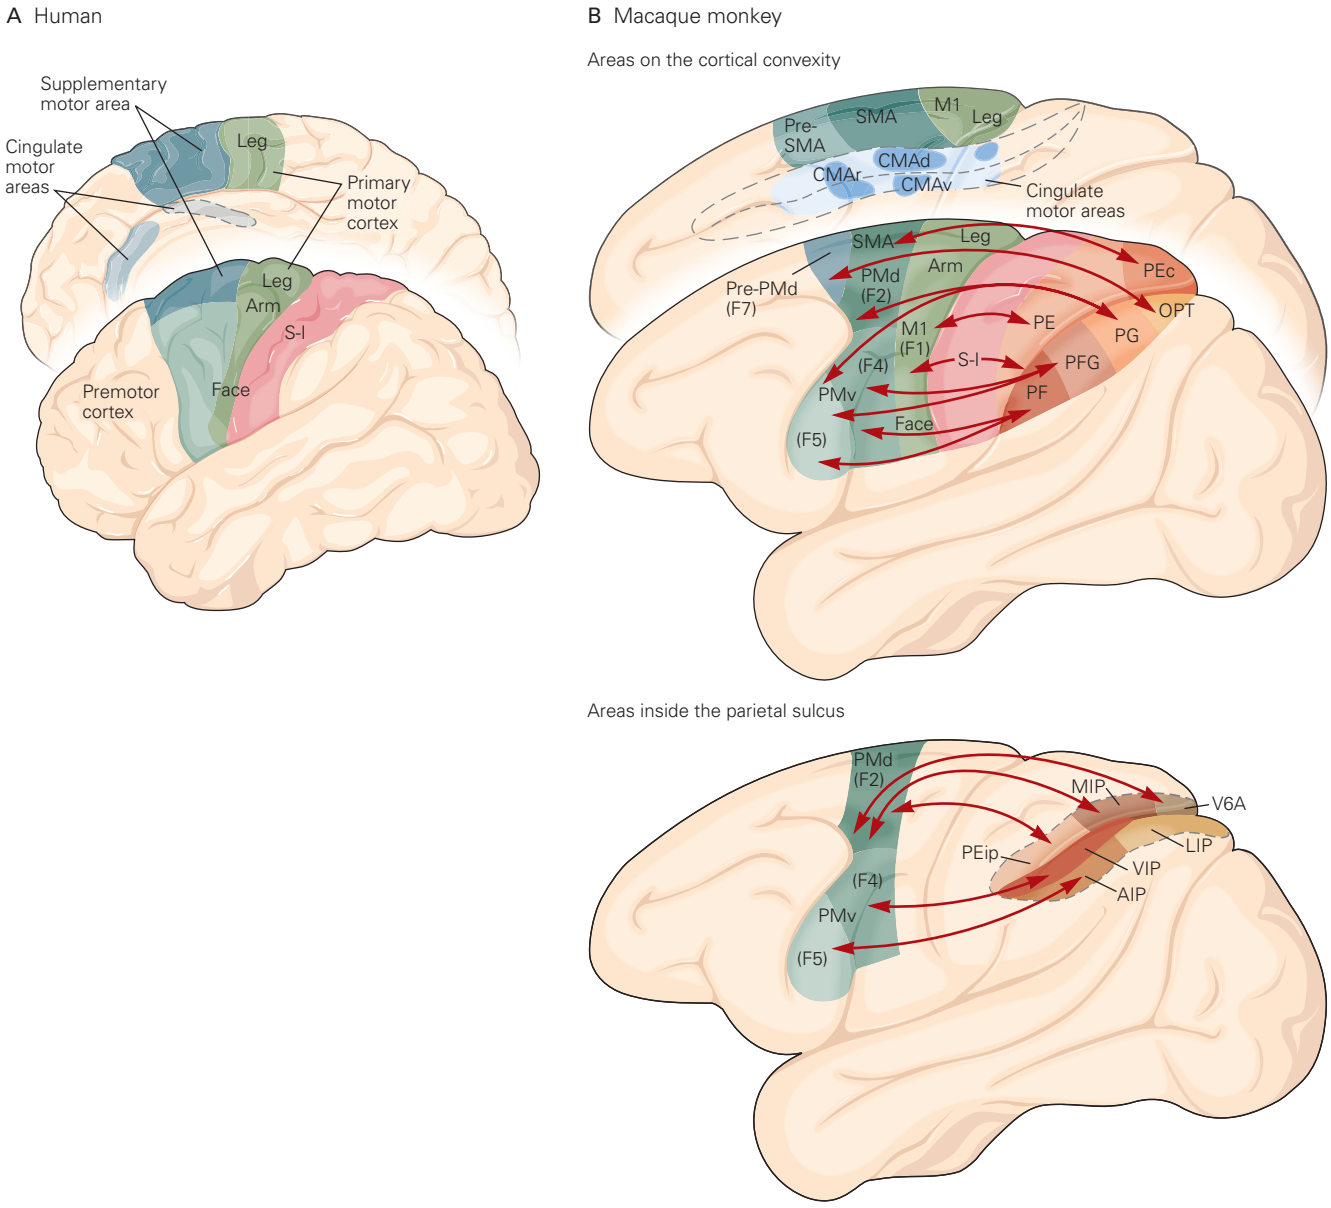

Figure 34–2 **Parietal and frontal motor areas that support voluntary control.** For illustration purposes, the intraparietal sulcus is opened in the bottom panel. The parietal areas are designated in Constantin von Economo's terminology by the letter **P** (parietal), followed by letters instead of numbers to indicate the cytoarchitectonically different areas. Areas PF and PFG roughly correspond to Brodmann's area 7b, and areas PG and OPT to Brodmann's area 7a. Areas inside the intraparietal sulcus include the anterior, lateral, medial, and ventral intraparietal areas (**AIP**, **LIP**, **MIP**, **VIP**, respectively), as well as the PE intraparietal area (**PEip**) and visual area 6A (**V6A**). **Arrows** show the patterns of the principal reciprocal connections between functionally related parietal and frontal motor areas. (Abbreviations: **CMAr**, rostral cingulate motor area; **CMAv**, ventral cingulate motor area; **CMd**, dorsal cingulate motor area; **F**, frontal; **M1**, primary motor cortex; **OPT**, occipito-parieto-temporal; **P**, parietal; **PE**, **PF**, and **PFG** are parietal areas according to the nomenclature of von Economo; **PMd**, dorsal premotor cortex; **PMv**, ventral premotor cortex; **Pre-PMd**, predorsal premotor cortex; **S-I**, primary somatosensory cortex; **SMA**, supplemental motor area.)

cortical motor areas were thought to influence voluntary movements via their projections to M1, which then formulated the descending motor command that was transmitted to the spinal cord. This is not correct.

Several cortical motor regions outside of M1 project to subcortical areas of the brain as well as to the spinal cord in parallel with the descending projections from M1. The key descending pathway for

voluntary control is the *pyramidal tract*, which originates in cortical layer V in a number of precentral and parietal areas. The pyramidal tract contains axons that terminate in brain stem motor structures (the *corticobulbar tract*) and axons that project down to the spinal cord (*corticospinal tract*). Precentral areas include not only M1 but also SMA, PMd, PMv, and the cingulate motor areas (Figure 34–3). Descending fibers from S-I and parietal areas, including PE and PFG, also travel in the pyramidal tract. The pre-SMA and pre-PMd do not send axons directly to the spinal cord; instead, their descending outputs reach the spinal cord indirectly through projections to other subcortical structures.

Most corticospinal tract axons originating in one hemisphere cross to the other side of the midline (decussate) at the pyramid in the caudal medulla, and from there project to the spinal cord itself, forming the lateral corticospinal tract. A small portion does not decussate and forms the ventral corticospinal tract. Many corticospinal axons in primates, and virtually all corticospinal axons in other mammals, terminate only on spinal interneurons and exert their influence on voluntary movement indirectly through spinal interneuronal and reflex pathways. In monkeys, all corticospinal axons from premotor cortical areas and many from M1 terminate on interneurons in the spinal intermediate zone, whereas postcentral and parietal areas target interneurons in the dorsal horn. The terminal endings of a sizeable portion of the corticospinal axons arising from M1 in primates, but not other mammals, arborize at their targets and synapse directly on spinal alpha motor neurons that in turn innervate muscles; these M1 neurons with direct monosynaptic projections to spinal motor neurons are called *corticomotoneuronal cells*.

Any voluntary arm movement can have destabilizing effects on the rest of the body due to mechanical interactions between body segments. Thus, control of voluntary arm movements requires coordination with neural circuits responsible for the control of posture and balance. This is mediated by descending projections from cortical motor areas to the reticular formation, which in turn project to the spinal cord via the reticulospinal tract (Chapters 33 and 36).

Imposing a Delay Period Before the Onset of Movement Isolates the Neural Activity Associated With Planning From That Associated With Executing the Action

Voluntary movement requires the intervention of a number of neural processes between the arrival of salient sensory inputs and the initiation of an appropriate motor response. With the development in the 1960s of single-cell recording in the cerebral cortex of awake animals, tasks that experimentally manipulate different attributes of movements have been used to study every cortical area involved in the control of arm and hand movements to try to identify neural correlates of the presumed control processes in each area.

In "reaction-time" tasks, animals make a prespecified response when they detect a particular stimulus, such as reaching to a target when it appears (Figure 34–4A). The stimulus informs the animal both what movement to make and when to make it. However, reaction times in such tasks are typically short, often less than 300 ms, and most or all putative planning stages leading up to the initiation of the movement are accomplished within that brief time. This makes it very difficult to discern what kinds of information are represented in the activity of the neurons at each given moment and thus to what processes they are contributing (Figure 34–4B).

However, a critical feature of voluntary behavior is that movement initiation is not obligatory the instant an intention to act is formed. This volitional control over the timing of movement has been exploited by so-called "instructed-delay" motor tasks (Figure 34–4A), in which an instructional cue informs the animal about specific aspects of an impending movement such as the location of a target, but the animal must withhold the response until a delayed stimulus signals when to make the movement. This protocol allows researchers to dissociate in time the neural processes associated with the early stages of planning the intended act from those that are directly coupled in real time to the initiation and control of the movement.

As expected, neurons in all the movement-related cortical areas discharge prior to and during movement execution in reaction-time tasks (Figure 34–4B), and their activity correlates systematically with different properties of movements, such as their direction, velocity, spatial trajectory, and causal forces and muscle activity. Critically, however, many neurons in the same areas also signal information about an intended motor act during an instructed-delay period long before its initiation (Figure 34–4B). Thus, even though planning and execution are distinct serial stages in voluntary motor control, they are not implemented by distinct neural populations in different cortical areas. Moreover, even a well-trained monkey will occasionally make the wrong movement in response to an instructional cue. In those trials, the activity during the delay period generally predicts the erroneous motor response that the monkey will eventually make. This is compelling evidence that the activity is a neural correlate of the monkey's motor intentions, not a passive sensory response to the instructional cues.

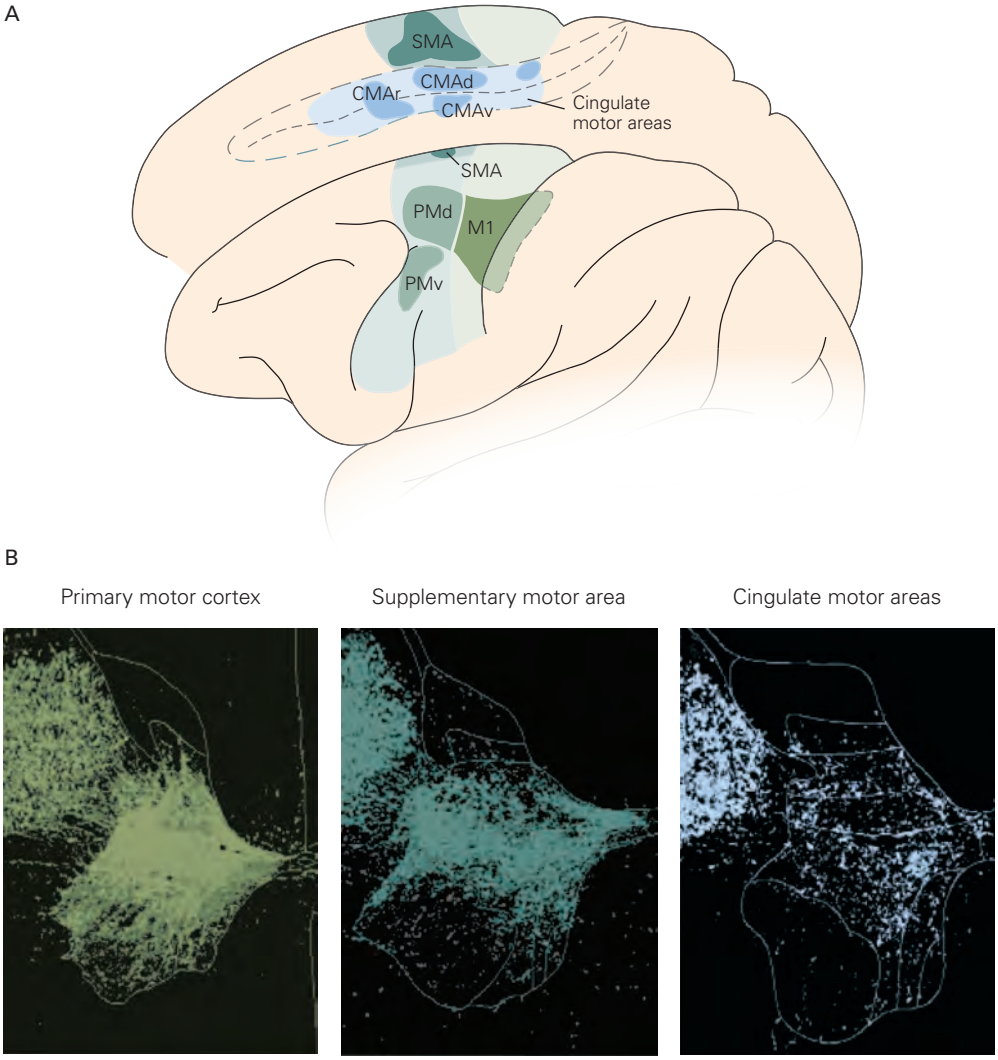

Figure 34–3 Cortical origins of the corticospinal tract. (Reproduced, with permission, from Dum and Strick 2002. Copyright © 2002 Elsevier Science Inc.)

A. Corticospinal neurons that modulate muscle activity in the contralateral arm and hand originate in the parts of the primary motor cortex (**M1**) motor map and many subdivisions of the premotor cortex (**PMd**, **PMv**, **SMA**) that are related to arm and hand movements (indicated by the darker zones). The axons from these areas project into the spinal cord cervical enlargement (see part **B**). Corticospinal fibers projecting to the leg, trunk, and other somatotopic parts of the brain stem and spinal motor system originate in the other parts of the motor and premotor cortex, indicated by the lighter zones. (Abbreviations: **CMAd**, dorsal cingulate motor area; **CMAr**, rostral cingulate motor area; **CMAv**, ventral cingulate motor area; **M1**, primary motor cortex; **PMd**, dorsal premotor cortex; **PMv**, ventral premotor cortex; **SMA**, supplementary motor area.)

B. Transverse sections of the spinal cord at the level of the cervical enlargement in monkeys after injection of the anterograde tracer horseradish peroxidase into different arm-related cortical motor regions to label the distribution of corticospinal axons arising from each cortical region. The corticospinal axons from the primary motor cortex (*left*), supplementary motor area (*middle*), and cingulate motor areas (*right*) all terminate on interneuronal networks in the intermediate laminae (V–VIII) of the spinal cord. Only the primary motor cortex contains corticospinal neurons (corticomotoneuronal cells) whose axons terminate directly on spinal motor neurons in the most ventral and lateral part of the spinal ventral horn (Rexed's lamina IX). Rexed's laminae I to IX of the dorsal and ventral horns are shown in faint outline in each section. The dense cluster of labeled axons adjacent to the dorsal horn (*upper left*) in each section are corticospinal axons descending in the dorsolateral funiculus, before entering the spinal intermediate and ventral laminae.

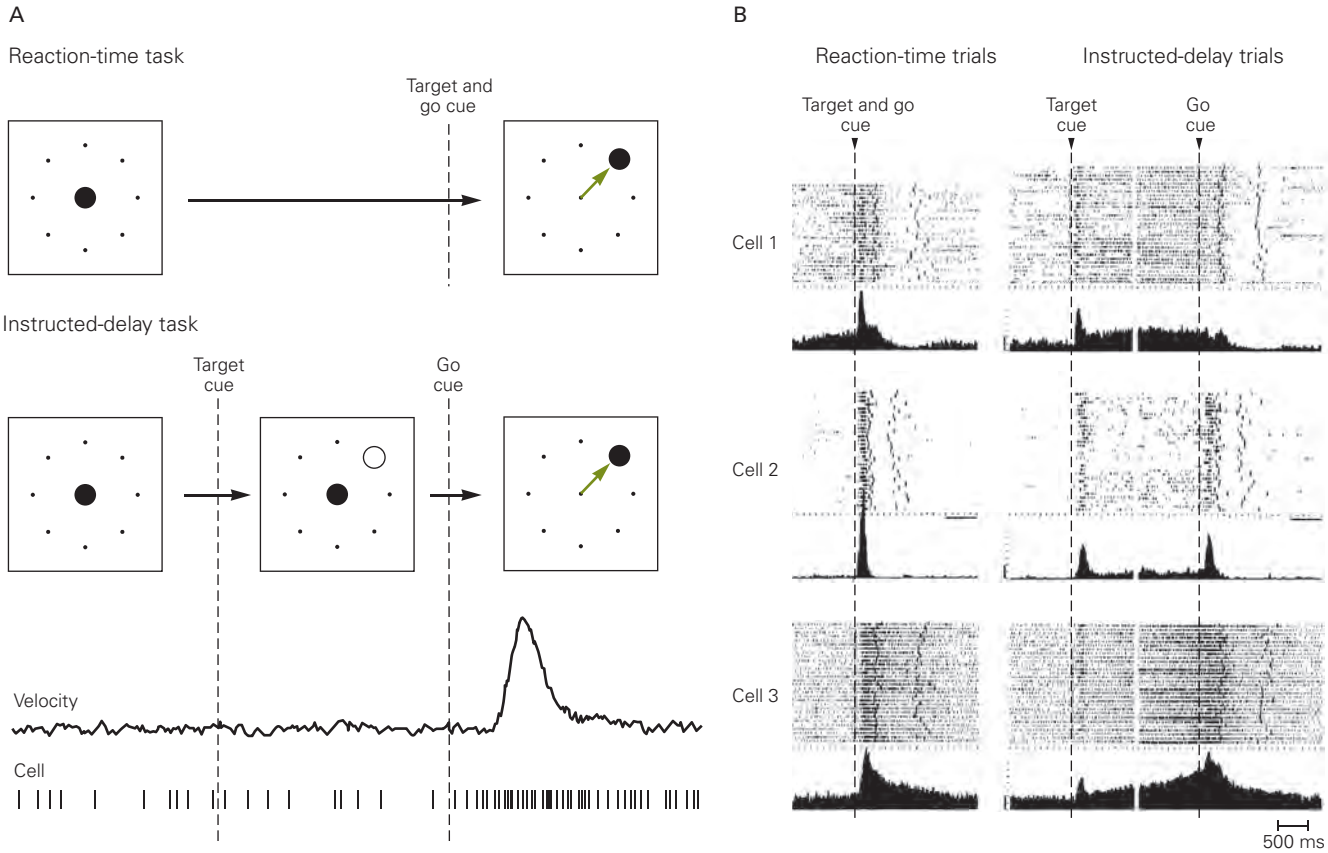

Figure 34–4 Neural processes related to movement planning and movement execution can be dissociated in time. (Reproduced, with permission, from Crammond and Kalaska 2000.)

A. In a *reaction-time task*, a sensory cue instructs the subject both where to move (target cue) and when to move (go cue). All neural operations required to plan and initiate the execution of the movement are performed in the brief time between the appearance of the cue and the onset of movement. In an *instructed-delay task*, an initial cue tells the subject where to move, and only later is the go cue given. The knowledge provided by the first cue permits the subject to plan the upcoming movement. Any changes in activity that occur after the first cue but before the second are presumed to be neural correlates of the planning stage.

B. Movement planning and execution are not completely segregated at the level of single neurons or neural populations in a given cortical area. Raster plots and cumulative histograms show the responses of three premotor cortex neurons to movements in each cell's preferred direction during reaction-time trials and instructed-delay trials. In the raster plots, each row represents activity in a single trial. The thin tics in each raster row represent action potentials, and the two thicker tics show the onset and end of movement. In reaction-time trials, the monkey does not know in which direction to move until the target appears. In contrast, in instructed-delay trials, an initial cue informs the monkey where the target lies well in advance of the appearance of a second signal to initiate the movement. During the delay period, activity in many premotor cells shows directionally tuned changes that signal the direction of the impending delayed movement. The activity in cell 1 appears to be strictly related to the planning phase of the task, for there is no execution-related activity after the go signal in the instructed-delay task. The other two cells show different degrees of activity related to both planning and execution.

Parietal Cortex Provides Information About the World and the Body for State Estimation to Plan and Execute Motor Actions

Sensory information is essential for selecting appropriate and effective actions. Before drinking from a cup, the brain uses visual input to identify which object is the cup, where it is located relative to the body, and its physical properties such as size, shape, and handle orientation. In addition, information about the current posture and motion of the arm and hand is provided by integrating proprioceptive signals from the limb with efference copies of motor commands (Chapter 30). Finally, cutaneous signals are critical when interacting manually with objects, such as grasping and lifting the cup.

Several lines of evidence implicate the parietal cortex as a key brain region in sensory processing for motor action. The parietal lobe, especially PE, PEip, and MIP,

receives strong somatic sensory inputs about body posture and movement from S-I. Several parietal regions along and within the IPS are major components of the dorsal visual pathway, which processes visuospatial information about objects that guides arm and hand movements while reaching to, grasping, and manipulating them. The parietal lobe is also reciprocally interconnected with precentral cortical motor areas to provide the precentral cortex with signals for the sensory guidance of movement and to receive efference copies of motor commands from those same precentral areas. Finally, human subjects with lesions of the posterior parietal cortex often demonstrate specific impairments in using sensory information to guide motor action (Box 34–1).

The Parietal Cortex Links Sensory Information to Motor Actions

We experience the space that surrounds us as a single unified environment within which objects have specific locations relative to each other and to ourselves. Classical neurology suggested that the parietal lobe constructed a unified multimodal neural representation of the world by integration of inputs from different sensory modalities. This single map of space was assumed to provide all the information necessary both for spatial perception and for the sensory guidance of movement, and so was shared by the different motor circuits that controlled different parts of the body, such as the eyes, arm, and hand.

However, the idea that the parietal cortex contains a single topographically organized representation of space is incorrect. Instead, the posterior parietal cortex contains several distinct functional areas that work in parallel and receive different combinations of sensory and motor inputs related to the guidance of movement of different effectors, such as the eyes, arm, and hand. Neurons in these areas are often multimodal, with both visual and somatic sensory receptive fields, and also discharge preferentially prior to and during movements of a specific effector. Each functional area is connected to frontal motor regions involved in control of the same effectors. Finally, each region is not topographically organized in the familiar sense of a faithful point-to-point representation of surrounding space, but rather comprises a complex mixture of neurons with different sensory inputs that may contribute to the multisensory integration required to guide motor actions with the environment.

Body Position and Motion Are Represented in Several Areas of Posterior Parietal Cortex

The S-I and adjacent superior parietal cortex regions PE, MIP, and PEip are a major source of proprioceptive and tactile sensory information about the position and motion of body parts. Neurons in S-I areas 1 and 2

Box 34–1 Lesion Studies of Posterior Parietal Cortex Lead to Deficits in the Use of Sensory Information to Guide Action

Naturally occurring or experimentally induced lesions have long been used to infer the roles of different neural structures. However, the effects of lesions must always be interpreted with caution. It is often incorrect to conclude that the function perturbed by an insult to a part of the motor system resides uniquely in the damaged structure or that the injured neurons explicitly perform that function. Furthermore, the adverse effects of lesions can be masked or altered by compensatory mechanisms in remaining, intact structures. Nevertheless, lesion experiments have been fundamental in differentiating the functional roles of brain regions.

Behavioral studies by Goodale, Milner, Rossetti, and others on patients with parietal cortical damage have led to the conclusion that a primary function of the parietal lobe is to extract sensory information about the external world and one's own body for the planning and guidance of movements. Such studies have shown that patients with lesions of certain parts of the parietal lobe suffer specific deficits in the ability to direct their arm and hand accurately to the spatial location of objects and to shape the orientation and grip aperture of the hand prior to grasping it.

They have also shown a particularly severe deficit in the ability to make rapid adjustments to their ongoing reach and grasping actions in response to unexpected changes in the location or orientation of the target object. This visual guidance of action is provided by visual signals that are routed through the dorsal visual stream and may operate in parallel with and independently of perceptual processes evoked by the visual inputs that are routed simultaneously through the ventral visual stream in the temporal lobe. For instance, whereas our visual perception of the size and orientation of objects can be deceived by certain perceptual illusions, the motor system often behaves as if it is not fooled and makes accurate movements.

typically respond to tactile input from a limited part of the contralateral body or to movements of one or a few adjacent joints in specific directions.

In contrast, many PE and MIP neurons discharge during passive and active movements of multiple joints. Some cells also respond during combined movements of multiple body parts, including bilateral movements of both arms. Many PE and MIP neurons also have large tactile receptive fields whose responses are modulated by context during limb movement or posture. For instance, a neuron with a tactile receptive field that covers the entire glabrous (palmar) surface of the hand may only respond to physical contact with an object when the hand is close to the body and not when it touches the object with the arm fully extended.

These findings indicate that while area 1 and 2 neurons encode the positions and movements of specific body parts, superior parietal neurons integrate information on the positions of individual joints as well as the positions of limb segments with respect to the body. This integration creates a neural "body schema" that provides information on where the arm is located with respect to the body and how different arm segments are positioned and moving with respect to one another. This body schema is critical for selecting how to attain behavioral goals and for ongoing control of movement.

For instance, a key requirement for efficient reaching is knowledge of where the arm is before and during the reach. Monkeys with experimental lesions in Brodmann's area 2 and the adjacent superior parietal lobule (area 5 or PE) show deficits in reaching to and manipulating objects under proprioceptive and tactile guidance without vision. Human patients with similar lesions show the same deficit, without the spatial neglect that is a common consequence of more lateral lesions in the inferior parietal lobe.

Spatial Goals Are Represented in Several Areas of Posterior Parietal Cortex

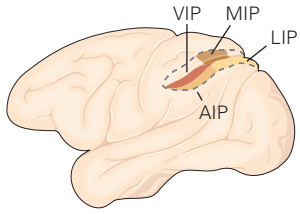
Functional areas within the IPS are strongly implicated in the processing of spatial, especially visual, information relevant to action. Each of these areas has unique ways of representing objects and spatial goals relative to the body and contributes to controlling motor actions of different parts of the body. For instance, many neurons in the lateral intraparietal area (LIP) receive visual input from extrastriate cortical areas. Their receptive fields are fixed in retinal coordinates and shift to new spatial locations whenever the monkey changes its direction of gaze. Neural responses also often increase when the animal attends to a stimulus within the receptive field even without looking at it, and they often discharge prior to a saccade that is directed toward a visual stimulus in their receptive field (Figure 34–5A; and see Chapter 35).

Several parietal regions are preferentially implicated in the control of arm and hand movements. For instance, the most medial regions of the superior parietal cortex, areas V6A and PEc, receive input from extrastriate visual areas V2 and V3. Many V6A and PEc neurons have visual receptive fields in retinal coordinates, but their activity is also frequently modulated by the direction of gaze, the current arm posture, and the direction of reaching movements.

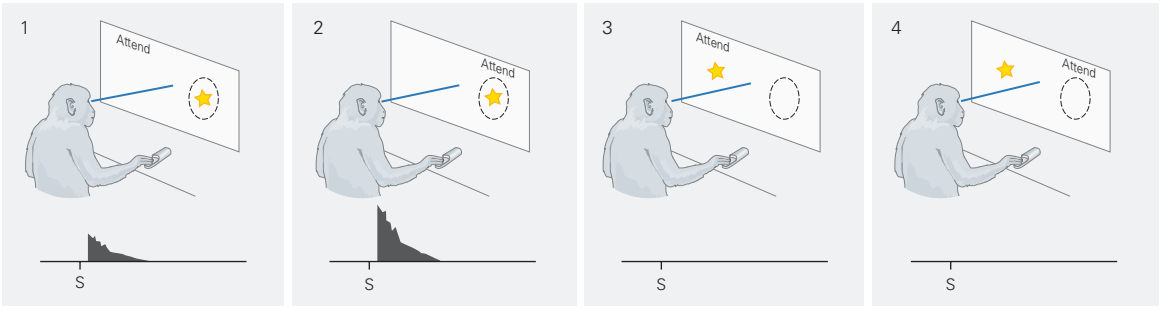
The ventral intraparietal area (VIP) in the fundus of the IPS receives inputs from two components of the dorsal visual stream, the medial temporal cortex and medial superior temporal cortex, which are involved in the analysis of optic flow and visual motion. Many VIP neurons respond to visual stimuli and somatosensory stimuli with receptive fields on the face or head and, in some cases, on the arm or trunk. Neural activity is in head-centered coordinates, as somatosensory and visual information remains in register even if the eyes move to fixate different spatial locations (Figure 34–5B). Some VIP neurons respond to both visual and tactile stimuli moving in the same direction, whereas others are strongly activated by visual stimuli that move toward their tactile receptive field but only if the path of motion will eventually intersect the tactile receptive field. These neurons may allow the monkeys to link the location and motion of objects in their immediate peripersonal space with different parts of their body.

Another area of parietal cortex related to reaching is the parietal reach region (PRR). The PRR likely corresponds to the medial intraparietal cortex (MIP) and adjacent arm-control parts of the superior and inferior parietal cortex. The activity of many PRR neurons varies with the location of reach targets relative to the hand. However, this signal is not fixed to the current location of the hand or target but rather on the current direction of gaze (Figure 34–5C). Each time the monkey looks in a different direction, the reach-related activity of PRR neurons changes, even if the location of the target and hand and the required reach trajectory do not change. In contrast, the reach-related activity of many neurons in areas PE and PEip is less related to gaze and more strongly related to the current hand position and arm posture. PE and PEip neurons thus provide a more stable signal about the location of the reach target relative to the current position of the hand compared to PRR.

Finally, neurons in the anterior intraparietal area (AIP) are primarily implicated in object grasping and manipulation by movements of the hand. Many AIP neurons are preferentially active while reaching for



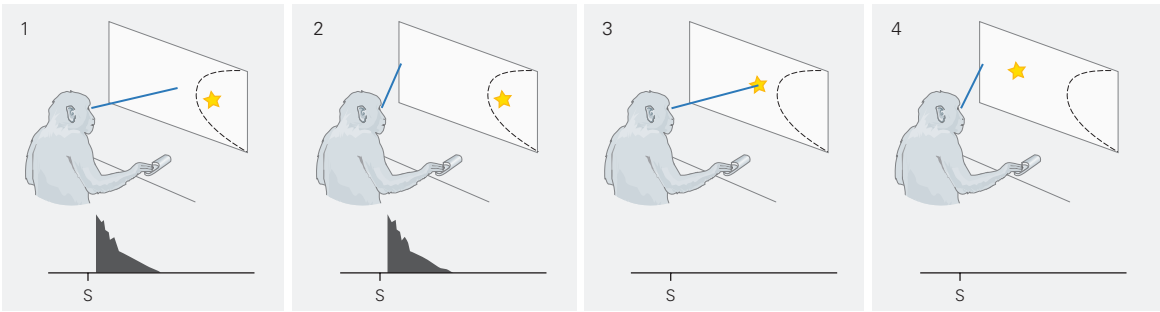
A Lateral intraparietal area (LIP)



Receptive field characteristics

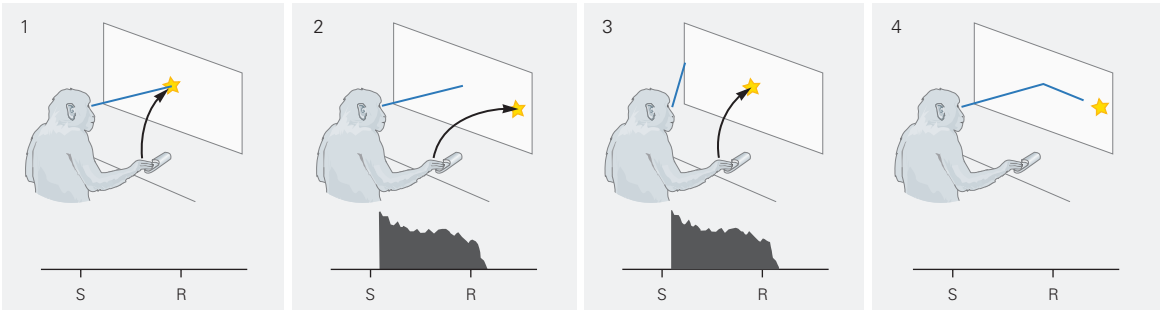
Retina-centered, attention sensitive

B Ventral intraparietal area (VIP)



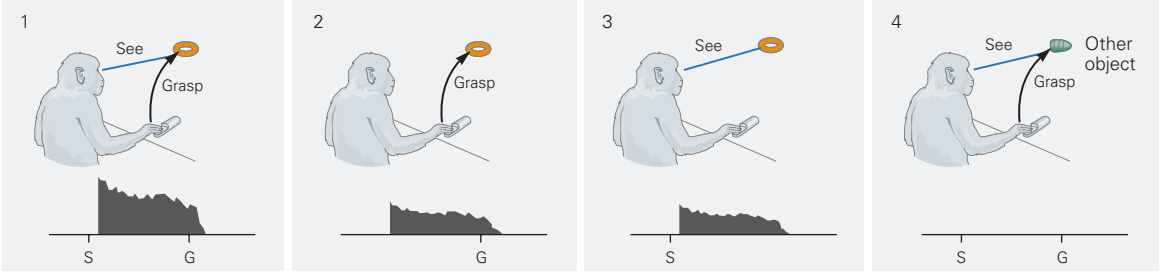
Head-centered

C Medial intraparietal area (MIP)



Retina-centered direction of reach; preparation to reach

D Anterior intraparietal area (AIP)



Retina-centered, object-specific viewing, grasping

and grasping objects of particular shapes, sizes, and spatial orientations, and often even while viewing those objects before grasping them (Figure 34–5D). There is a broad range of neural response properties, from neurons that respond almost exclusively to visual input about the objects but not to the grasping actions to neurons that discharge only during the hand movements themselves even in the dark. This suggests that the AIP contains neural circuits that begin to transform visual information about the physical properties of an object that are relevant to how it could be handled—what James Gibson has called the object's *affordances*—into appropriate hand actions (Chapter 56).

A fascinating discovery about the parietal cortex is that the receptive fields of neurons can be altered by individual experience, such as tool use. Monkeys were trained to retrieve food pellets that were out of normal reach of the arm and hand by using a rake-shaped tool. Many VIP neurons normally respond to visual objects when they are either located near the current position of the hand or anywhere within reach with the arm. After training, their visual receptive fields transiently expand to incorporate the tool when the monkey grasps it, as if the distal end of the tool had become a functional extension of the monkey's own hand and arm (Figure 34–6).

Internally Generated Feedback May Influence Parietal Cortex Activity

The delays involved in the transmission of visual and somatic feedback about arm movements from the periphery to cortical circuits can lead to oscillations or even instabilities in real-time sensorimotor control. One theoretical solution to this problem is to use a forward internal model to make predictive estimates of body motion based on internal efference copies of outgoing motor commands as well as from slower peripheral feedback signals (Chapter 30).

Several lines of evidence suggest that parietal cortex circuits, along with the cerebellum (Chapter 37), may implement a similar solution. Many reach-related neurons in PE, MIP, and PRR are active not only in response to passive sensory inputs but also before the onset of movement and during the instructed-delay period of delayed-reaching tasks. These responses suggest that these neurons process centrally generated signals about motor intentions prior to movement onset. This premovement activity is often interpreted as evidence that the parietal cortex generates feedforward signals that contribute to the early planning of movements. However, an alternate interpretation is that the premovement activity is driven by an efference copy of the motor command for the intended movement that is transmitted into the parietal cortex via its reciprocal connections with precentral motor areas. This combination of peripheral sensory inputs and central efference copies could permit some parietal reach-related circuits to compute a continuously updated estimate of the current state of the arm and its position relative to the behavioral goal. This estimate could be used to make rapid corrections for errors in ongoing arm movements.

Whether the parietal circuits are primarily involved in the formation of a subject's motor intentions or in

Figure 34–5 (Opposite) Neurons in the parietal cortex of the monkey are selective for the location of objects in the visual field relative to particular parts of the body. Each histogram represents the firing rate of a representative neuron as a function of time following presentation of a stimulus. In each diagram, the line emanating from the eyes indicates where the monkey is looking.

A. Neurons in the lateral intraparietal area have *retina-centered* receptive fields. The strength of the visual response depends on whether the monkey is paying attention to the stimulus (**S**). The neuron fires when a light is flashed inside its receptive field (**dotted circle**) (**1**). The response is more robust if the monkey is instructed to attend to the location of the stimulus (**2**). The neuron does not fire if the stimulus is presented outside the receptive field, regardless of where attention is directed (**3**, **4**).

B. In the ventral intraparietal area, some neurons have *head-centered* receptive fields. This is determined by keeping the head in a fixed position while the monkey is instructed to shift its gaze to various locations. This neuron fires when a light appears to the right of the midline of the head (**1**, **2**). It does not fire when the light appears at another location relative to the head, such as the midline or to the left. (**3**, **4**). The critical contrast is between situations 1 and 4. The retinal location of the light is the same in both (slightly to the right of the fixation point), yet the neuron fires in 1, when the stimulus is to the right of the head, but not in 4, when the stimulus is to the left of the head.

C. In the medial intraparietal area, neurons are selective for the retina-centered direction of the reach (**R**) and fire when the monkey is preparing to reach for a visual target. This neuron fires when the monkey reaches for a target to the right of where he is looking (**2**, **3**). It does not fire when he reaches for a target at which he is looking (**1**) or when he moves only his eyes to the target at the right (**4**). The physical direction of the reach is not a factor in the neuron's firing: It is the same in 1 and 3, and yet, the neuron fires only in 3.

D. In the anterior intraparietal area, neurons are selective for objects of particular shapes and fire when the monkey is looking at or preparing to grasp (**G**) an object. This neuron fires when the monkey is viewing a ring (**3**) or making a memory-guided reach to it in the dark (**2**). It fires especially strongly when the monkey is grasping the ring under visual guidance (**1**). It does not fire during viewing or grasping of other objects (**4**).

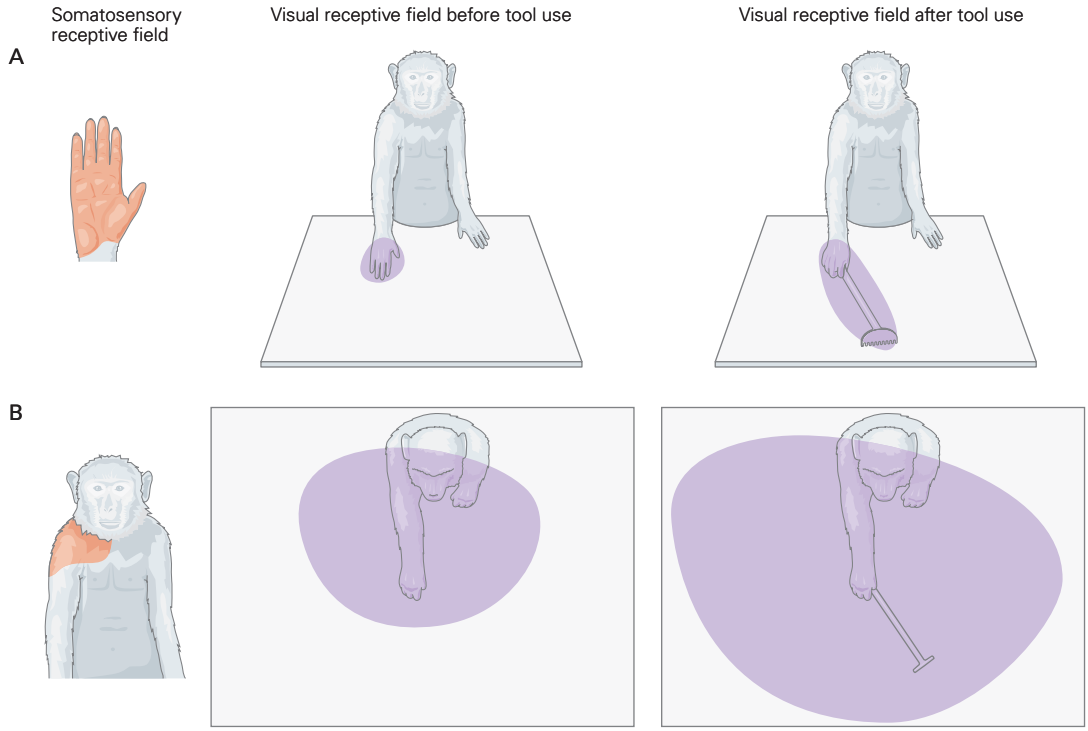


Figure 34–6 Some neurons in the parietal cortex of the monkey have receptive fields that dynamically expand once a tool is grasped. (Adapted from Maravita and Iriki, 2004. Copyright © 2003 Published by Elsevier Ltd.)

A. The **orange** area on the hand (*left*) indicates the somatosensory receptive field for a neuron. The **purple** area (*middle*) indicates the neuron's visual receptive field (vRF) region around the hand. The vRF is anchored to the hand and changes spatial location whenever the monkey moves its arm. The vRF expands when the monkey grasps a rake after it has learned how to use the rake to reach for objects in the workspace (*right*).

B. A single neuron that has a shoulder-centered bimodal somatosensory (**orange**) and visual (**purple**) receptive field is illustrated. The vRF for this neuron (*middle*) is larger than the one shown in part **A**, possibly reflecting the potential workspace related to whole-arm function. The vRF also expands to incorporate the extended workspace permitted by use of a rake (*right*).

state estimation will depend on the origin of its premovement activity. If it is mainly generated within the parietal cortex itself, this will strongly implicate the parietal cortex in the planning of intended movements. In contrast, if it is primarily driven by an efference copy relayed from precentral motor areas, this would strongly implicate the parietal circuits in state estimation, including predicting how the arm should move in response to the motor command.

Premotor Cortex Supports Motor Selection and Planning

As outlined at the beginning of this chapter, a decision to act in a particular way in a given situation is shaped by many factors, including sensory information about objects, events, and opportunities for action from the environment, body position and motion, internal motivational states, prior experiences, reward preferences, and learned arbitrary rules and strategies linking sensory inputs to motor actions. There can be many reasons why you want to drink some coffee, and that desire can be fulfilled by actions ranging from simply reaching out to your full coffee cup to making coffee at home or going to a café.

Frontal premotor cortical regions just rostral to M1 play an important role in early movement planning or task-selection processes. Many neurons in those areas, such as the PMd neurons shown in Figure 34–4, generate activity during instructed-delay tasks that reflect the motor intentions of the monkey and even the factors that influenced those action choices. The different premotor cortical regions are presumed to make different but overlapping contributions to motor selection and planning. For instance, the lateral premotor

cortex, including PMd and PMv, have traditionally been implicated in actions initiated and guided by external sensory inputs. In contrast, medial premotor areas, including SMA, pre-SMA, and CMA, have been implicated in the control of self-initiated movements as well as the suppression of actions. However, the distinction between their respective contributions is not absolute.

Medial Premotor Cortex Is Involved in the Contextual Control of Voluntary Actions

Clinton Woolsey's pioneering electrical stimulation studies showed that, in addition to the motor map in M1, the medial wall of the frontal cortex contains an array of neurons that also regulate body movements. This medial motor map, now called the supplementary motor area (SMA), includes the entire contralateral body but is coarser than the detailed map in M1, as described later. Strong stimulus currents are required to evoke movements, which are often complex actions such as postural adjustments or stepping and climbing and can involve both sides of the body. Today, there is agreement that this region contains two areas that have distinct cytoarchitectonic characteristics, axonal connections, and functional properties: a more caudal SMA proper and a more rostral presupplementary motor area (pre-SMA), which we will collectively call the supplementary motor cortex (SMC).

The SMC has been implicated in many aspects of voluntary behavior, although its contribution remains controversial. Several lines of evidence support a role in self-initiated behavior. In humans, electrical stimulation of SMC below the threshold for movement initiation can evoke an introspective sense of an urge to move that does not arise during M1 stimulation. Lesions of SMC produce problems initiating desired movements or suppressing undesirable movements (Box 34–2). Moreover, recordings of slow cortical potentials at the surface of the skull during the execution of self-paced movements show that the initial potential arises in the frontal cortex as much as 0.8 to 1.0 second before the onset of movement. This signal, named the *readiness*

Box 34–2 Lesions of Premotor Cortex Lead to Impairments in the Selection, Initiation, and Suppression of Voluntary Behavior

Lesions of the supplementary motor area (SMA) and presupplementary motor area (pre-SMA) and the prefrontal areas connected with them produce deficits in the initiation and suppression of movements. Initiation deficits manifest themselves as loss of self-initiated arm movements, even though the patient can move when adequately prompted. This deficit can involve movement of parts of the body (*akinesia*) contralateral to the region and speech (*mutism*).

Deficits in movement suppression, in contrast, include the inability to suppress behaviors that are socially inappropriate. These include compulsive grasping of an object when the hand touches it (*forced grasping*), irrepressible reaching and searching movements aimed at an object that has been presented visually (*groping movements*), and impulsive arm and hand movements to grab nearby objects and even people without conscious awareness of the intention to do so (*alien-hand* or *anarchic-hand syndrome*).

Another striking syndrome is *utilization behavior*, in which a patient compulsively grabs and uses objects without consideration of need or the social context. Examples are picking up and putting on multiple pairs of glasses or reaching for and eating food when the patient is not hungry or when the food is clearly part of someone else's meal.

These deficits in the initiation and suppression of actions may represent opposite facets of the same functional role for SMA and especially pre-SMA in the conditional or context-dependent control of voluntary behavior.

Lesions affecting premotor cortex also lead to impairments in the selection of motor actions. For example, when a normal monkey sees a tasty food treat behind a small transparent barrier, it readily reaches around the barrier to grasp it. However, after a large premotor cortex lesion, the monkey may persistently try to reach directly toward the treat and so repeatedly strikes the barrier with its hand, rather than making a detour around the barrier.

More focal lesions or inactivation of the ventral premotor cortex perturbs the ability to use visual information about an object to shape the hand appropriately for the object's size, shape, and orientation before grasping it. Focal lesions of the dorsal premotor cortex affect the ability to learn and recall arbitrary sensorimotor mappings or conditional stimulus–response associations, whereas supplementary motor cortex lesions impede the ability to learn and recall temporal sequences of movement.

potential, has its peak in the cortex centered in SMC. Because it occurs well before movement, the readiness potential has been widely interpreted as evidence that neural activity in this region is involved in forming the intention to move, not just in executing movement.

Neurons in both SMA and pre-SMA discharge before and during voluntary movements. Unlike M1 neurons, the activity of most SMA neurons is less tightly coupled to particular actions of a body part and appears instead to be associated with more complex, coordinated motor acts of the hand, arm, head, or trunk. Compared to SMA neurons, pre-SMA neurons often begin to discharge much earlier in advance of movement onset and are less tightly coupled to the execution of movements.

The SMC has been implicated in the so-called *executive control* of behavior, such as operations required to switch between different actions, plans, and strategies. For example, in monkeys, some SMC neurons discharge strongly when a subject is presented with a cue instructing it to change movement targets or to suppress a previously intended movement. The SMC may therefore contain a system that can override motor plans when they are no longer appropriate.

The SMC has also been implicated in the organization and execution of movement sequences. Some SMC neurons discharge before the start of a particular sequence of three movements but not before a different sequence of the same three movements (Figure 34–7). Other neurons discharge only when a particular movement occurs in a specific position in a sequence or when a particular pair of consecutive movements occurs regardless of their position in the sequence. In contrast, some other SMC neurons discharge only when the monkey makes the movement that occurs in a particular ordinal position of a sequence (eg, only the third) irrespective of its nature or how many movements remain to be executed in the sequence.

These seemingly disparate functions may reflect a more general role of the SMC in *contextual control* of voluntary behavior. Contextual control involves selecting and executing those actions deemed appropriate on the basis of different combinations of internal and external cues as well as withholding inappropriate actions in

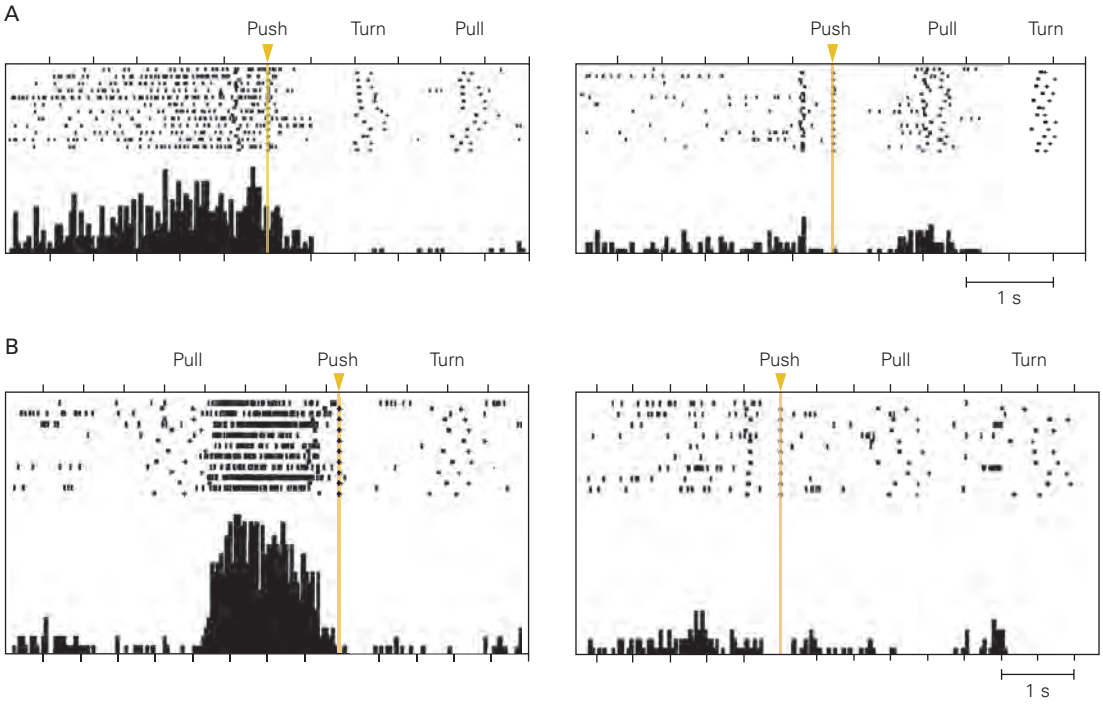

Figure 34–7 Some neurons in the supplementary motor complex of monkeys encode a specific sequence of motor acts. (Adapted, with permission, from Tanji 2001. Copyright © 2001 by Annual Reviews.)

A. A neuron discharges selectively during the waiting period before the first movement of the memorized sequence push-turn-pull (*left*). When the sequence is push-pull-turn (*right*), the cell remains relatively silent, even though the first movement in both sequences is the same (push). Triangles at the top of each raster plot indicate the start of the push movement.

B. Records of a neuron whose activity increases selectively during the interval between completion of one motor act, a pull, and the initiation of another act, a push. The cell is not active when a push is the first movement in the sequence or when pull is followed by turn.

a specific environmental or social context. It also can involve organizing the sequence of actions required to achieve a particular goal. Contextual control likely also involves contributions from other neural circuits such as regions of the prefrontal cortex and the basal ganglia.

The cingulate motor areas (CMA) may also contribute to the contextual control of behavior. CMA appears to be involved in selecting alternate actions following motor errors or in response to changing reward contingencies. For example, monkeys were trained to push or turn a handle in response to a noninstructive trigger signal. Initially, the monkeys received a large reward if they made the same movement (pushing or turning the handle) in sequential trials. After several trials, the reward size began to decrease. If the monkeys then switched to the other movement, the reward size returned to maximum once that movement was repeated for several trials. The best strategy for the monkeys, therefore, was to switch between repetitions of either pushing or turning the handle as soon as they detected a reduction in reward size.

In this task, some neurons in the rostral CMA responded during the interval between the reception of reward and the start of the next trial. On trials with a reduced reward, task-related activity in these neurons did not change when the monkeys made the same movement in the next trial; their activity only changed when the monkeys switched to the other movement in the next trial. Importantly, those same neurons did not show the same response change when a visual cue instructed the monkeys to change movements in the next trial. This suggests that these rostral CMA neurons were preferentially involved in the voluntary decision to switch and move to the alternate goal based on action outcomes (reward size), but not by visual instructions to switch.

Dorsal Premotor Cortex Is Involved in Planning Sensory-Guided Movement of the Arm

Some of the first neural evidence that the lateral premotor cortex, including PMd and PMv, plays a crucial role in the selection and planning of sensory-guided motor actions came from recording studies by Ed Evarts, Steven Wise, and colleagues in the 1980s. These studies showed that many premotor neurons emitted brief short-latency discharge bursts in response to instructional cues that signaled specific movements, or sustained activity during the instructed-delay period between the appearance of the instructional cue and a second cue that permitted the instructed movement (Figure 34–4).

This activity reflects information about the intended act, including the spatial location of the target, the direction of arm movement, and other movement attributes. Importantly, PMd delay-period activity can reflect the intention to reach to a particular location with either the contralateral or ipsilateral arm, even though the biomechanical details of the two arm movements are very different. This suggests that PMd activity can signal the intention to generate a motor act independent of the effector used to generate the action, in an extrinsic spatial coordinate framework consistent with a prediction of the sensorimotor coordinate transformation model of motor planning. Imaging studies have likewise found evidence for an extrinsic spatial representation of finger-tapping sequences made with either hand in human premotor cortex.

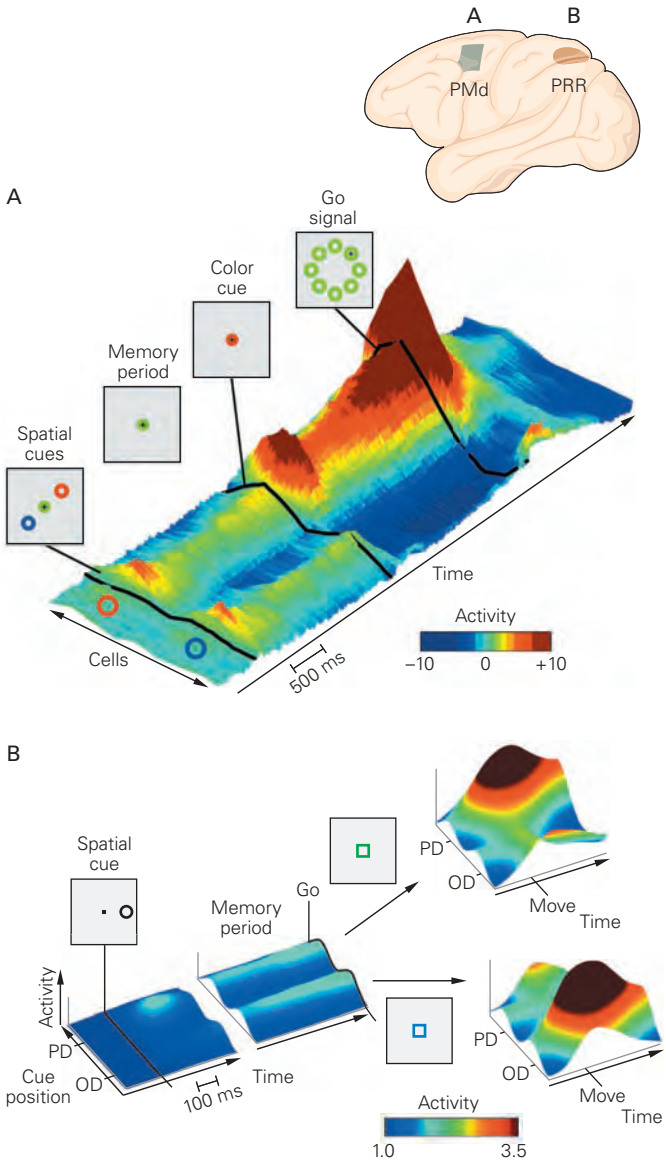
Selection of an appropriate action from among multiple alternatives is a critical aspect of voluntary control. Delay-period activity in PMd can reflect that process. For example, in one experiment, recordings were made from PMd neurons in monkeys during a task in which the animals first received two colored spatial cues that identified two potential targets for reaching in opposite directions. After a memorized-delay period, a new centrally-located color cue informed the monkeys which of the spatial cues was the correct target. Following the first instruction, neural activity in PMd signaled both potential-reaching movements, but immediately after the second instruction, activity in PMd signaled only the monkeys' reaching choice (Figure 34–8A). This showed that PMd can prepare multiple potential motor actions prior to the final decision about which action to take. Subsequent studies suggest that this might be limited to no more than three to four simultaneous potential actions. Reach-related neurons in parietal area PRR also contribute to the preparation for two potential motor actions before the final action decision is made (Figure 34–8B), revealing how this process is distributed across multiple arm movement–related cortical neural populations.

PMd neurons can also signal a deliberate decision not to move. Many PMd neurons generate directionally tuned activity during an instructed-delay period when a colored visual cue at a target location instructs a monkey to reach to the target, but decrease their activity when a different colored cue at the same location instructs the monkey to refrain from reaching to it. This differential activity is an unequivocal signal, seconds before the action is executed, about the monkey's intention to reach in a particular direction or not to move in response to an instructional cue (Figure 34–9). Interestingly, many neurons in the parietal area PE/MIP studied in the same task continue to generate directionally tuned activity during the delay period even after the instructional cue to withhold

Figure 34–8 Activity of reach-related cortical neurons in monkeys during a target selection task reflects potential movements to different targets as well as the chosen direction of reach.

A. The three-dimensional colored surface depicts the mean level of activity of a population of dorsal premotor cortex (**PMd**) neurons with respect to baseline in a task in which a monkey must choose one of two color-coded reach targets in each trial. Cells are sorted along one axis (labeled "cells") based on their preferred movement direction (neurons located at the **red** and **blue circles** prefer movements at 45° and 215°, respectively). Diagrams beside the neural response profile display the stimuli presented to the monkey at different times during the trial. **Red** and **blue** cues provide information about potential actions; **green** cues guide the monkeys through different stages of each trial but provide no information about what reach to make. Shortly after the start of each trial, two potential reach targets (**blue** and **red** spatial cues) appear in opposite locations relative to the starting position of the arm (**green circle**) for 500 ms and then disappear. After a memorized delay period, the color of the starting circle changes to either **red** or **blue** (color cue), indicating to the monkey which is the correct target, in this case at 45°. After a further delay period, the go signal (**green circles** at all eight possible target locations) instructs the monkey to begin reaching to its chosen target. During the period of target uncertainty between the appearance of the two spatial cues and the central color cue, PMd neurons that prefer the two potential reach movements (**red** and **blue circles**) are simultaneously activated, whereas neurons that prefer other movements are inactive or suppressed, so that the entire PMd population encodes the two potential reach actions. As soon as the color cue appears to identify the correct target, the PMd neural activity changes rapidly to signal the reach movement chosen by the monkey. Had the color cue designated the target at 215°, the neurons preferring that target (**blue circle**) would increase their activity, and the neurons preferring the target at 45° (**red circle**) would decrease their activity (not shown). (Reproduced, with permission, from Cisek and Kalaska 2010. Copyright © 2010 by Annual Reviews.)

B. In a second study of neural activity in the parietal reach region (**PRR**), the format of data is the same as in part **A**. In this study, the monkey is presented with a single spatial cue that instructs it to prepare to reach either to the cue's location (**PD**) or in the opposite direction (**OD**). After a random memorized delay period, a color cue specifies whether the reach should be to the remembered location of the spatial cue (**green**; PD) or in the OD (**blue**). PRR neural activity is sorted according to the preferred movement direction of each neuron, as in part **A**. Population activity initially specifies the spatial cue location but then reflects both potential movement directions during the remainder of the memorized delay period. Shortly after the color cue appears, the activity quickly shifts to reflect the chosen reach direction, either the PD or OD. (Reproduced, with permission, from Klaes et al. 2011. Copyright © 2011 Elsevier Inc.)



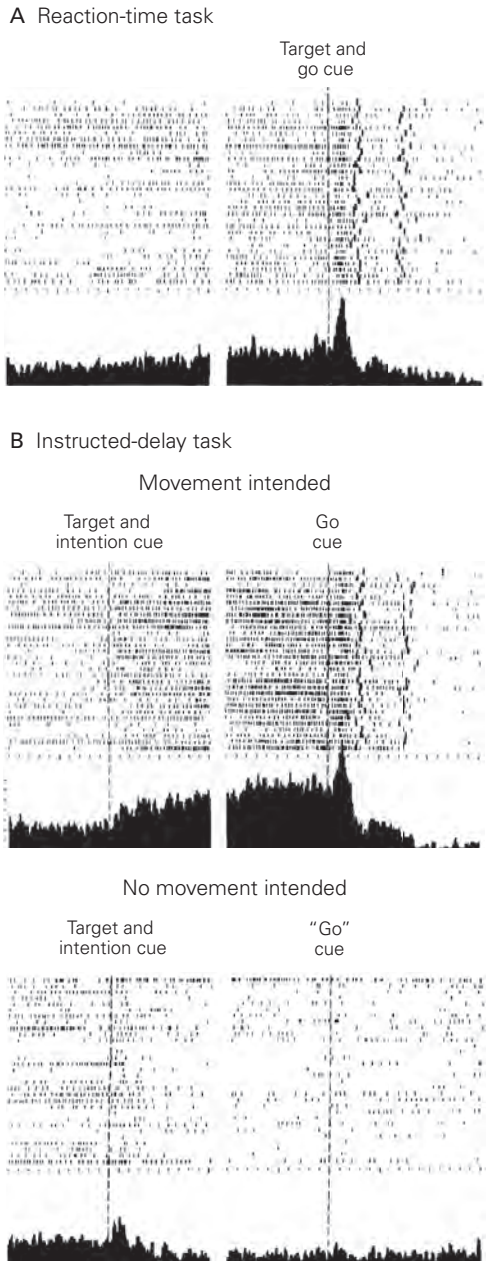


Figure 34–9 Decisions about response choices are evident in the activity of premotor cortex neurons in the monkey. (Reproduced, with permission, from Crammond and Kalaska 2000.)

A. In a reaction-time task (reaching), a cell exhibits gradually increasing tonic firing while waiting for the appearance of a target. When the target appears (go cue), the cell generates a directionally tuned response.

B. In an instructed-delay task, when a monkey is shown the target and instructed to move once the go cue appears, the cell generates a strong directionally tuned signal for the duration of the delay period before the go cue (top). When the monkey is shown the target and instructed not to move when the go cue appears, the cell's activity decreases (bottom).

reaching, suggesting that the parietal cortex retains a representation of potential actions that ultimately are not executed.

Many neurons in premotor cortex also discharge during movement execution. Given this close proximity of planning- and execution-related activity, even at the level of individual neurons, a major question is why planning-related neural activity does not immediately initiate a movement. What prevents the movement from being executed prematurely? It does not appear that planning-related activity simply fails to exceed a minimum threshold required to initiate the movement or that there is a separate overt braking mechanism that must be released to allow the movement to begin.

A different way to interpret neural processing during the planning and execution of reaching that might provide answers to such questions comes from a dynamical-systems perspective. The idea is that cortical motor circuits form a dynamical system whose distributed activity patterns evolve in time as a function of their initial state, input signals, and stochastic neural response variability ("noise"). Activity patterns during different stages of planning and execution thus reflect different states of the network, including a specific state during the delay period that can prepare the movement but not activate muscles (Figure 34–10). The overall similarity of the population-level activity patterns during repetitions of the same movement shows that the entire population undergoes a coordinated pattern of co-modulation of activity during the planning and execution of the movement, determined by the synaptic connectivity within the neural circuit.

Dorsal Premotor Cortex Is Involved in Applying Rules (Associations) That Govern Behavior

Behavior is often guided by arbitrary rules that link specific symbolic cues to particular actions. When driving your car, you must perform different actions depending on whether a traffic light is green, amber, or red. In monkeys that have learned to associate arbitrary cues with specific movements, many cells in premotor areas respond selectively to specific cues. For instance, in order to select the correct target in the two-target study in Figure 34–8, the monkeys had to apply a rule that mapped color to target location provided by the two sequential instructional cues.

The PMd is implicated in the acquisition of new movement-related associations or rules. In one experiment, recordings from PMd neurons were made while the monkeys learned the association between four unfamiliar visual cues and four different movement

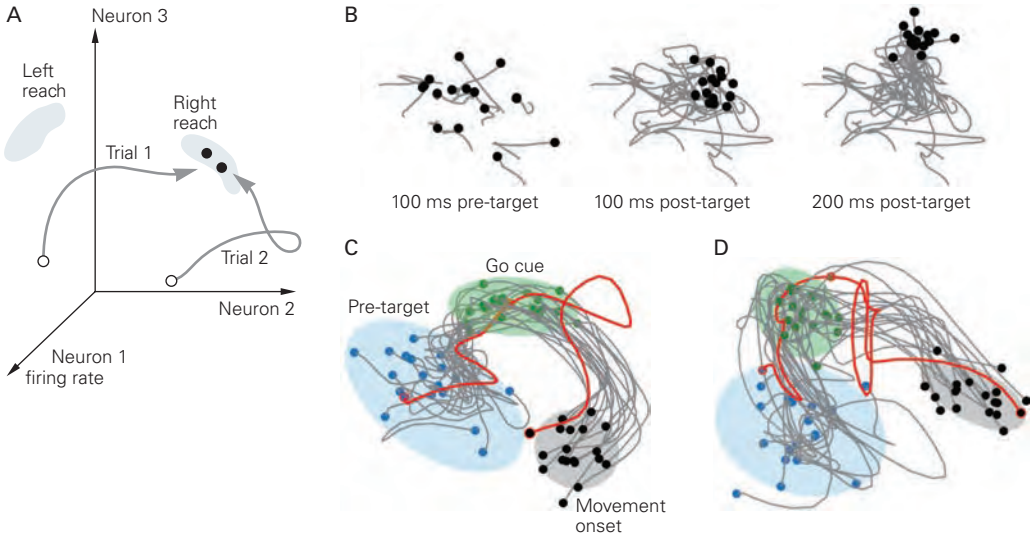

Figure 34–10 **The time-varying neural activity in the dorsal premotor cortex of monkeys during different stages of the planning and execution of a movement can be viewed as transitions between different activation states.** (Adapted, with permission, from Churchland MM et al. 2010. Stimulus onset quenches neural variability: a widespread cortical phenomenon. Nat Neurosci 13:369-378. Copyright © Springer Nature.)

A. A schematic illustration of how the simultaneous activity of neurons can be viewed as a trajectory through a multi-neuron activity "state space." The time-varying activity level of three simultaneously recorded neurons is represented along three axes, which defines a three-neuron state space. A specific plan (reach left or reach right) requires different combinations of preparatory firing rates for the three neurons (**gray zones**). Prior to the formation of the intention to move left or right, the baseline activity of the three neurons occupies a region in state space that is associated with holding the arm in its current position (**open circles**, for two different trials). When an instruction appears to make a reach to the right, the combined activity of the three neurons changes in a coordinated fashion, creating time-varying "neural trajectories" (**gray arrows**) that converge on the region of state space that is associated with generating a rightward movement (**filled circles** within the "right reach" gray zone).

B. Projection of the simultaneous activity of a large population of dorsal premotor cortex (PMd) neurons onto a two-dimensional state space shortly before (pre-target) and after (post-target) the appearance of a reach target cue in a task in which the reach movement must be delayed until a subsequent go cue is presented. **Gray lines** show the temporal evolution of the neural trajectories during the earliest part of movement preparation from 200 ms before target cue until the specified pre- or post-target time (**black dots**) in 15 different trials to the same target location. Neural activity initially meanders randomly within the region of state space associated with the starting posture of the arm (*left*). It then begins to converge onto a smaller region of the state space shortly after the reach target instruction appears (*center*) and begins to evolve along the neural trajectory associated with entering the preparatory state for the reach (*right*).

C. A more complete illustration of the neural trajectories recorded during 18 different repeated trials to the same target in this delayed reaching task from the initial pre-target postural state to the onset of movement. **Blue dots** indicate activity while holding the arm in the starting posture 100 ms before appearance of the target instruction onset. Once the target instruction appears, the neural trajectories evolve toward a region of state space associated with the preparatory activity state during the delay period (**green zone**), where it dwells until a go cue appears that allows the monkey to initiate the withheld movement (**green dots**). While in this reach-preparatory part of the state space during the delay period, the arm stays at the start position because PMd activity in that part of state space is not capable of activating muscles (ie, it is "output-null"). When the go cue appears, the neural trajectories unfold toward a different region of state space associated with the initiation of the intended reach movement (**gray zone** and **black dots**). The neural activity can only cause the muscle activity for the intended movement when it enters this "output-potent" zone of state space. The trial-to-trial variability of the neural trajectories can account for intertrial variability in movement kinematics and reaction times. One outlier trial (**red**) had a long reaction time and followed a more complex and time-consuming neural trajectory from the **green** to the **gray** zone. The output-null preparatory (**green**) and output-potent movement-initiation (**gray**) zones for reaches to different target locations occupy different regions of the total population state space distinct from those associated with this reach target.

D. Data are for the same target location as in part **C** but were recorded on a different day. The neural trajectory structure is fundamentally similar for the same movements between recording sessions. Differences in the overall pattern of activity can be explained by interday differences in the activity of individual neurons and differences in the composition of the recorded neural population between sessions.

directions. Although the monkeys' choices were initially random, they learned the rules within a few dozen trials. The monkeys made an arm movement in response to each cue; during the early "guessing" phase of learning, the activity of many PMd neurons was weak but gradually increased in strength and directional tuning as the monkeys learned which cue signaled which movement. Other neurons showed a reciprocal decline in activity as the rules were acquired. These changes in activity during learning reflected both the movement choices and the rising level of knowledge of the rules linking cues with actions.

The nature of the rule can also have a strong effect on neural responses. In monkeys that have been trained to choose between several possible movements based on a spatial rule (a visual cue's location) or a semantic rule (a cue's arbitrarily designated meaning independent of its location), many prefrontal and PMd neurons are preferentially active when the animal chooses a movement using one rule but not the other. This shows that the neural activity is related not just to a particular cue or action but also to the association between them.

Premotor areas are involved in the implementation of even abstract rules. For example, monkeys were trained in a task that required two decisions, one perceptual and the other behavioral, that had no prior association. In each trial, the monkeys first had to decide whether two sequentially presented visual images were the same or different (a *match/nonmatch perceptual decision*). In some trials, a *rule cue* presented at the same time as the sample visual image instructed the monkeys to move their hand if the two images were identical and to refrain from moving if they differed (a *go/no-go motor decision*); in other trials, the rule was reversed—move if the images differ and do not move if they match. Neural activity in PMd after the test visual images were presented was correlated more strongly to the motor decision than the perceptual decision in each trial, but both decisions were expressed in PMd. More strikingly, PMd activity was also correlated with the match/non-match *behavioral rule* during the delay period between the two visual images that guided the motor decision after the test image appeared (Figure 34–11). These results suggest that PMd has a major role in applying rules that govern the appropriateness of a behavior and in making behavioral decisions according to the prevailing rules. Neural recordings in prefrontal cortex during the same task (not shown) found a strong representation of the physical identity of the visual images, but weaker and later correlates of the behavioral rule and the motor decision than in PMd.

Ventral Premotor Cortex Is Involved in Planning Motor Actions of the Hand

The most lateral part of the premotor cortex, area PMv, is reciprocally connected with parietal cortex areas AIP, PF, and PFG and the secondary somatosensory area. Electrical stimulation shows that PMv contains extensively overlapping circuits that control hand and mouth movements.

Like AIP neurons, many PMv neurons appear to contribute to the control of hand actions based on the physical affordances offered by target objects. These neurons tend to fire preferentially during certain stereotypical hand actions, such as grasping, holding, tearing, or manipulating objects. Many neurons discharge only if the monkey uses a specific type of grip, such as a precision grip, whole-hand prehension, or finger prehension (Figure 34–12). Precision grip is the type most often represented. Some PMv neurons discharge throughout the entire action, while others discharge selectively at particular stages of one type of prehension, such as during the opening or closing of the fingers.

Another striking property of PMv neurons is that their discharge often correlates with the goal of a motor act and not with the individual movements forming it. Thus, many PMv neurons discharge when grasping an object is executed with effectors as different as the right hand, the left hand, and even the mouth. Conversely, a PMv neuron may be active when an index finger is flexed to grasp an object but not when the animal flexes the same finger to scratch itself.

Premotor Cortex May Contribute to Perceptual Decisions That Guide Motor Actions

A series of studies provide evidence that cortical motor areas not only represent the sensory information that guides voluntary movements but also express the neural operations necessary to make and act on perceptual decisions. Monkeys were trained to discriminate the difference in frequency between two brief vibratory stimuli applied to one finger and separated in time by a few seconds. The animals had to decide whether the frequency of the second stimulus was higher or lower than the first and to report their perceptual decision by reaching out to push one of two buttons with the other hand.

The decision-making process in this task can be conceived as a chain of neural operations: (1) encode the first stimulus frequency (f1) when it is presented; (2) maintain a representation of f1 in working memory during the interval between the two stimuli; (3) encode the second stimulus frequency (f2) when it is

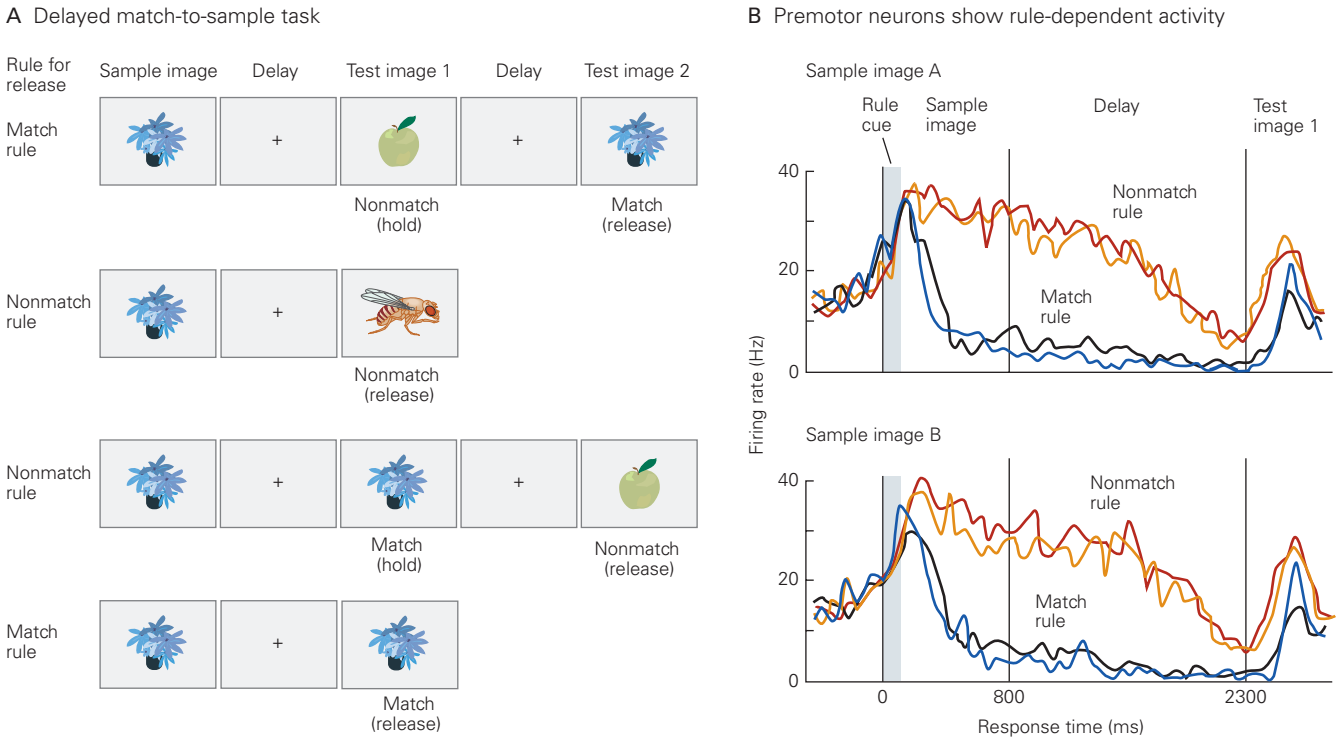

Figure 34–11 **Premotor cortex neurons in the monkey choose particular voluntary behaviors based on decisional rules.** (Reproduced, with permission, from Wallis and Miller 2003.)

A. A monkey must make a decision about whether to release a lever or keep holding it based on two prior decisions: a perceptual choice, whether a test image is the same as or different from a sample image presented earlier, and a behavioral choice, whether the current rule is to release the lever when the test image is the same as the sample (match rule) or when it is different (nonmatch rule). The monkey is informed of the behavioral rule that applies in each trial by a rule cue, such as an auditory tone or juice drops, which is presented for 100 ms at the same time as the onset of the sample image at the start of the trial.

B. A neuron in the dorsal premotor cortex has a higher discharge rate whenever the nonmatch rule is in effect during the delay between the presentation of the first and second images. The responses to two different sample images (upper and lower plots) were recorded from the same cell, indicating that the rule-dependent activity is not altered by changing the images. Nor, as shown by the pairs of curves associated with each rule, does activity depend on the type of rule cue (auditory tone or juice drops). (Tone cue trials: **orange** and **blue curves**; juice cue trials: **red** and **black curves**). Other dorsal premotor cortex cells (not shown) respond preferentially to the match rule over the nonmatch rule. The differential activity of the neuron up to presentation of the test image reflects the rule that will guide the animal's motor response to the test image, not the physical properties of the visual stimuli or the motor response.

presented; (4) compare f2 to the memory trace of f1; (5) decide whether the frequency of f2 is higher or lower than that of f1; and finally, (6) use that decision to choose the appropriate movement of the other hand. Everything prior to the last step would appear to fall entirely within the domain of sensory discriminative processing.

While the monkeys performed the task, neurons in the primary (S-I) and secondary (S-II) somatosensory cortices encoded the frequencies of the stimuli while they were presented. During the interval between f1 and f2, there was no sustained activity in S-I representing the memorized f1 and only a transient representation in S-II, which vanished before f2 was presented.

Strikingly, however, the activity of many neurons in the prefrontal cortex, SMC, and PMv scaled with the frequencies of f1 and f2 while they were being delivered. Furthermore, some prefrontal and premotor neurons showed sustained activity proportional to the frequency of f1 during the delay period between f1 and f2. Most remarkably, many neurons in those areas, especially in PMv, encoded the *difference* in frequency between f2 and f1 independently of their actual frequencies when f2 was delivered (Figure 34–13). This centrally generated signal is appropriate to mediate the perceptual discrimination that determines which button to push. Neurons that encoded the f2–f1 difference were absent in S-I and were far more common in SMC and PMv than in S-II.

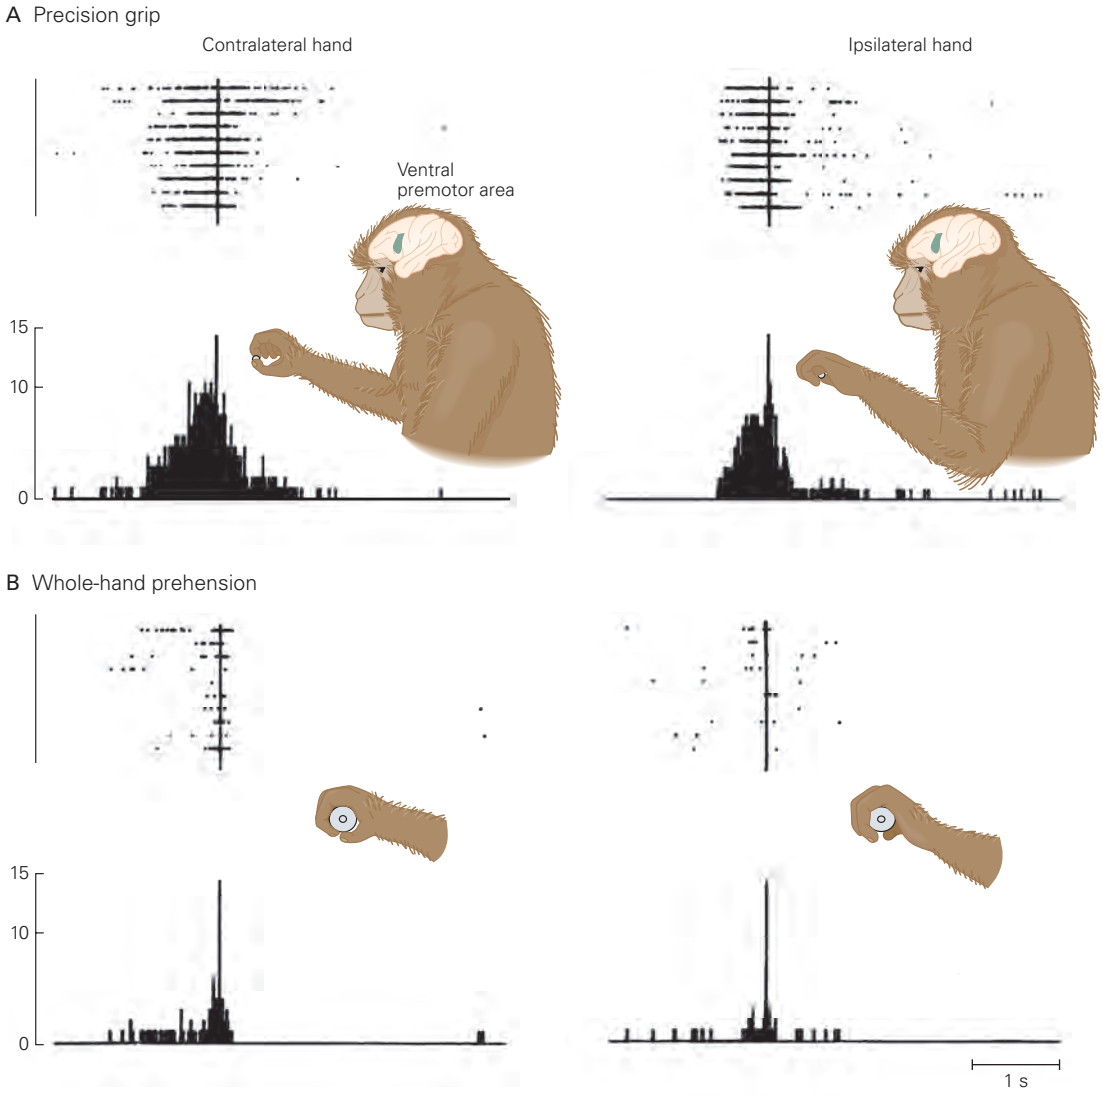

Figure 34–12 Some neurons in the ventral premotor cortex of a monkey discharge selectively during one type of grasping. This neuron discharges vigorously during a precision grip with the thumb and index finger of either the right or the left hand but very weakly during whole-hand prehension with either hand. Raster plots and histograms are aligned (**vertical line**) with the moment the monkey touches the food (**A**) or grasps the handle (**B**). Several Cortical Motor Areas Are Active When the Motor Actions of Others Are Being Observed

Some premotor and parietal areas can be activated when no overt action is intended, such as when an individual is asked to imagine performing a certain motor act. This phenomenon, termed *motor imagery*, has been demonstrated in humans using functional brain imaging. The neural activity evoked by motor imagery presumably reflects brain mechanisms associated with motor planning and preparation that have been disassociated from its overt execution.

A second condition in which cortical motor circuits are activated without intending overt action is when an individual observes another individual performing motor acts that are part of her own motor repertoire. The control of behavior and social interaction depends greatly on the ability to recognize and understand what others are doing and why they are doing it. Such understanding could result from a high-order visual perceptual analysis of the nature of the observed behavior and by drawing inferences about the motivation and purpose of the behavior based on

one's own experience. An alternative explanation is the *direct-matching hypothesis*, the idea that observation of the actions of others activates motor circuits in the observer that control similar motor actions. According to this hypothesis, empathetic activation of motor circuits could provide a link between the observed actions and the observer's stored knowledge of the nature, motives, and consequences of similar actions that they had performed in the past.

Striking evidence in support of the direct-matching hypothesis was provided by the discovery of a remarkable population of neurons called mirror neurons, first in PMv and later in the parietal AIP of monkeys. Mirror neurons discharge both when the monkey actively grasps and manipulates objects and when it observes similar actions performed by another monkey or the experimenter (Figure 34–14). Mirror neurons typically do not respond when a monkey simply observes a potential target object or when it observes mimed arm and hand actions without a target object. Some parietal mirror neurons can even differentiate the ultimate goal of similar observed actions, such as grasping and picking up food to eat it versus putting it into a cup.

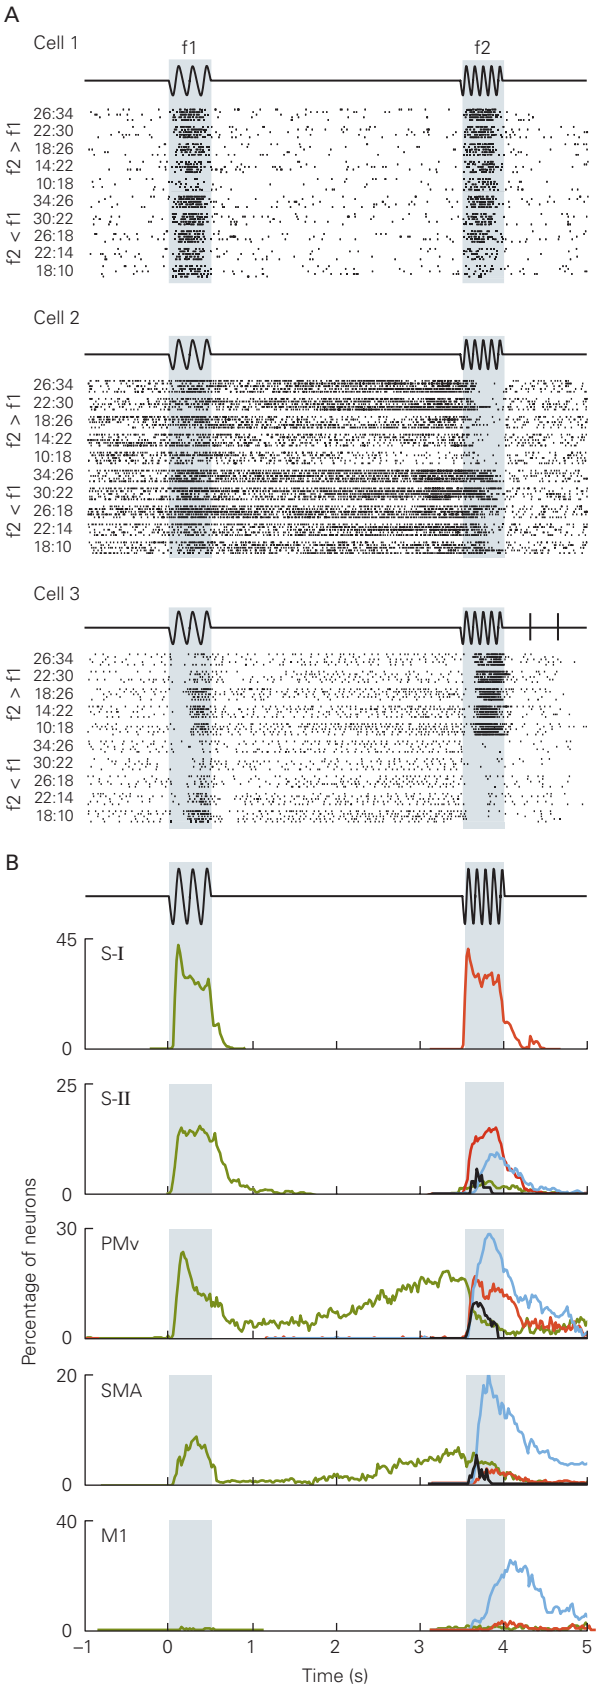

Figure 34–13 (Right) Neural activity in ventral premotor cortex in monkeys expresses the operations required to choose a motor response based on sensory information. (Adapted, with permission, from Romo, Hernández, and Zainos 2004. Copyright © 2004 Cell Press.)

A. These records of three neurons in the ventral premotor cortex of a monkey were made while the animal performed a task in which it had to decide whether the second of two vibration stimuli (**f1** and **f2**, applied to the index finger of one hand) was of higher or lower frequency than the first. The choice was signaled by pushing one of two buttons with the nonstimulated hand. The frequencies of f1 and f2 are indicated by the numbers on the left of each set of raster plots. Cell 1 encoded the frequencies of both f1 and f2 while the stimuli were being presented but was not active at any other time. This response profile resembles that of many neurons in the primary somatosensory cortex. Cell 2 encoded the frequency of f1 and sustained its response during the delay period. During the presentation of f2, the neuron's response was enhanced when f1 was higher than f2 and suppressed when it was lower. Cell 3 responded to f1 during stimulation and was weakly active during the delay period. However, during exposure to f2, the cell's activity robustly signaled the difference f2–f1 independently of the specific frequencies f1 and f2.

B. Histograms show the percentage of neurons in different cortical areas whose activity correlated at each instant with different parameters during the tactile discrimination task. **Green** shows the correlation with f1, **red** the correlation with f2, **black** the interaction between f1and f2, and **blue** the correlation with the difference between f2–f1. (Abbreviations: **M1**, primary motor cortex; **PMv**, ventral premotor cortex; **S-I**, primary somatosensory cortex; **S-II**, secondary somatosensory cortex; **SMA**, supplementary motor area.)

Neural-recording and brain-imaging studies show that humans are also endowed with a mirror-like mechanism to match observed actions with actions encoded in their motor system. This activity arises in various areas of cortex, including the rostral inferior parietal lobule, IPS, PMv, and posterior sector of the inferior frontal gyrus.

Cortical motor circuits appear to be involved in understanding and predicting the outcomes of observed events. In one experiment, PMd neurons implicated in the selection of reaching targets using visual cues (Figure 34–8) also discharged when monkeys simply watched the same cues and cursor motions on the monitor while an unseen party performed the task. The monkeys received a free juice reward when the cursor moved to the correct target but not if it moved to the wrong target. The monkeys began to lick the juice tube shortly after the cursor started to move to the correct target well before the juice was actually delivered, but quickly removed their mouth from the tube when the cursor moved toward the wrong target. This behavior showed that the monkeys correctly interpreted what they saw and accurately predicted its consequences.

Remarkably, the activity of most of the task-related PMd neurons was strikingly similar whether the monkeys used visual cues to plan and make arm movements or simply observed the visual events and predicted their outcome. Those neurons stopped responding during observation if no reward was delivered after correct trials or if the animal was sated and not interested in drinking juice. This showed that the neurons were not simply responding to the sensory inputs, but instead were processing the observed sensory events to predict their ultimate outcome for the monkey, namely the likelihood of a free juice reward.

This activation in connection with passive observation supports the idea that activation of premotor

A. The neuron is active when the monkey grasps an object.

B. The same neuron is also excited when the monkey observes another monkey grasping the object.

C. The neuron is similarly activated when the monkey observes the human experimenter grasping the object.

Time zero in the cell activity rasters corresponds approximately to the time of presentation of the object to grasp (panel A) or the onset of the observed grasping actions (panels B and C).

circuits in nonmotor contexts may contribute to understanding the nature and consequences of observed events in the environment. It has also been implicated in the ability of human subjects to learn new motor skills simply by observing a skilled person perform the same actions. Moreover, dysfunction of the mirror-neuron system in young children may contribute to some of the symptoms of autism.

Many Aspects of Voluntary Control Are Distributed Across Parietal and Premotor Cortex

While we have described the roles of premotor areas in parietal and precentral cortex separately, it must be emphasized that major sensorimotor control processes are shared across multiple cortical regions via their reciprocal interconnections.

For instance, the neural processes that link the physical affordances of target objects to appropriate hand actions are distributed across parietal area AIP, premotor area PMv, and M1, with visuospatial aspects of the process more prominent in AIP and motor components more prevalent in precentral cortex (Figure 34–15). Likewise, as already noted, neural correlates of reach target selection in PRR (Figure 34–8B) strikingly resemble those reported in PMd (Figure 34–8A).

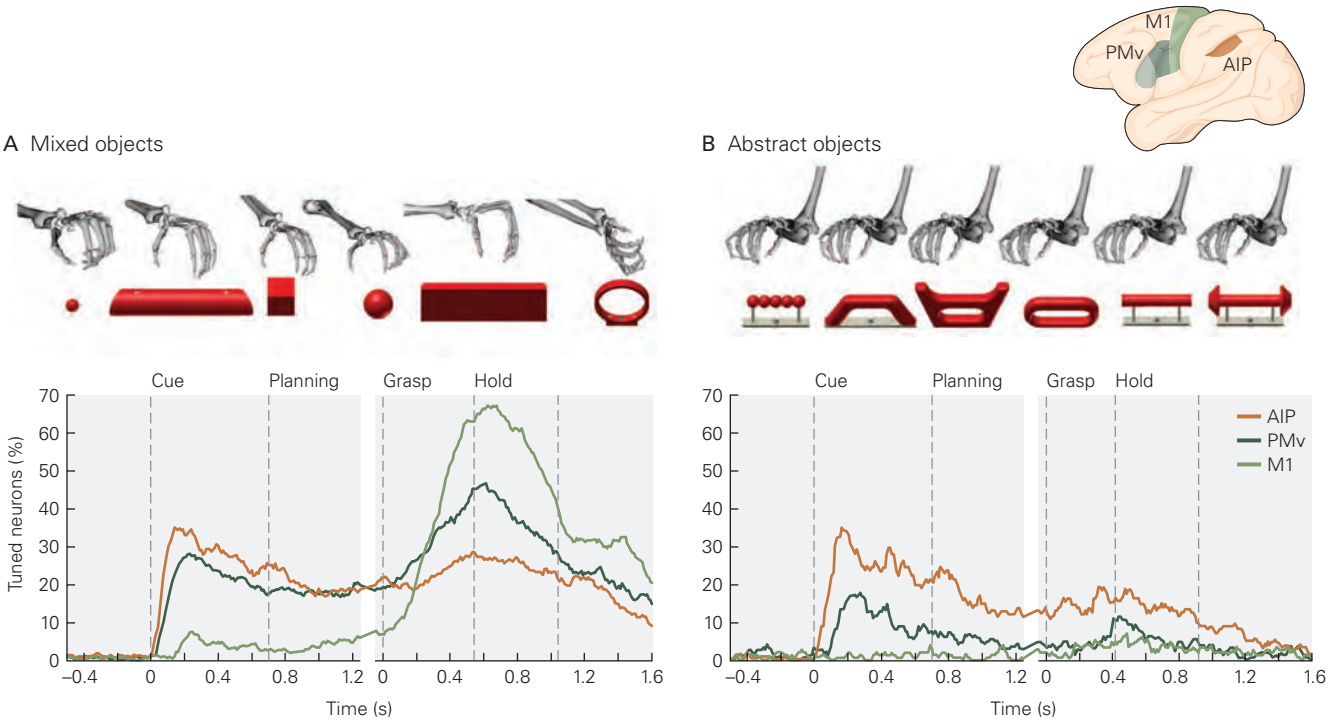

Figure 34–15 Visuomotor processing of object shape is distributed across several cortical areas in the monkey. (Reproduced, with permission, from Schaffelhofer and Scherberger 2016.)

A. A set of "mixed" objects elicit different visual responses and require different motor responses to grasp them. The plots show the percentages of neurons in the anterior intraparietal areas (**AIP**; **orange**), ventral premotor cortex (**PMv**; F5; **dark green**), and primary motor cortex (**M1**; **light green**) that significantly modulated their response as a function of object identity across time. Monkeys were first shown the object to grasp (cue and planning periods) and then allowed to reach to, grasp, and hold the object (grasp and hold periods). The proportion of neurons that varied their activity across object types (tuned neurons) during the cue and planning periods was greatest in AIP and least in M1, indicating that sensitivity to object visual shape was most prominent in AIP. During motor action (grasp and hold periods), the reverse pattern was observed, with many neurons in PMv and especially M1 displaying a strong dependence on the different grasping actions required to hold onto the different objects.

B. A set of "abstract" objects elicit different visual responses but require similar motor responses to grasp them. As with the "mixed" object set, many AIP neurons varied their activity as a function of object shape during the cue and planning periods, but fewer PMv and almost no M1 neurons showed sensitivity to observed object shape. During motor action (grasp and hold periods), very few PMv and M1 neurons showed any difference in activity as a function of the shape of the different objects, all of which required the same grasping action.

The Primary Motor Cortex Plays an Important Role in Motor Execution

Once an individual has decided on a behavioral goal, motor commands must then be communicated to muscles to move the body. The complexity of this problem cannot be underestimated as it requires precise control of the spatiotemporal patterns of activity of large numbers of muscles acting across many joints to achieve the behavioral goal, while also accounting for the complex, nonlinear mechanical properties of the musculoskeletal system and forces and loads imposed by the environment. These detailed patterns of muscle activity are coordinated by spinal motor neurons and interneuronal circuits (Chapter 32). However, the primary motor cortex (M1) plays an important role in generating the motor commands that control that spinal activity, including essential information necessary to select and control the timing and magnitude of muscle activity.

The Primary Motor Cortex Includes a Detailed Map of the Motor Periphery

The idea that a local region of the cerebral cortex contains a motor map of the body dedicated to voluntary motor control dates back to the work of the English neurologist John Hughlings Jackson in the middle of the 19th century. He reached this conclusion while treating patients with epileptic seizures that were characterized by recurring spasmodic involuntary movements that sometimes resembled fragments of purposive voluntary actions and that progressed systematically to include different parts of the body during each seizure episode (Chapter 58). Later in the 19th century, improved anesthesia and aseptic surgical techniques allowed direct experimental study of the cerebral cortex in experimental animals. Using those new methods, Gustav Fritsch and Eduard Hitzig in Berlin and David Ferrier in England showed that electrical stimulation of the surface of a limited area of cortex in different anesthetized mammalian species evoked movements of parts of the contralateral body. In monkeys, the electric currents needed to evoke movements were lowest in a narrow strip along the rostral bank of the central sulcus, the same region now called primary motor cortex.

Their experiments demonstrated that within this strip of tissue stimulation of adjacent sites evoked movements in adjacent body parts, starting with the foot, leg, and tail medially, and proceeding to the trunk, arm, hand, face, mouth, and tongue more laterally. When they lesioned a cortical site at which stimulation had evoked movements of a part of the body, movement of that body part was perturbed or lost after the animal recovered from surgery. These early experiments showed that the motor cortex contains an orderly motor map of major parts of the contralateral body and that the integrity of the motor map is necessary for voluntary control of the corresponding body parts. Studies in the first half of the 20th century on many species by Clinton Woolsey and on humans undergoing surgery by Wilder Penfield demonstrated that the general topographic organization of the rostral bank of the central sulcus is conserved across many species (Figure 34–16). One important observation was that the motor map is not an exact point-to-point reproduction of the body's anatomical form. Instead, the most finely controlled body parts, such as the fingers, face, and mouth, are represented by disproportionately large areas, reflecting the larger number of neurons needed for fine motor control.

Today the best-studied regions of the map are those parts controlling the arm and hand and reveal far more complexity than conveyed in the classic diagrams shown in Figure 34–16A,B. First, neurons controlling the muscles of the digits, hand, and distal arm tend to be concentrated within a central zone, whereas those controlling more proximal arm muscles are located in a horseshoe-shaped ring around the central core (Figure 34–16C). Second, stimulation sites overlap extensively, allowing control of muscles acting across different joints; conversely, each muscle can be activated by stimulating many sites dispersed across the arm/hand motor map. Finally, local horizontal axonal connections link different sites across the motor map, likely allowing coordination of activity across the map during the formation of motor commands.

Some Neurons in the Primary Motor Cortex Project Directly to Spinal Motor Neurons

As already noted, while many corticospinal axons in primates terminate only on spinal interneurons, others also synapse directly onto spinal motor neurons. These corticomotoneuronal (CM) cells are found only in the most caudal part of M1 that lies within the anterior bank of the central sulcus. There is extensive overlap in the distribution of the CM cells that project to the spinal motor neuron pools innervating different muscles (Figure 34–17A).

CM cells are very rare or absent in nonprimate species and become a progressively larger component of the corticospinal tract in primate phylogeny from prosimians to monkeys, great apes, and humans. In monkeys, more CM cells project to the motor pools for muscles of the digits, hand, and wrist than to

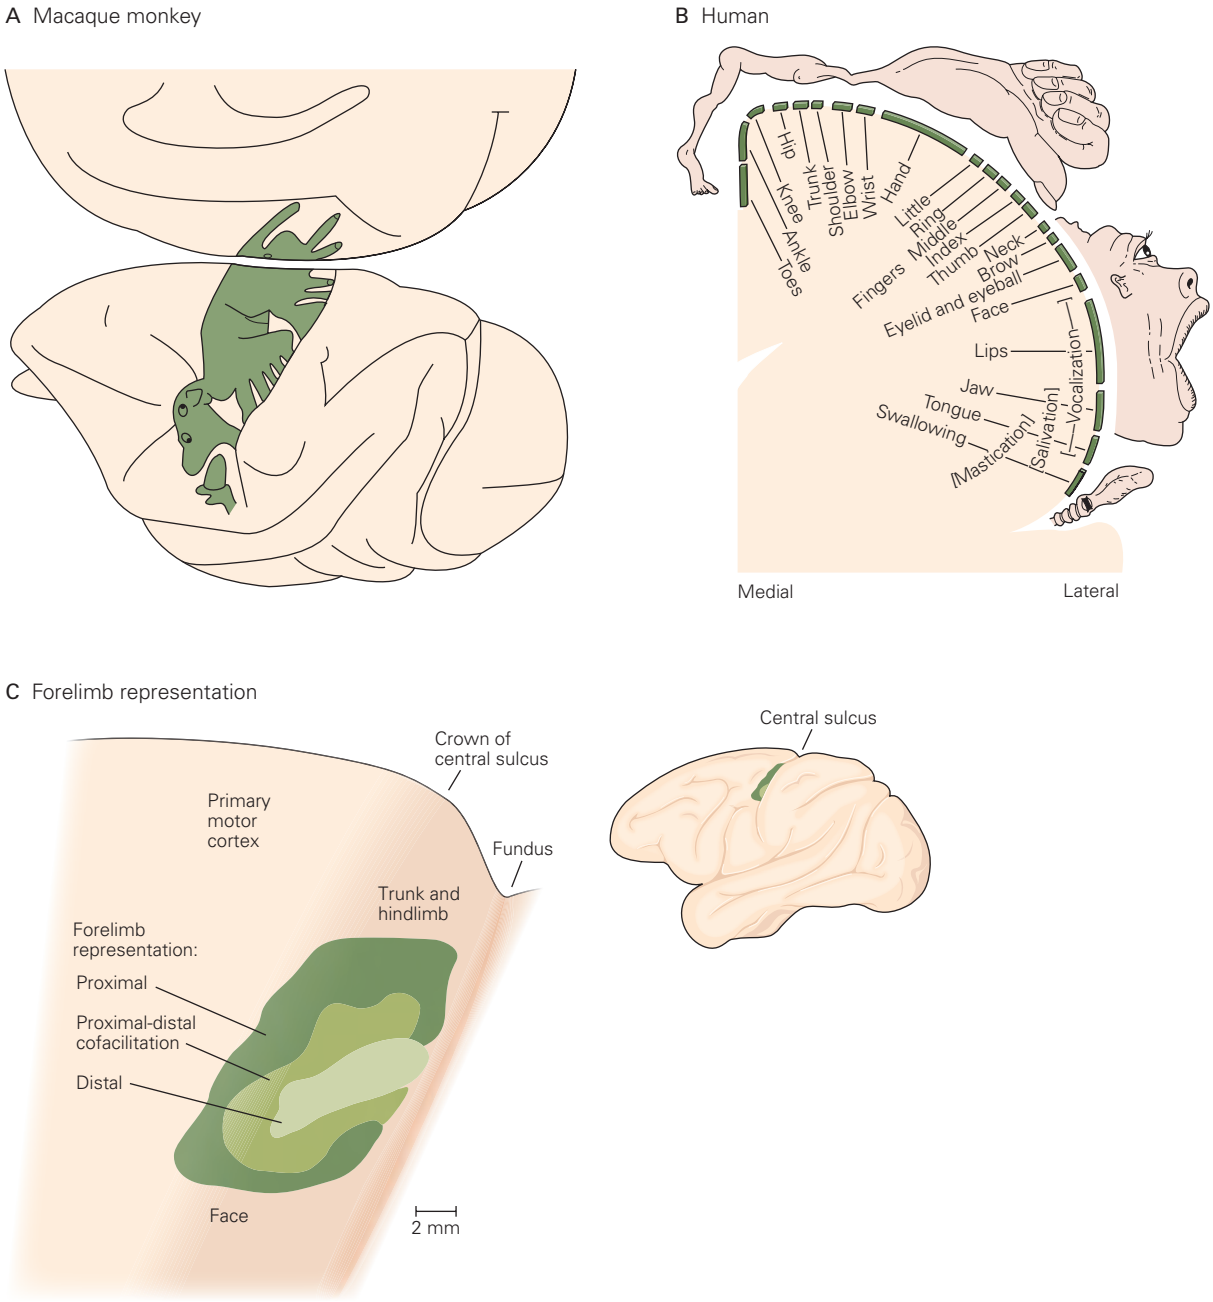

Figure 34–16 **The motor cortex contains a topographic map of motor output to different parts of the body.**

A. Studies by Clinton Woolsey and colleagues confirmed that the representation of different body parts in the monkey follows an orderly plan. Motor output to the foot and leg is medial, whereas the arm, face, and mouth areas are more lateral. The areas of cortex controlling the foot, hand, and mouth are much larger than the regions controlling other parts of the body.

B. Wilder Penfield and colleagues showed that the human motor cortex motor map has the same general mediolateral organization as in the monkey. However, the areas controlling the hand and mouth are even larger than in monkeys, whereas the area controlling the foot is much smaller. Penfield emphasized that this cartoon illustrated the relative size of the representation of each body part in the motor map; he did not claim that each body part was controlled by a single separate part of the motor map.

C. The arm motor map in monkeys has a concentric, horseshoe-shaped organization. Neurons that control the distal arm (digits and wrist) are concentrated in a central core (**pale green**) surrounded by neurons that control the proximal arm (elbow and shoulder; **dark green**). The neuron populations that control the distal and proximal parts of the arm overlap extensively in a zone of proximal-distal co-facilitation (**intermediate green**). (Reproduced, with permission, from Park et al. 2001. Copyright © 2001 Society for Neuroscience.)

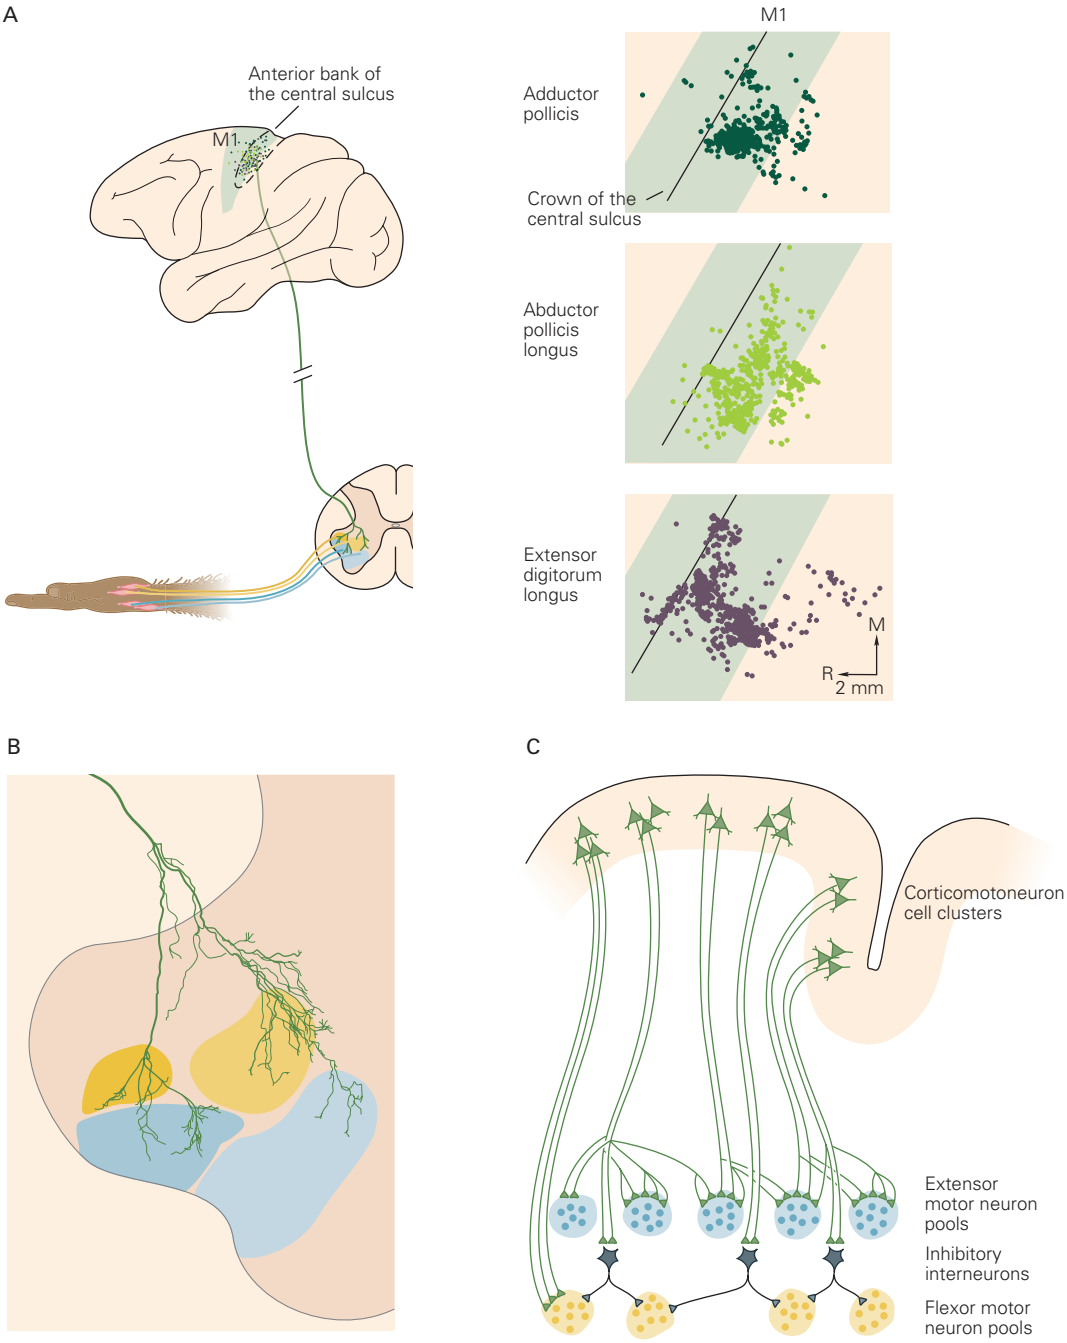

Figure 34–17 **Corticomotoneuronal cells activate complex muscle patterns through divergent connections with spinal motor neurons that innervate different arm muscles.**

A. Corticomotoneuronal (CM) cells, which project monosynaptically to spinal motor neurons, are located almost exclusively within the anterior bank of the central sulcus in the caudal part of the primary motor cortex (**M1**). The CM cells that control a single hand muscle are widely distributed throughout the arm motor map, and there is extensive overlap of the distribution of neurons projecting to different hand muscles. The distributions of the cell bodies of CM cells that project to the spinal motor pools that innervate the adductor pollicis, abductor pollicis longus, and extensor digitorum communis (shown on the right) illustrate this pattern of wide distribution and extensive overlap of CM cells projecting to different muscles. (Abbreviations: **M**, medial; **R**, rostral.) (Reproduced, with permission, from Rathelot and Strick 2006.)

B. A single CM axon terminal is shown arborized in the ventral horn of one segment of the spinal cord. It forms synapses with the spinal motor neuron pools of four different intrinsic hand muscles (**yellow** and **blue** zones), as well as with surrounding interneuronal networks. Each axon has several such terminal arborizations distributed along several spinal segments. (Reproduced, with permission, from Shinoda, Yokota, and Futami 1981.)

C. Different colonies of CM cells in the primary motor cortex terminate on different combinations of spinal interneuron networks and spinal motor pools, thus activating different combinations of agonist and antagonist muscles. Many other corticospinal axons terminate only on spinal interneurons (not shown). The figure shows CM projections largely onto extensor motor neuron pools. Flexor motor pools receive similar complex projections (not shown). (Adapted, with permission, from Cheney, Fetz, and Palmer 1985.)

those for more proximal parts of the arm. The terminal of a CM cell axon often branches and terminates on spinal motor neurons for several different agonist muscles and can also influence the contractile activity of still more muscles through synapses on spinal interneurons (Figure 34–17B,C). This termination pattern is organized to produce coordinated patterns of activity in a *muscle field* of agonist and antagonist muscles. Most frequently, a CM cell axon directly excites the spinal motor neurons for several agonist muscles and indirectly suppresses the activity of some antagonist muscles through spinal inhibitory interneurons (Figure 34–17C). The fact that CM cells are more prominent in humans than in other species may be one of the reasons why lesions of M1 in humans have a more profound effect on voluntary motor control compared to other mammals (Box 34–3).

The complexity of the motor map in M1—as revealed by short trains of electrical stimuli and anatomical and neurophysiological studies of direct and indirect M1 descending outputs targeting single muscles and small muscle groups—shows how motor commands from M1 to the spinal motor apparatus are able to control movements of every part of the body, with special focus on the fingers, hand, arm, face, and mouth in primates.

Activity in the Primary Motor Cortex Reflects Many Spatial and Temporal Features of Motor Output

As already noted, a given action such as reaching for an object can be described on many levels, ranging from the hand's spatial trajectory and velocity to its joint-centered causal forces and muscle activity (Figure 34–1A). Representational models assume that the motor system directly plans and controls specific parameters of movement. They predict that different neural populations encode the intended movement in a parameter space (ie, hand or joint motion or joint muscular torque) and perform the transformations between them. Dynamical models predict that neural circuits control movements through changes in their activation state from its current state to the desired final state. As their activity changes across time, correlates of various parameters and properties of the intended movement can be observed in the activity

Box 34–3 Lesions in Primary Motor Cortex Lead to Impairments in Motor Execution

The effects of primary motor cortex (M1) lesions differ across species. Large lesions in cats do not cause paralysis; the animals can move and walk on a flat open surface. However, they have severe difficulties using visual information to navigate within a complex environment, avoid obstacles, or climb the rungs of a ladder. In cats, the pyramidal tract neurons in M1 are much more strongly activated when an animal must modify its normal stepping motion to clear an obstacle under visual guidance than during normal unimpeded locomotion over a flat, featureless surface (Chapter 33).

Large M1 lesions in monkeys have more drastic consequences, including initial paralysis and usually the permanent loss of independent movements of the thumb and fingers. Monkeys nevertheless recover some ability to make clumsy movements of the hands and arms and to walk and climb.

More focal lesions of M1 typically result in muscle weakness, slowing and imprecision of movements, and discoordination of multi-joint motions, perhaps as a result of selective perturbations of the control circuitry for specific muscles or muscle groups. Lesions limited to part of the motor map, such as the contralateral arm, leg, or face, lead to paralysis of that body part. There is diminished use of the affected body part, and movements of the distal extremities are much more affected than those of the proximal arm and trunk.

The severity of the deficits also depends on the level of required skill. Control of fine motor skills, such as independent movements of the fingers and hand and precision grip, is abolished. Any residual control of the fingers and the hand is usually reduced to clumsy, claw-like, synchronous flexion and extension motions of all fingers, not unlike the unskilled grasps of young infants. Remaining motor functions, such as postural activity, locomotion, reaching, and grasping objects with the whole hand, are often clumsy.

In humans, large motor cortex lesions are particularly devastating, resulting in severe motor deficits or complete paralysis of affected body parts, usually with limited potential for recovery. This presumably reflects the increased importance in humans of descending signals from M1 onto spinal interneuronal circuits and spinal motor neurons and a diminished capacity of other cortical and subcortical motor structures to compensate for the loss of those descending M1 signals.

of single neurons and neural populations. However, the activity of most neurons reflects a combination of parameters that does not correspond to any identifiable parameter in any specific coordinate framework.

Despite their different assumptions, both perspectives suggest that one can infer the possible contribution of different neurons and different neural structures to motor control by studying how their activity correlates with different parameters of movements. The activity of M1 neurons has been intensively studied since the 1960s to try to reveal, for instance, whether M1 generates a high-level signal about the hand motion or a lower-level kinetic signal more related to the causal forces and muscle activity.

Knowledge about the nature of the control signals generated by M1 also helps to clarify the role of other motor structures, notably the spinal cord. If M1 encodes specific information about muscle activity patterns, less computational processing would be necessary at the spinal level. In contrast, if M1 mainly encodes higher-level information about the intended movement, the spinal cord would have to perform the processes that convert this global signal into detailed patterns of muscle activity.

However, one of the major experimental challenges in identifying how M1 controls movement is the fact that virtually all movement-related parameters are intercorrelated through the laws of motion. As a consequence, a particular muscular force (kinetics) will cause a specific motion (kinematics) given an initial condition (posture, movement) of the body. As a result, if one recorded neural activity while a monkey makes reaching movements in different directions, a neuron that theoretically signals the spatial direction of movement will also inevitably show a correlation with the direction of causal forces. Likewise, the contractile activity of a muscle will co-vary systematically with the spatial direction of movement even though it is clearly generating the causal forces. Unless the task design adequately dissociates these different classes of parameters, it will yield ambiguous information about the functional role of each neuron.

Edward Evarts was the first to examine this issue in the 1960s, in pioneering single-neuron recordings in monkeys while they made simple flexion/extension movements of the wrist. Using a system of pulleys and weights, he applied a load to the wrist of the monkey that pulled the wrist in either the direction of flexion or extension in different trials. This required the monkey to alter the level of wrist muscle activity to compensate for the load while making the movements. As a result, the kinematics (direction and amplitude) of wrist movements remained constant, but the kinetics (forces and muscle activity) changed with the load.

Using a microelectrode, he located single neurons in the M1 motor map that modulated their activity when the monkey made movements of the wrist without the external load. In some neurons, their discharge increased during wrist flexion (*preferred movement direction*) and was suppressed during extension, whereas others displayed the opposite pattern. This movement-related activity typically began 50 to 150 ms before the onset of agonist muscle activity, supporting a causal link between M1 neural activity and movement. When a load was applied, many M1 neurons increased their activity when the load resisted movement in their preferred direction and decreased activity when the load assisted the movement (Figure 34–18). These changes in neural activity paralleled the changes in muscle activity required to compensate for the external load.

Subsequent studies have confirmed that the activity of many M1 neurons varies systematically with the magnitude of muscle force output. This is best shown in tasks in which monkeys generate isometric forces against immovable objects that prevent movement. The activity of many M1 neurons, including CM cells, varies with the direction and level of static isometric output forces generated across a single joint, such as the wrist or elbow, as well as during precise pinches using the thumb and index finger (Figure 34–19A). At least over part of the tested range, these responses vary linearly with the level of static force.

Most natural behaviors involve multi-joint, multi-muscle actions. For instance, reaching movements of the arm in different directions requires different patterns of coordinated motions at the shoulder and elbow. Proximal limb muscle activity during reaching shows a roughly cosine pattern of activity with maximal activity in a specific movement direction, its preferred movement direction, that gradually diminishes as the angle between the desired direction of reach and the muscle's preferred direction increases (Figure 34–20A). Like the proximal arm muscles, single neurons related to shoulder and elbow movements respond in a continuously graded fashion during movements in different reach directions centered on a preferred direction of maximal activity (Figure 34–20B). Different neurons have different preferred directions that cover the entire directional continuum around the circle, and during any given movement, neurons with a wide range of preferred directions discharge at different rates.

As Ed Evarts had shown in single-joint tasks, much of the M1 activity during reaching is closely related to the causal kinetics. For instance, in monkeys trained to make reaching movements in eight directions while compensating for external loads that pulled the arm in different directions, the reach-related activity of both

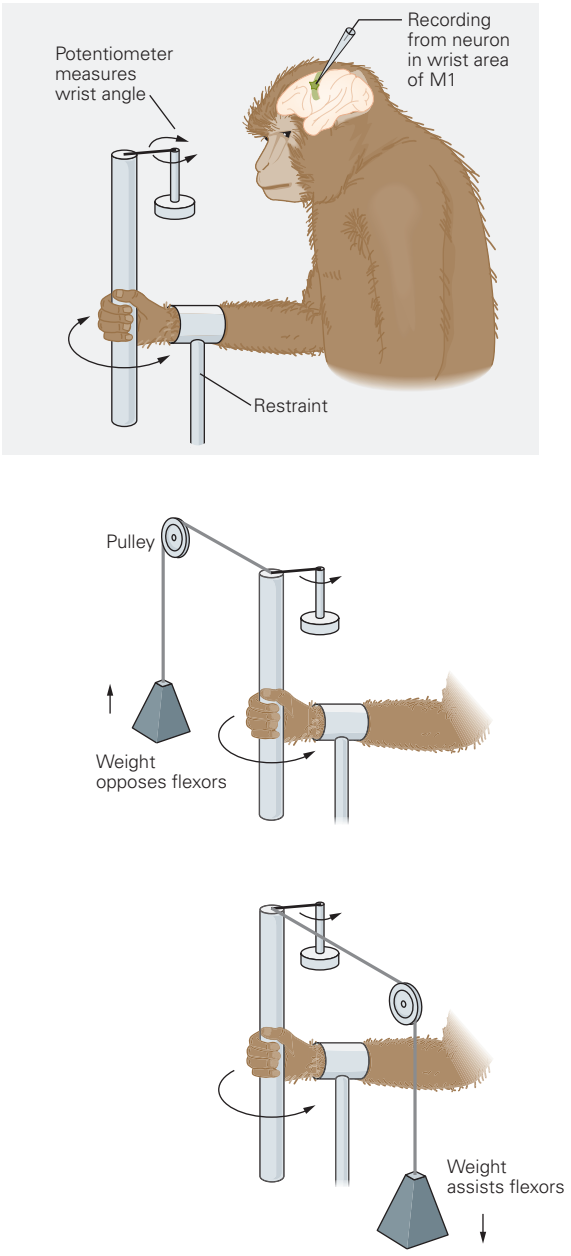

Figure 34–18 Activity of a motor cortex neuron correlates with changes in the direction and amplitude of muscle forces during wrist movements. The records are from an M1 neuron with an axon that projected down the pyramidal tract. The monkey flexes its wrist under three load conditions. When no load is applied to the wrist, the neuron fires before and during flexion (**A**). When a load opposing flexion is applied, the activity of the flexor muscles and the neuron increases (**B**). When a load assisting wrist flexion is applied, the flexor muscles and neuron fall silent (**C**). In all three conditions, the wrist displacement is the same, but the neural activity changes as the loads and compensatory muscle activity change. Thus, the activity of this motor cortex neuron is better related to the direction and level of forces and to muscle activity exerted during the movement than to the direction of wrist displacement. (Adapted from Evarts 1968.)

proximal-arm muscles and many M1 neurons changed systematically with the direction of the external loads and the corresponding corrective forces that the monkeys had to generate for each reach direction. Both muscle and neural activity increased when the load resisted movements in their preferred directions and decreased when the loads assisted those movements. In addition, when a monkey uses its whole arm to exert constant isometric force levels in different directions at the hand, the activity of many M1 neurons varies

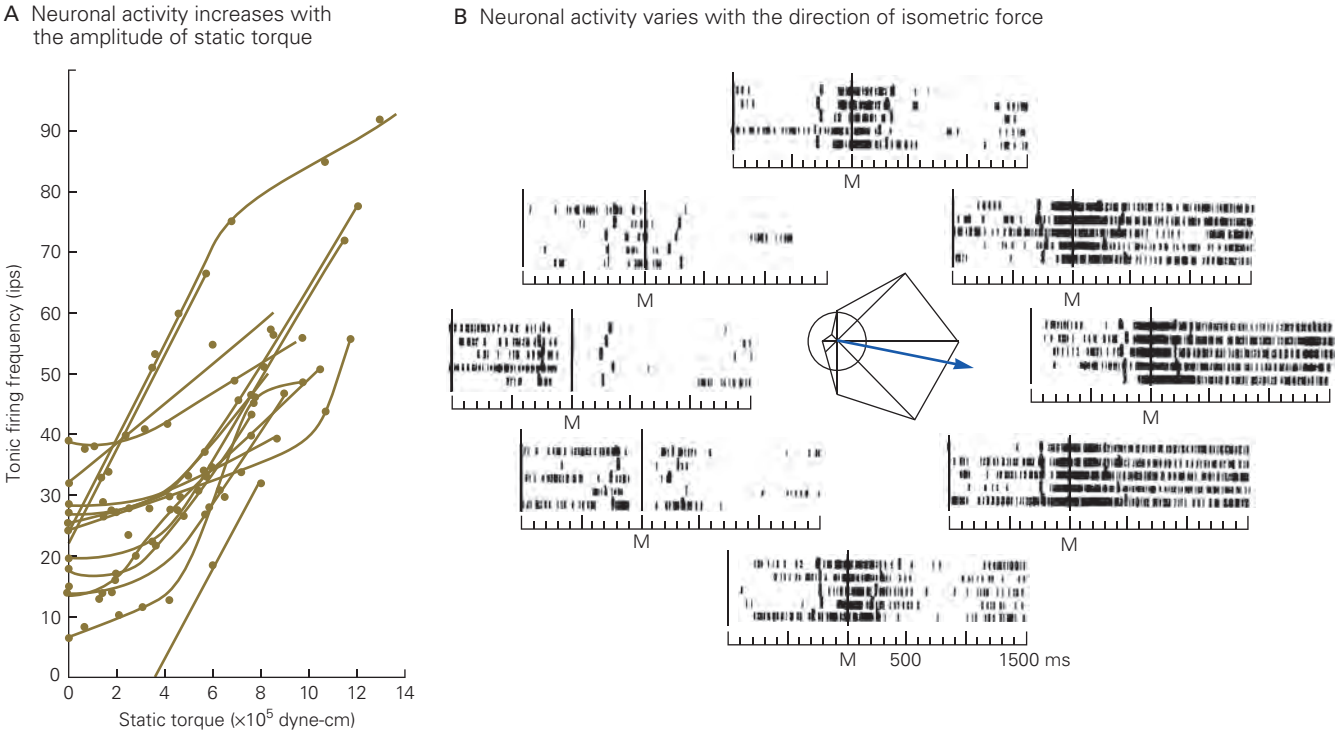

Figure 34–19 Activity in many primary motor cortex neurons correlates with the level and direction of force exerted in an isometric action.

A. The activity of many primary motor cortex neurons increases with the amplitude of static torque generated across a single joint. The plot shows the tonic firing rates of several different corticomotoneuronal cells at different levels of static torque exerted in the direction of wrist extension. Other motor cortex neurons show increasing activity with torque exerted in the direction of wrist flexion, and so would show response functions with the opposite slope (not shown). (Reproduced, with permission, from Fetz and Cheney 1980.)

B. When a monkey uses its whole arm to push on an immovable handle in its hand, the activity of some primary motor cortex neurons varies with the direction of isometric forces. Each of the eight raster plots shows the activity of the same primary motor cortex neuron during five repeated force ramps in one direction. Each row shows the pattern of spikes during a single trial of the task. The position of each raster of activity corresponds to the direction in which the monkey is generating isometric forces on the handle. The onset of the force ramp is indicated by the vertical line labeled **M**. The **thick ticks** on the left of that line in each row indicate when the target appeared on a computer monitor, telling the monkey the direction in which it should push on the handle. The central polar plot illustrates the directional tuning function of the neuron as a function of the direction of isometric forces. (Reproduced, with permission, from Sergio and Kalaska 2003.)

systematically with force direction, and the directional tuning curves for isometric force resemble those for activity during reaching movements (Figure 34–19B).

The complex and nonlinear properties of multisegmented limbs present a major control problem for the motor system. For instance, one can make reaching movements with similar hand trajectories but different arm geometries that require changes in the causal joint-centered torques and muscle activity. In one experiment, when monkeys made horizontal reaching movements along the same planar spatial hand trajectories while holding the arm in different spatial orientations (ie, elbow raised versus lowered), the activity of proximal-arm muscles and many M1 neurons showed corresponding changes in the strength and directional tuning of their reach-related activity. This indicates that the M1 neurons generate signals that take into account the changes in intrinsic limb biomechanics during the reaching movements.

Similarly, arm movements toward or away from the body require much larger angular motion at the shoulder and elbow joints compared to movements to the right or left. In contrast, muscular torques tend to be larger for movements to the right and left. Both of these factors influence the amount of muscle activity required to move the limb, which can be quantified by a single term, joint muscular power (joint angular velocity multiplied by net muscular torque about that joint). With the limb in the horizontal plane, joint power is greatest for movements away from the body and slightly to the left,

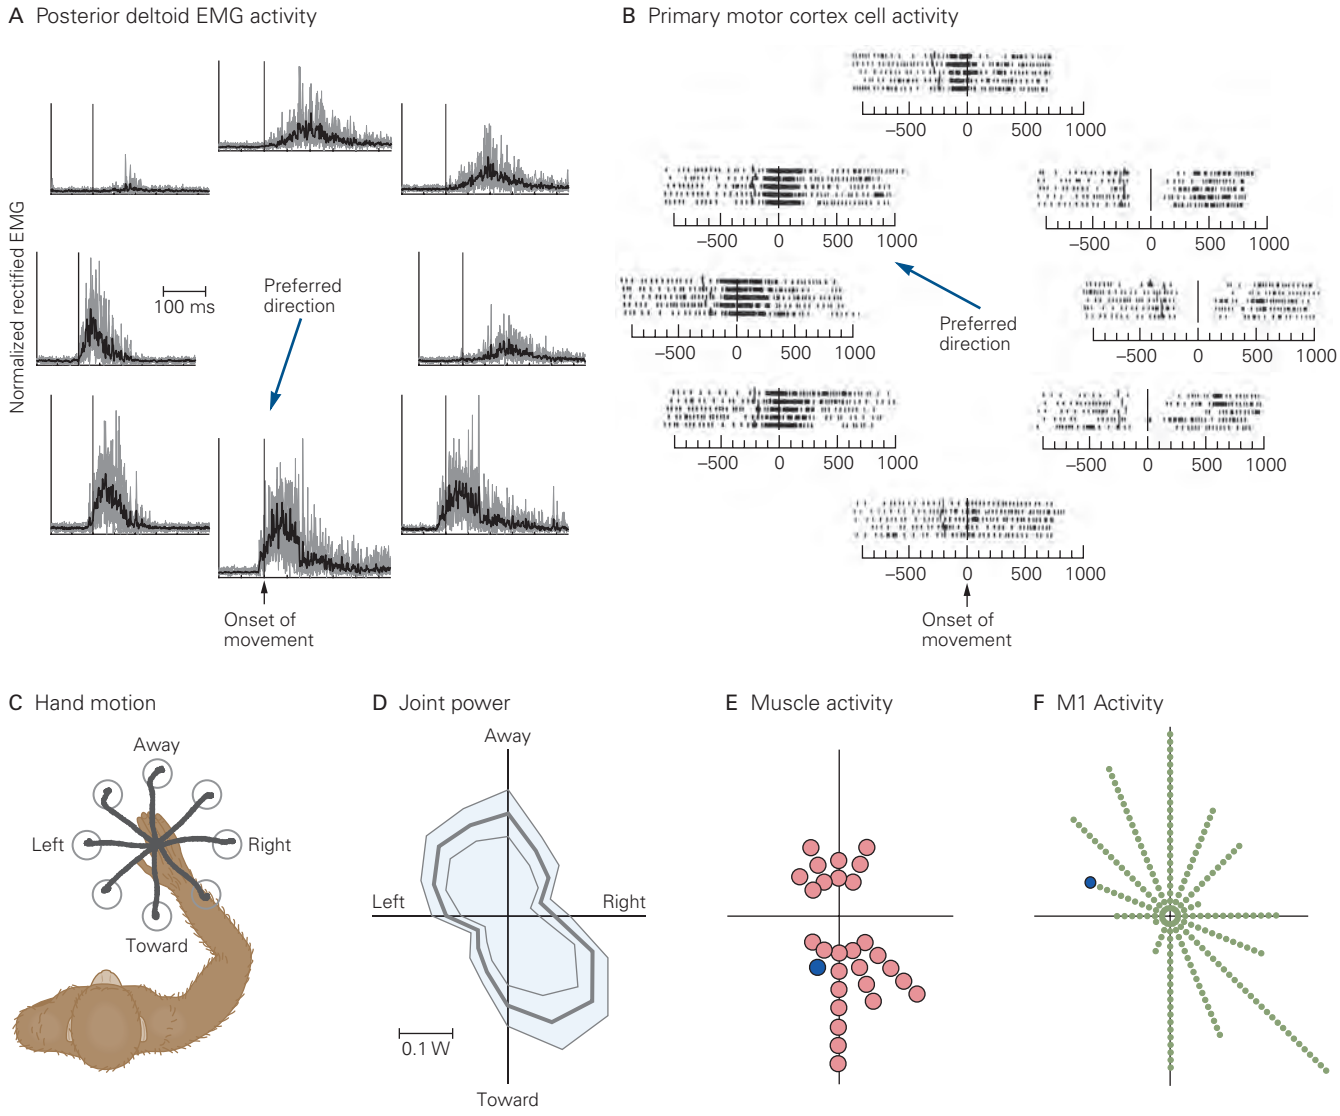

Figure 34–20 Limb muscles and primary motor cortical neurons are broadly tuned to the direction of reaching.

A. Plots show the activity of posterior deltoid of the right arm, a shoulder extensor, during arm movements in eight directions (see panel C) (central panel displays mean hand trajectories). The muscle is initially maximally active for movements at 270° (towards the body, preferred direction = 250°) and diminishes for movements in other directions. **Black lines** denote the mean activity of the muscle across multiple trials, and data are aligned on movement onset (**vertical thin line**). (Abbreviation: **EMG**, electromyography.)

B. Raster plots show the firing pattern of a single primary motor cortex neuron during whole-arm movements in eight directions. The neuron discharges at the maximal rate for movements near 135° and 180° and at lesser intensities for movements in other directions. The cell's lowest firing rate is for movements opposite the cell's preferred direction. Each row of **thin tics** in each raster plot represents the activity in a single trial, aligned at the time of movement onset (time 0); **thick tics**, time of target appearance. (Reproduced, with permission, from Georgopoulos et al. 1982. Copyright © 1982 Society for Neuroscience.)

C. Hand trajectories when reaching from a central position in the horizontal plane.

D. Peak joint power (joint muscular torques multiplied by joint velocity) for movements performed in different spatial directions (shoulder and elbow power added together). A large amount of power is required to reach away from the body and to the upper left and to reach toward the body and to the lower right. (Right X-axis is at 0°.)

E. Preferred directions of proximal-limb muscles tend to be for movements that require greater muscular power, reflecting the obvious link between muscle use and the physical requirements of the motor task. Each **dot** represents an individual muscle binned into 22.5° sectors; the **blue dot** represents the preferred direction of the muscle displayed in panel **A**.

F. Distribution of preferred directions of neurons in primary motor cortex (**M1**). Each **dot** represents an individual neuron, and the **blue dot** represents the preferred direction of the neuron displayed in panel **B**. (Adapted, with permission, from Scott et al. 2001.)

and toward the body and to the right (Figure 34–20C,D). This bias in the physics of limb movement leads to a bias in the preferred directions of shoulder and elbow muscles, which tend to be maximally active in these same directions (Figure 34–20E). Correspondingly, the distribution of preferred directions of neurons in M1 also parallels this bias, with neurons tending to have preferred directions either away and slightly to the left or toward and to the right (Figure 34–20F). Thus, the physics of the limb dictates the pattern of muscle activity needed to generate movement, and this in turn is reflected in the pattern of neural activity in M1.

The impact of limb physics on M1 activity extends to the level of muscle-related signals. The activity of some single M1 neurons, including CM cells, can be correlated with specific components of the contraction patterns of different muscles during such diverse tasks as isometric force generation, precision pinching of objects between the thumb and index finger, and complex reaching and grasping actions (Figure 34–21). These findings highlight how M1 contributes to the specification of muscle activity patterns for motor actions, including onset times and magnitudes. Nevertheless, the final pattern of muscle activity will only be generated by the spinal motor neurons since they alone take into account the additional influence of other descending supraspinal inputs and local spinal interneuronal processes.

All the studies described so far related the activity of single M1 neurons to motor output. However, voluntary motor control is implemented by the simultaneous coordinated activity of many neurons throughout the motor system. Their activity is noisy, varying stochastically between repetitions of the same movement. Furthermore, their broad symmetrical movement-related tuning curves introduce a high level of uncertainty as to what the limb should do in response to the ambiguous signal generated by each neuron.

A simple computational approach was developed to extract a unique signal about each reaching movement by pooling the heterogeneous single-neuron activity of the recorded M1 population. The activity of each neuron is represented by a vector pointing in its preferred direction; the length of the vector varies as a function of its mean discharge rate during reaches in each direction. This vector notation implies that an increase in the activity of a given M1 neuron evokes changes in activity in the spinal motor apparatus and muscles that causes the arm to move along a path corresponding to the neuron's task-related preferred direction; the strength of that single-neuron influence varies systematically with the difference between the neuron's preferred direction and the desired movement (Chapter 39, Figure 39–6). When the reach-related

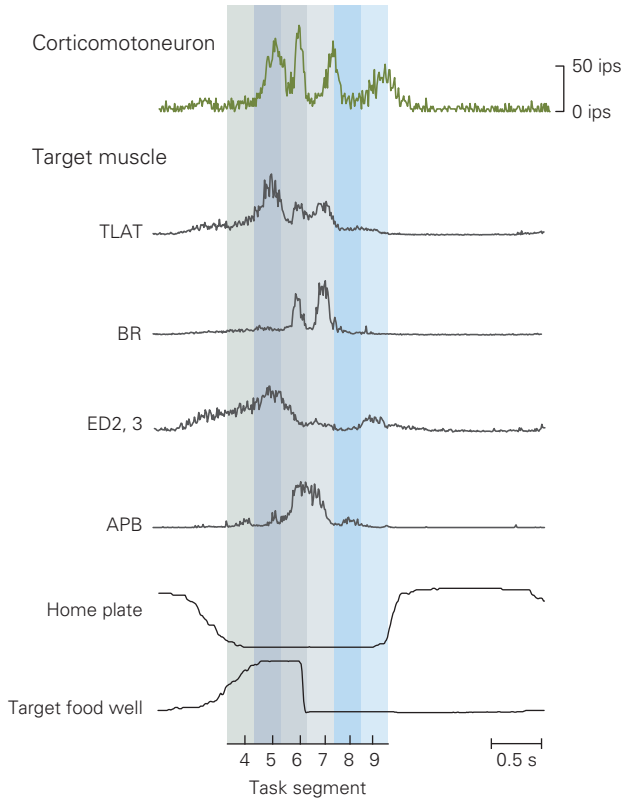

Figure 34–21 The activity of some primary motor cortex neurons can be correlated with particular patterns of muscle activity. Bursts of activity in a single corticomotoneuron during a reach-and-grasp movement to retrieve food pellets from a small well are correlated with bursts of contractile activity in several of its target muscles at different times during the movement. (Abbreviations: **APB**, abductor pollicis brevis; **BR**, brachioradialis; **ED2, 3**, extensor digitorum 2, 3; **ips**, impulses per second;**TLAT**, lateral triceps.) (Reproduced, with permission, from Griffin et al. 2008.)

activity of about 250 M1 neurons was represented by variable-length vectors for each of the eight reach directions and summed, the direction of the net resultant *population vectors* varied systematically with the actual reach directions (Figure 34–22A).

The novel insights of this analysis were that the control of a given reach movement involves coordinated changes in the activity of M1 neurons distributed throughout the M1 arm motor map and that their pooled activity clearly distinguishes the unique identity of each of the reach actions generated by the eight different distributed patterns of population activity. Subsequent studies demonstrated that "instantaneous" population vectors extracted from the pooled activity of large populations of M1 neurons during sequential 20-ms time bins from the start to the end of movement predicted the continually changing trajectory of the

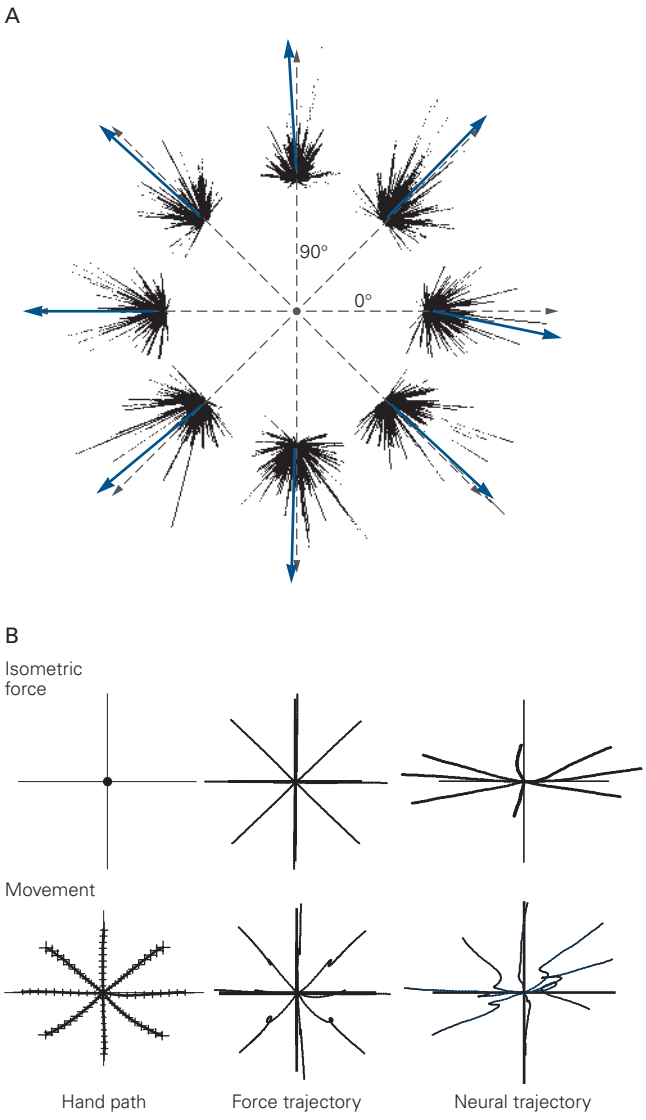

Figure 34–22 Population codes relate M1 activity to different properties of movement.

A. The eight single-neuron vector clusters (**thin black lines**) and the population vectors (**blue arrows**) represent the activity of the same population of cells during reaching movements in eight different directions. Each single-neuron vector points in the neuron's preferred movement direction, and its length is proportional to the discharge of the neuron during that movement. The population vectors were calculated by vectorial addition of all the single-cell vectors in each cluster; **dashed arrows** represent the direction of movement of the arm. (Reproduced, with permission, from Georgopoulos et al. 1983.)

B. Comparison of hand kinematics and kinetics and neural population activity in an isometric task and when moving a handle with a large mass. Force and neural trajectories were generated by linking sequences of 20-ms output force vectors or neural population vectors tip-to-tail for each direction of force or movement output. (Reproduced, with permission, from Sergio et al. 2005.)

arm motions 100 to 150 ms into the future while monkeys made reaching movements or traced spirals on a computer monitor. This showed that the simple vector notation could be used to extract from the activity of populations of neurons a signal about intended motor output even on a moment-to-moment basis. These findings were anticipated by a prescient study in 1970 by Donald Humphrey and colleagues, who showed that the appropriately summed activity of three to five M1 neurons was better correlated to the temporal patterns of motor output during single-joint movements than was the signal of any of the single neurons.

Subsequent studies used the population-vector decoder algorithm to provide further insight into neural processing in M1. In one study, the activity of proximal arm–related M1 neurons was recorded while monkeys performed two tasks (Figure 34–22B). In the first task, they generated isometric force ramps in eight different spatial directions uniformly distributed at 45° intervals in a horizontal plane against a rigid handle that they held in their hand, without arm movements. A 20-ms population-vector decoder was used to extract the net directional bias of the pooled activity of many M1 neurons, and the result showed that these pooled signals varied systematically with the direction of output forces throughout the duration of the force-ramp generation, even though there were no movements. However, unlike the actual uniformly distributed directions of the forces generated by the monkey at the hand, the decoded population-vector signals were skewed toward the *x*-axis. This showed that the M1 activity reflected the nonlinear relationship between causal shoulder muscle torques and measured isometric forces at the hand resulting from the complex biomechanical properties of the arm (see Figure 34–20).

In the second task, the monkeys made reaching movements of the arm in the same eight directions to move a heavy handle. This required an initial accelerative force in the direction of movement and then a transient reversal of the direction of forces to decelerate the movement of their arm and the mass as it approached the target. The decoded M1 population-vector signals in this task varied dramatically through time. They were directed initially toward the target but then transiently reversed just before the peak of hand velocity. This showed once again that the M1 activity was more closely correlated with the time course of causal forces generating the reaching movements, including their transient directional reversal, than to the uninterrupted motion of the hand toward the target. They also found that correlates of the forces to generate reaching were strongest in M1, weaker in PMd, and largely absent in PE/MIP. This indicated that, unlike M1,

reach-related neurons in area PE/MIP generated a reliable signal about stable arm postures and the kinematics of arm movements independent of the underlying causal forces and muscle activity.

Finally, one study has shown that reliable signals about the time-varying activity of proximal-arm muscles during reaching movements can be extracted from the activity of a population of simultaneously recorded M1 neurons. Another study found that the pooled activity of M1 neurons that fire selectively in connection with either shoulder or elbow movements can predict the changes in onset times and levels of contractile activity of the shoulder or elbow muscles during reaches in different directions.

These studies showed that the pooled activity of many M1 neurons is a rich and reliable source of signals about different time-varying attributes of whole-arm movements. This provided an important conceptual foundation for the development of more sophisticated decoder algorithms in brain–machine interfaces that make use of the movement-related information available in the simultaneous activity of many M1 neurons to allow subjects to control the actions of neuroprosthetic devices by covert modulations of M1 neuron activity without overt limb movements (Chapter 39).

Primary Motor Cortical Activity Also Reflects Higher-Order Features of Movement

Activity in M1 is not correlated only with causal forces and muscle activity. Many studies, beginning with those of Ed Evarts, that have attempted to dissociate kinematic from kinetic properties of motor outputs have found that the activity of some M1 neurons varies with the direction of movement but is only weakly influenced or not influenced at all by changes in output forces. Such neurons appear to preferentially signal the kinematic aspects of limb motion.

Changes in behavioral task can influence the relationship between M1 activity and motor output. One study has highlighted how contextual changes in an isometric force task altered the coding of force magnitude by M1 neurons. Either the order of forces or the range of expected forces results in changes in the activity in M1. They suggested that M1 neurons could dynamically adjust their relationship to output forces to optimize precision of control as a function of the range of forces that would be encountered in a given context. Another study found that many CM neurons may discharge intensely when monkeys performed precisely controlled force tasks with low force levels but are relatively inactive when the monkeys generate powerful contractions of the same muscles to make brisk, back-and-forth movements of the handle. Likewise, a study demonstrated that CM cells in M1 could be very active when monkeys generated a precision-pinch grip of the thumb and index finger with relatively low force output, but were much less active or nearly silent when the animals generated much larger forces with a power grip involving the entire hand.

Still another study has shown that some M1 neurons that respond to loads applied to the limb during postural control can lose this load sensitivity as soon as the monkey makes a reaching movement to another spatial target, and vice versa. That is, those neurons can reflect output forces during postural control, but reflect only kinematics during movement. This change in the cell's response occurs quite abruptly, about 150 ms before the onset of movement. Importantly, any neurons that are sensitive to loads during both posture and movement will retain the same motor field across behaviors; that is, if the neuron responds only to shoulder flexor loads during postural control, it will respond only to shoulder flexor loads during reaching.

Even a simple change in the metrics of limb movement can have a large influence on M1 activity. In a study of monkeys making slow or fast reaching movements in different directions from a central target to peripheral targets, proximal limb muscles displayed relatively simple scaling of their activity patterns, reflecting increased forces for faster and longer reaches. In contrast, M1 neurons displayed a broad range of changes in their activity patterns that rarely paralleled the pattern of changes observed for muscles.

Activity in neurons can also correlate with higher-level features of movement such as the nature of an upcoming motor action. This was demonstrated in a study in which monkeys were trained to make wrist movements to three targets in a row starting from one extreme, stopping at a central position, and then finishing at the other extreme. Visual cues instructed the monkeys when to make each movement. Because the task used a predictable sequence of wrist movements, the monkeys knew before the visual cues appeared what would be the next direction of movement. While many M1 neurons signaled the current wrist posture or the direction of each movement while they were being performed, some M1 neurons reliably signaled the next movement in the sequence before the visual cue appeared. Many subsequent studies have confirmed that M1 neurons can signal impending intended movements, although these planning-like signals are not as prominent in M1 as in premotor cortical areas.

In summary, neural recording studies have revealed a diverse range of response properties within

and across movement-related cortical areas, with stronger correlations to causal movement kinetics in M1 and to higher-order motor parameters in premotor and parietal cortex. However, these experimental findings have not yet led to a single unifying hypothesis about how cortical motor circuits control voluntary movements. Part of this uncertainty may result from inadequacies in experimental task design.

Representational motor-control models have interpreted these complex results as evidence of the transformations between different levels of representation of intended movements performed by neural populations distributed across different cortical motor areas. In contrast, nonrepresentational motor-control models such as optimal feedback control argue that these same results can only be interpreted as evidence of when and where neural correlates of different motor output parameters emerge in the dynamical activity distributed across cortical motor areas but do not shed much insight into the underlying neural computations. This illustrates the experimental challenges still confronting researchers as they try to reverse engineer the cortical motor circuitry to reveal its internal computational organization.

Sensory Feedback Is Transmitted Rapidly to the Primary Motor Cortex and Other Cortical Regions

Postcentral and posterior parietal cortex provide much of the sensory information related to the position and motion of the body and the location of spatial goals that is important in voluntary motor control, although the cerebellum is likely another important source (Chapter 37).

The type of afferent information transmitted to M1 differs between the proximal and distal portions of the limb. Afferent input from cutaneous and muscle sensory neurons is equally prevalent for hand-related neurons, reflecting the importance for both sources of sensory feedback when grasping and manipulating objects with the hand. Muscle afferents provide the major source of feedback from the proximal limb. Information from muscles is more prevalent in the rostral M1, whereas cutaneous input is more common in the caudal M1. Muscle afferent feedback to M1 is surprisingly rapid as it takes as little as 20 ms for M1 neurons to respond following a mechanical disturbance to the limb. Analogous to reaching, neural activity is broadly tuned to the direction of the mechanical disturbance.

Sensory feedback supports our ability to make rapid goal-directed corrections for motor errors that arise during movement planning and execution or are caused by unexpected disturbances of the limb. When a perturbing mechanical load is applied to the limb, the motor system generates a multipeaked compensatory electromyographic response, beginning with a short-latency stretch response (20–40 ms after the perturbation), followed by a long-latency response (50–100 ms) and then a so-called "voluntary" response (≥100 ms). The short latency of the initial response indicates that it is generated at the spinal level. The response is relatively small and stereotyped, and its intensity scales with the magnitude of the applied load. In contrast, motor corrections beginning in the long-latency epoch (50–100 ms) are modulated by a broad range of factors necessary to attain a behavioral goal, including the physics of the limb and environment, the presence of obstacles in the environment, the urgency of the goal, and properties of the target, including alternate goals. These context-dependent features suggest the long-latency feedback epoch is an adaptive process in which the control policy (ie, feedback gains) is adjusted based on the behavioral goal, as predicted by the optimal feedback control model.

The ability of the motor system to rapidly generate these goal-directed long-latency motor responses is supported by a transcortical feedback pathway. Neural activity across frontoparietal circuits responds rapidly to mechanical disturbances to a limb, and the pattern of activity across the cortex depends on the behavioral context. Perturbation-related activity is observed in all cortical regions beginning at approximately 20 ms after the disturbance even if the monkey is distracted by watching a movie and does not have to respond to the disturbance (Figure 34–23A,B). If the monkey is actively maintaining its hand at a spatial goal, there is an immediate increase in the neural response in parietal area PE following the disturbance, followed shortly thereafter by changes in activity in other cortical regions (Figure 34–23A,B). If the disturbance is a cue that instructs the monkey to move to another spatial target, then M1 activity reflects the need for a more vigorous response if the disturbance knocks the hand away from the target compared to knocking the hand into the target (Figure 34–23C). In contrast, perturbation-related activity in PE remains similar regardless of target location.

The Primary Motor Cortex Is Dynamic and Adaptable

One of the most remarkable properties of the brain is the adaptability of its circuitry to changes in the environment—the capacity to learn from experience and to store the acquired knowledge as memories. When human subjects practice a motor skill, performance improves.

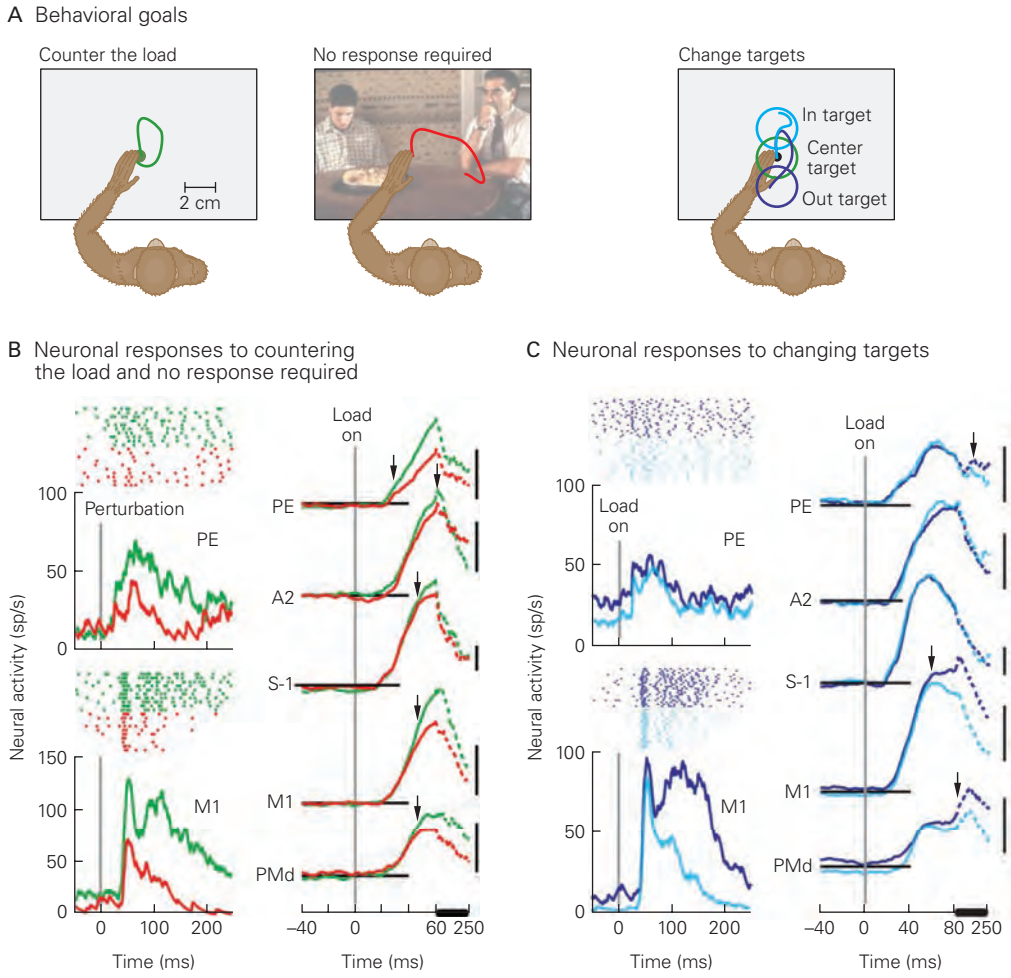

Figure 34–23 **Changes in behavioral goals alter rapid sensory feedback to parietal and frontal motor cortices.** (Reproduced, with permission, from Omrani et al. 2016. A. In the experiment described here, the responses of cortical regions to mechanical loads randomly applied to the arm are compared. In the *left* panel, motor corrections return the hand to the spatial goal following the disturbance (**green hand trajectory**). In the *middle* panel, the monkey watches a movie and does not have to respond to the disturbance, leading to the hand remaining to the right following the disturbance (**red hand trajectory**). In the *right* panel, the monkey places its hand at a central start target, and one of two other targets is also presented. The disturbance applied to the limb is a cue for the monkey to move to this second target with its position being either in the direction of the disturbance (**cyan** "in target" trajectory) or away from the disturbance (**blue** "out target" trajectory).

B. *Left:* Response of a neuron in PE and in M1 when a mechanical load was applied to the limb and the monkey had to counter the load and return the hand to a spatial target (**green**) or was not required to respond to the disturbance (**red**). *Right:* Population signals in each cortical region in response to perturbations. Note how all cortical areas show an increase in activity approximately 20 ms after the applied load. **Arrows** denote when activity was different when the monkey had to respond to the disturbance (**green curve**) as compared to not being required to respond to the disturbance (**red curve**). Note that PE is the first to show a difference in activity between the two conditions. Other cortical areas show changes at 40 ms or later. **A2** is a subregion of S-I. (For B and C: Vertical scale bars, 20/spikes/s); Activity between 60–250 ms (**thick horizontal line**) compressed for visualization purposes.)

C. *Left:* Responses of single neurons in PE and M1 when a mechanical load was a cue and instructed the monkey to move to another target. The disturbance either pushed the hand toward the target (**cyan**) or away from it (**blue**). *Right:* Population signals based on perturbation-related activity in each cortical region for the "in target" and "out target" conditions. The initial responses are similar for both "in target" and "out target" disturbances across all cortical areas, and **arrows** denote when there is a difference in activity between conditions. M1 is the first to display an increase in activity for the "out target" disturbance just prior to changes in muscle activity moving the hand to the spatial target.

Motor experience can also modify the motor map. In monkeys trained to use precise movements of the thumb, index finger, and wrist to extract treats from a small well, the area of the motor map in which intracortical microstimulation (ICMS) could evoke movements at these joints was larger than before training (Figure 34–24). If a monkey did not practice the task for a lengthy period, its skill level decreased, as did the cortical area from which the trained movements could be elicited by ICMS. Similar modifications of the

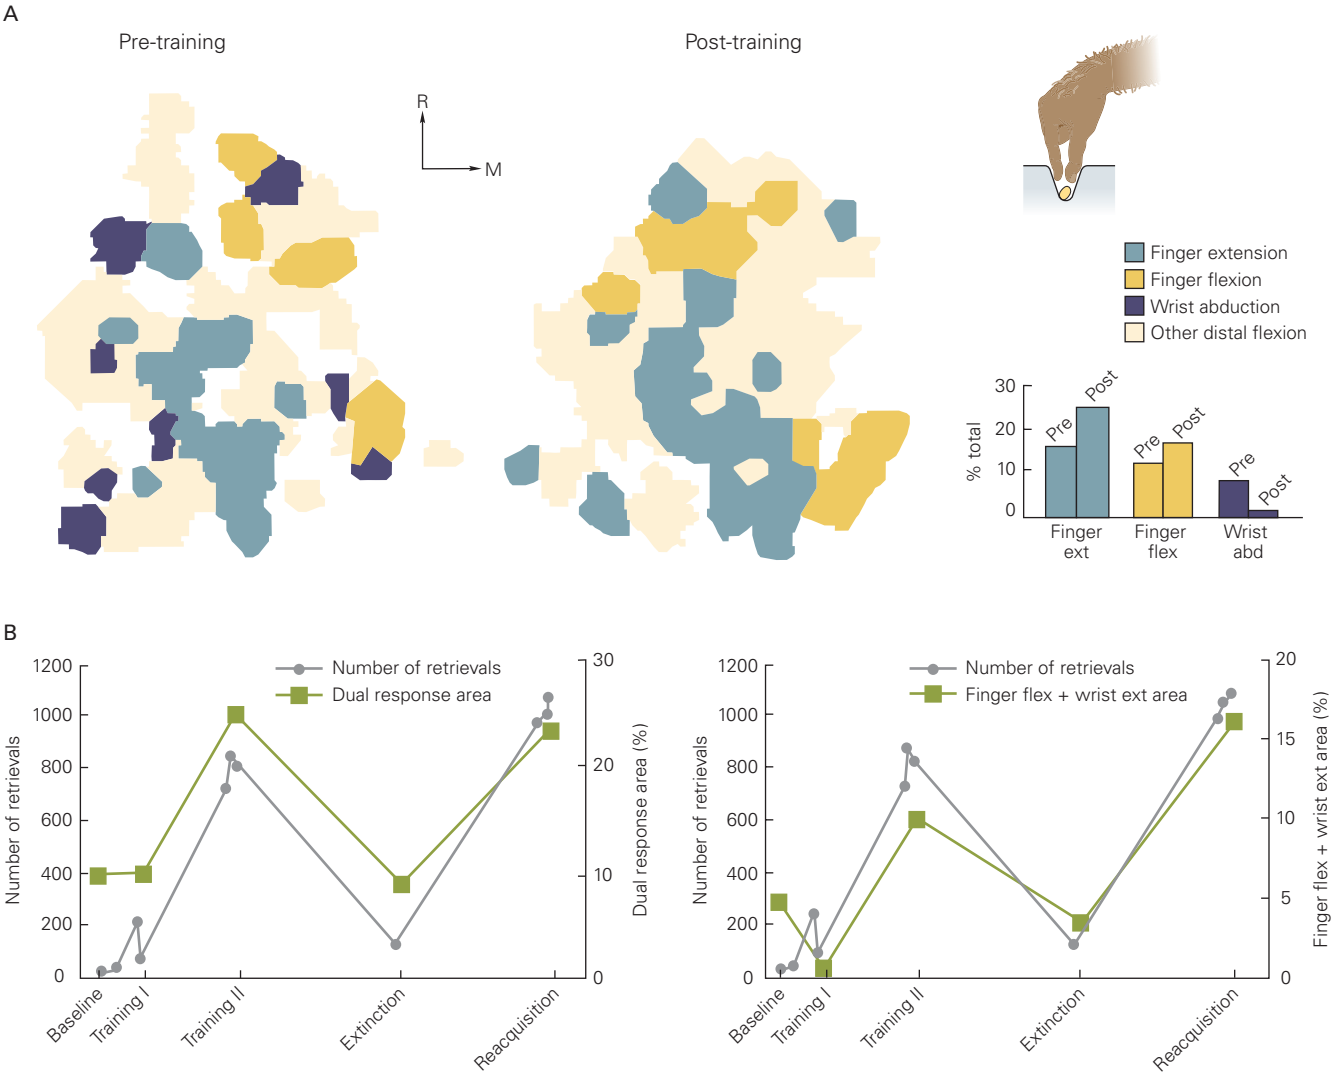

Figure 34–24 Learning a motor skill changes the organization of the M1 motor map. (Reproduced, with permission, from Nudo et al. 1996. Copyright © 1996 Society for Neuroscience.)

A. Motor maps for the hand in a monkey before and after training on retrieval of treats from a small well. Before training, areas of the motor map that generate index finger and wrist movements occupy less than half of a monkey's motor map. After training, the area from which the trained movements can be evoked by intracortical microstimulation expands substantially. The area of the map from which one could elicit individuated movements such as finger extension and flexion has expanded considerably, while the areas controlling wrist abduction, which this monkey used less in the new skill, became less prominent. (Abbreviations: **M**, medial; **R**, rostral.)

B. The areas of the motor output map parallel the level of performance (number of successful pellet retrievals) during acquisition of the motor skill and extinction (due to lack of practice). Two areas were tested: a "dual response" area (*left plot*), from which any combination of finger and wrist motions could be evoked, and an area from which the specific combination of finger flexion and wrist extension could be evoked (*right plot*). Both areas increased as the monkey's skill improved with practice and decreased as the monkey's skill was extinguished through lack of practice. These data are from a different monkey than the one in part **A** but trained for same task.

cortical representation of practiced actions in humans have been demonstrated by functional imaging and transcranial magnetic stimulation.

At least some of the processes contributing to these changes to the motor map are local to M1 itself. One of the mechanisms contributing to the cortical reorganization underlying improved reach-to-grasp performance in rodents involves changes in synaptic strength similar to long-term potentiation and depression within the local horizontal connections linking different parts of the arm motor map. It has been shown that spike-triggered ICMS could cause specific alterations to the M1 motor output map even without specific training. For instance, one study first identified two different cortical sites (A and B) that caused contractions of different muscles (muscle A and muscle B, respectively) when electrically stimulated. They then recorded the activity of a neuron at site A; whenever that neuron fired, they stimulated site B. Within a day or two of this ICMS conditioning at site B, electrical stimulation of site A was able to cause simultaneous contractions of both muscles A and B. The change likely resulted from a spike-timing dependent increase in synaptic strength that was limited to the horizontal cortical projection from site A to site B. Electromyographic responses elicited by ICMS at a third site that did not receive similar conditioning did not change, confirming that the effect was not generalized.

Motor adaptation to visual or mechanical disturbances has been studied extensively in human subjects (Chapter 30). Neural-recording studies have demonstrated that these alterations lead to changes in the activity of M1 neurons in monkeys as the animals adapt to the perturbations. For instance, when monkeys make reaching movements in a predictable external force field that pushes on the arm in a direction perpendicular to the direction of movement, their initially curved reach trajectories get straighter. As this adaptation evolves, large increases gradually arise in the activity of M1 cells whose preferred directional tuning is opposite to the applied force field. The magnitude of such adaptation-dependent changes in activity diminishes progressively as the angle between the force direction and cell preferred direction increases, following a cosine-like function. This shows that the adaptive changes were specific to the neurons that would make the greatest contribution to compensate for the external force field.

Another example of selective changes in M1 activity during motor learning comes from a visuomotor learning study in which visual feedback from a computer monitor is rotated 90° clockwise such that movements of a monkey's arm to the right result in downward movement of the cursor. Initially, the monkeys make arm movements in the original direction aimed at the visual target location, with corrections made online after movement onset. However, with practice, the monkeys begin to move in a new direction rotated counterclockwise to the visual target so that the cursor moves directly to the target. When training occurs for only one direction, learning generalizes poorly to other directions, suggesting that the adaptive changes occur only in neurons that evoke the adapted movement. The tuning curves of neurons with preferred directions near the learned direction were altered during training, whereas neurons with other preferred directions were not affected by the training. This confirmed that the adaptation was local, consistent with the findings of the force-field adaptation study, and explained why adaptation to the visuomotor rotation in one direction generalized poorly to other directions.

Motor-error signals in the precentral cortex also play an important role in trial-by-trial motor adaptation based on feedback learning. In one study with monkeys, an adjustable prism was used to displace the apparent location of the reach target in the environment. Visual feedback of the target and arm were blocked during the reaching movements, leading to systematic errors in touching the target. The monkeys were allowed to see visual feedback of the position of the hand relative to the target for a brief period of time at the end of movement (Figure 34–25). Activity in M1 and PMd during that brief period of visual feedback after movement reflected the direction of reach end-point errors and could be involved in adapting reaching movements to correct these errors. To test that hypothesis, ICMS was then used in M1 and PMd to simulate those error responses and showed that the monkeys began to make adaptive changes in their reaching movements to compensate for the simulated errors even though no reaching error was actually made.

Some motor skills are relatively easy to learn, such as compensation for a visuomotor rotation. Others, however, are very difficult to learn. Recent studies examined this discrepancy by first measuring the activity of a population of M1 neurons as the monkey moved a cursor on a computer screen using a brain–machine interface and a neural activity decoder. This population-level mapping between M1 activity and cursor motion was then altered by changing the association between the directional tuning of each neuron and cursor motion in the decoder. When the altered decoder mapping retained the normal co-modulation structure of neural activity, as would be the case for instance if the mapping between the activity of all

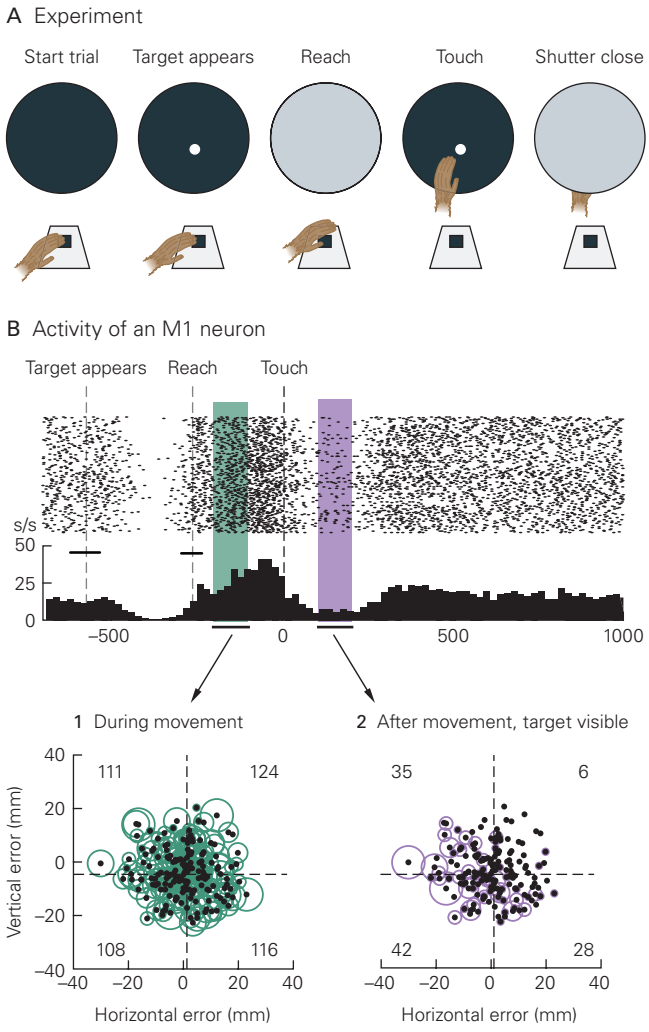

Figure 34–25 (right) **Error signals in the primary motor cortex drive adaptation.** After a movement is complete, M1 activity reflects the error between the spatial target and final hand position. A. Monkeys made reaching movements to spatial targets on a touch screen. On each trial, adjustable prism goggles shifted the viewed position of the spatial target by a variable amount during the movement, while a shutter blocked vision of the monkey's hand and the target. Feedback of the final hand position was only provided for 300 ms after contact with the touch screen at the end of movement.

B. Top: Discharge response of a typical M1 neuron. Raster plots and spike-timing histograms are aligned with the initial screen contact (touch).

1. Distribution of reach endpoint errors (**black dots**) where the origin represents the center of the target. **Diameters of green circles** denote the firing rate of the neuron during each movement (**green bar** in **B**); the firing rates were unrelated to the subsequent endpoint error. The numbers in each quadrant indicate the summed spike activity during movements that ended in the corresponding quadrant; they are all nearly equal.

2. Same as in part **B** except **purple circles** denote firing rate 100 to 200 ms after movement while the monkey can see its hand while touching the screen (**purple bar** in part **B**). The circles and spike counts show that the firing rate is greatest for endpoint errors down and to the left relative to the position of the target (0,0), revealing that that the neural activity during this postmovement period is strongly modulated by visual feedback of reach endpoint error.

neurons and cursor motions was rotated clockwise by 45°, the monkeys showed significant adaptation to the perturbation within a few hundred trials during a single recording session. In contrast, when the perturbation required the monkeys to learn a more complex "unnatural" remapping, for instance, random clockwise and counterclockwise rotations of the apparent directional tuning of neurons by different amounts, the monkeys showed little ability to recover proficient cursor control over several hundred trials in a single recording session. Importantly, another study found that monkeys could eventually master an "unnatural" change in an M1 neural activity decoder mapping if they could practice with the same altered decoder over several days, indicating that they could learn a new neural co-modulation structure if allowed enough experience with it. These studies reinforce how neural circuits in these cortical motor regions are critical for motor skill learning.

The studies just described used brain–machine interfaces and neural decoders to explore how single neurons and neural populations contribute to motor skill learning. This technology promises to be an increasingly important research tool for developing new insights into the neural mechanisms of voluntary motor control and motor skill learning (Chapter 39).

Highlights

1. Voluntary motor behavior implements an individual's intentional choice or decision to move within, and to interact physically with objects in, the environment. A hallmark of human motor action is the breadth of skills we possess and, when highly practiced, the ease and automaticity of these actions.
2. Voluntary motor control has long been separated into two stages—planning and execution—that

can be dissociated in time. Neural recording studies have found correlates of these two stages differentially distributed across many movement-related cortical areas.

3. The overall computational problem that the motor system must resolve to control voluntary movement is to convert sensory information about the current state of the world and the body into plans for action and ultimately into patterns of muscle activity that generate the causal forces required to execute the desired movement(s), while avoiding or correcting for errors.
4. Representational models of voluntary motor control such as the sensorimotor coordinate transformation hypothesis assume that the motor system directly plans and controls specific features or parameters of intended movements. Single neurons and neural populations express those parameters in their activity and perform definable computations to effect the transformations between the controlled movement parameters in corresponding coordinate frameworks.
5. Dynamical systems models of voluntary motor control, in contrast, assume that motor circuits find empirical solutions for the computations underlying the planning and execution of movements by evolutionary and individual adaptive processes. One recent theory, optimal feedback control, proposes that planning and execution of voluntary movements involve three functional processes, namely, state estimation, task selection, and a control policy. Single neurons and neural populations contribute to voluntary motor control by participating in the computations underlying these three processes.
6. Distributed frontoparietal circuits in cerebral cortex play a pivotal role in voluntary control. There are substantial reciprocal axonal interconnections between frontal and parietal cortical regions, partially segregated based on body part (eg, hand, arm, eye). Frontal motor and parietal cortical regions both directly influence spinal processing through the corticospinal tract and indirectly through brain stem descending pathways.
7. Posterior parietal cortex plays a prominent role in identifying potential goals and objects in the environment, state estimation of the body, and sensory guidance of motor actions. Important sources of sensory signals are transmitted from visual cortex through the dorsal visual pathway and from primary somatosensory cortex. Behavioral goals and objects are represented in many parietal subregions, but how they are represented (relative to the orientation of the eye, head, or arm) varies across subregions. The presence of multiple representations provides a rich basis for defining the movement-relevant properties and the locations of objects in the world and relative to the body that can be used to select and guide movement.
8. Premotor and prefrontal cortices play a prominent role in task selection and motor planning. The dorsal and ventral premotor regions are often implicated when external sensory information plays a dominant role in selecting motor actions. In contrast, more medial premotor regions, such as the supplementary and cingulate motor areas, may play a more dominant role when internal desires are more critical in selecting and initiating a motor action. However, this dichotomy is not absolute, and multiple premotor and prefrontal cortical areas all contribute to the control of voluntary behavior in a broad range of contexts and conditions.
9. Primary motor cortex in primates has a representation of the entire body along its mediolateral axis, with larger cortical territories associated with the hand and face relative to other body parts. This cortical region also provides a large component of the corticospinal tract and has projections to both interneurons and alpha motor neurons in the spinal cord.
10. Neural activity that reflects the causal forces and the spatiotemporal features of muscle activity necessary to move the limb is particularly prominent in the primary motor cortex and can be rapidly altered to correct movement errors or to compensate for displacements of the limb away from the desired movement if the limb is perturbed. However, neural activity in primary motor cortex can also show more complex properties, reflecting changes based on the behavioral context, performance goals and constraints, and features such as movement kinematics. These properties of primary motor cortex activity may reflect the formation of a task-specific control policy within the motor system.
11. Although parietal, premotor, and primary motor cortical regions play prominent roles in state estimation, motor planning, and motor execution, respectively, they are not uniquely responsible for any one aspect; they are instead distributed to some degree across most or all of these cortical regions.
12. The cortical motor system is adaptive and can undergo changes in its functional architecture to adapt to long-term changes in the physical

properties of the world and the body, as well as acquire, retain, and recall new motor skills.

13. New technologies such as large-scale multi-neuron recording and imaging methods, enhanced multi-neuron activity decoding algorithms, and optogenetic control of the activity of specific neural populations will lead to deeper insights into the functional architecture of cortical motor circuits.

The Control of Gaze

In preceding chapters, we learned about the motor systems that control the movements of the body in space. In this and the next chapter, we consider the motor systems that control our gaze, balance, and posture as we move through the world around us. In examining these motor systems, we will focus on three biological challenges that these systems resolve: How do we visually explore our environment quickly and efficiently? How do we compensate for planned and unplanned movements of the head? How do we stay upright?

In this chapter, we describe the oculomotor system and how it uses visual information to guide eye movements. It is one of the simplest motor systems, requiring the coordination of only the 12 evolutionarily old muscles that move the two eyes. In humans and other primates, the primary objective of the oculomotor system is to control the position of the fovea, the central point in the retina that has the highest density of photoreceptors and thus the sharpest vision. The fovea is less than 1 mm in diameter and covers less than 1% of the visual field. When we want to examine an object, we must move its image onto the fovea (Chapter 22).

The Eye Is Moved by the Six Extraocular Muscles

Eye Movements Rotate the Eye in the Orbit

To a good approximation, the eye is a sphere that sits in a socket, the orbit. Eye movements are simply rotations of the eye in the orbit. The eye's orientation can be defined by three axes of rotation—horizontal, vertical, and torsional—that intersect at the center of the eyeball, and eye movements are described as rotations

around these axes. Horizontal and vertical eye movements change the line of sight by redirecting the fovea; torsional eye movements rotate the eye around the line of sight but do not change where the eyes are looking.

Horizontal rotation of the eye away from the nose is called *abduction*, and rotation toward the nose is *adduction* (Figure 35–1A). Vertical movements are referred to as *elevation* (upward rotation) and *depression* (downward rotation). Finally, torsional movements include *intorsion* (rotation of the top of the cornea toward the nose) and *extorsion* (rotation away from the nose).

Most eye movements are conjugate; that is, both eyes move in the same direction. These eye movements are called *version* movements. For example, during gaze to the right, the right eye abducts and the left eye adducts. Similarly, if the right eye extorts, the left eye intorts. When you change your gaze from far to near, the eyes move in opposite directions—both eyes adduct. These movements are called *vergence* movements.

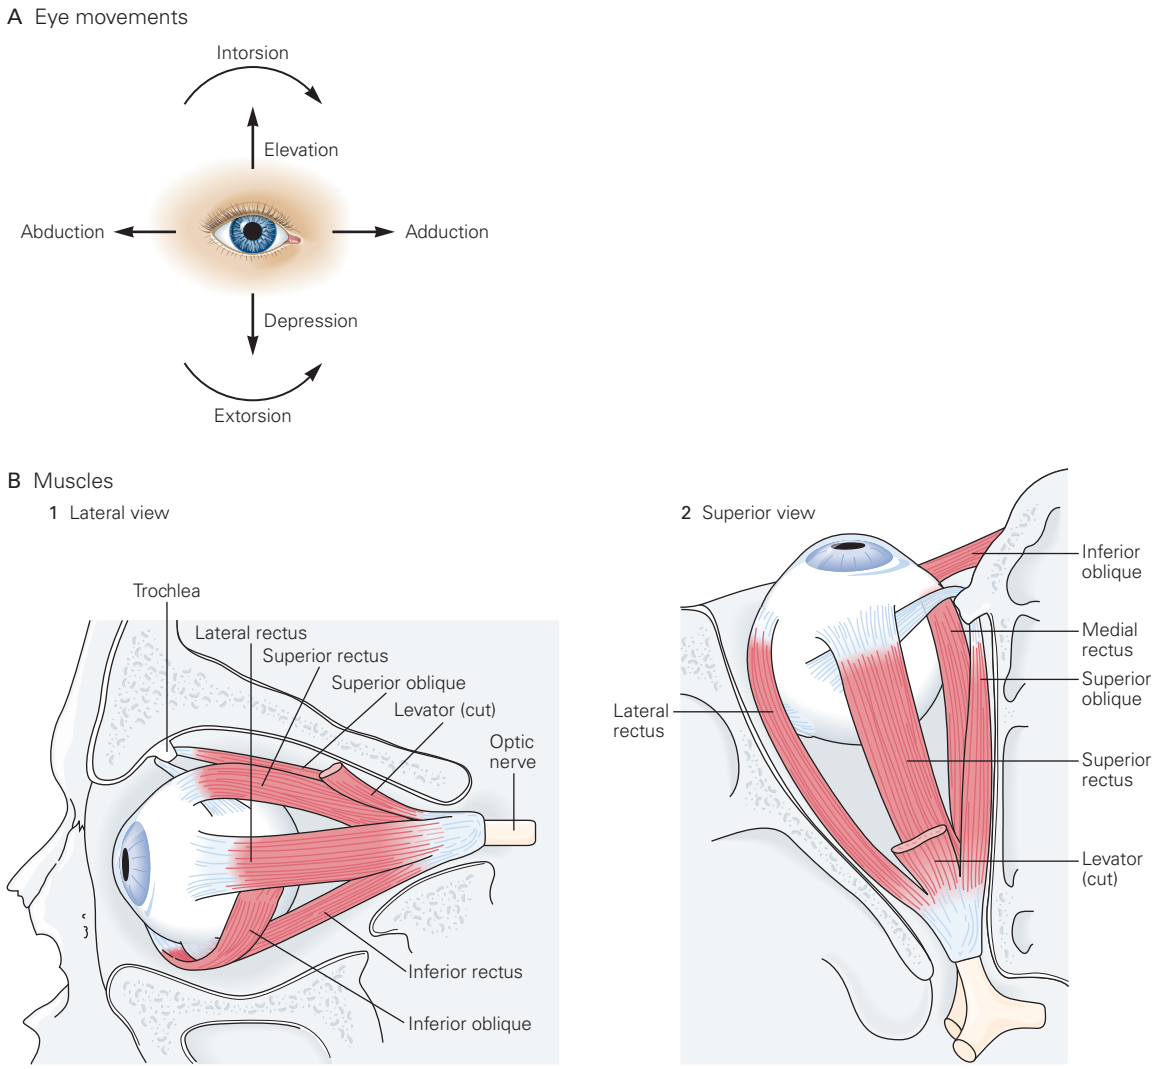

Figure 35–1 The different actions of eye movements and the muscles that control them.

A. View of the left eye and the three dimensions of eye movement.

B. 1. Lateral view of the left eye with the orbital wall cut away. Each rectus muscle inserts in front of the equator of the globe so that contraction rotates the cornea toward the muscle. Conversely, the oblique muscles insert behind the equator, and contraction rotates the cornea away from the insertion. The superior oblique tendon passes through the trochlea, a bony pulley on the nasal side of the orbit, before it inserts on the globe. The levator muscle of the upper eyelid raises the lid. 2. Superior view of the left eye with the roof of the orbit and the levator muscle cut away. The superior rectus passes over the superior oblique and inserts in front of it on the globe.

The Six Extraocular Muscles Form Three Agonist–Antagonist Pairs

Each eye is rotated by six extraocular muscles arranged in three agonist–antagonist pairs (Figure 35–1B). The four rectus muscles (lateral, medial, superior, and inferior) share a common origin, the annulus of Zinn, at the apex of the orbit. They insert on the surface of the eye, or sclera, anterior to the center of the eye, so the superior rectus elevates the eye and the inferior rectus depresses it. The origin of the inferior oblique muscle is on the medial wall of the orbit; the superior oblique muscle's tendon passes through the trochlea, or pulley, before inserting on the globe, so that its effective origin is also on the anteromedial wall of the orbit. The oblique muscles insert posterior to the center of the eye, so the superior oblique depresses the eye and the inferior oblique elevates it.

Each muscle has a dual insertion. The part of the muscle farthest from the eye inserts on a soft-tissue pulley through which the rest of the muscle passes on its way to the eye. When the extraocular muscles contract, they not only rotate the eye but also change their pulling directions as a result of these pulleys.

The actions of the extraocular muscles are determined by their geometry and by the position of the eye in the orbit. The medial and lateral recti rotate the eye horizontally; the medial rectus adducts, whereas the lateral rectus abducts. The superior and inferior recti and the obliques rotate the eye both vertically and torsionally. The superior rectus and inferior oblique elevate the eye, and the inferior rectus and superior oblique depress it. The superior rectus and superior oblique intort the eye, whereas the inferior rectus and inferior oblique extort it.

The superior and inferior recti and the obliques are often called the cyclovertical muscles because they produce both vertical and torsional eye rotation. The relative amounts of each rotation depend on eye position. The superior and inferior recti exert their maximal vertical action when the eye is abducted, that is, when the line of sight is parallel to the muscles' pulling directions, while the oblique muscles exert their maximal vertical action when the eye is adducted (Figure 35–2).

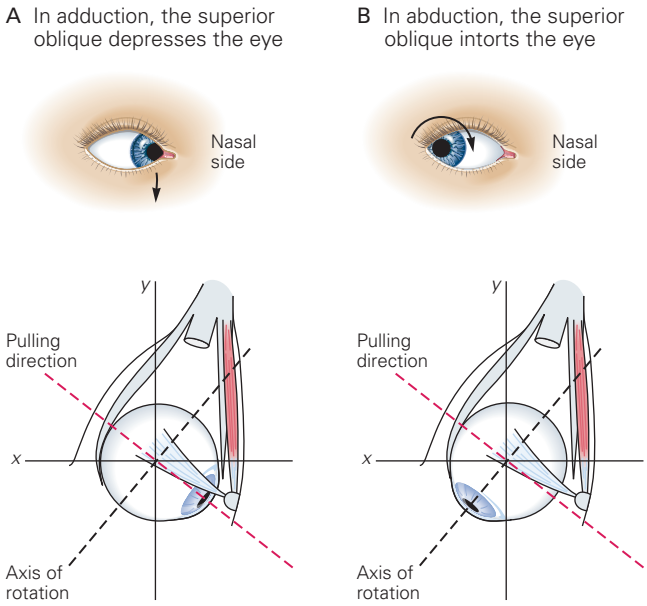

Figure 35–2 The effect of orbital position on the action of the superior oblique muscle.

A. When the eye is adducted (looking toward the nose), contraction of the superior oblique depresses the eye.

B. When the eye is abducted (looking away from the nose), contraction of the superior oblique intorts the eye.

Movements of the Two Eyes Are Coordinated

Humans and other frontal-eyed animals have binocular vision—the fields of vision of the two eyes overlap. This facilitates stereopsis, the ability to perceive a visual scene in three dimensions, as well as depth perception. At the same time, binocular vision requires precise coordination of the movements of the two eyes so that both foveae are always directed at the target of interest. For most eye movements, both eyes must move by the same amount and in the same direction. This is accomplished, in large part, through the pairing of eye muscles in the two eyes.

Just as each eye muscle is paired with its antagonist in the same orbit (eg, the medial and lateral recti), it is also paired with the muscle that moves the opposite eye in the same direction. For example, coupling of the left lateral rectus and right medial rectus moves both eyes to the left during a leftward saccade. The orientations of the vertical muscles are such that each pair consists of one rectus muscle and one oblique muscle. For example, the left superior rectus and the right inferior oblique both move the eyes upward in left gaze, while the right inferior rectus and the left superior oblique both move the eyes downward in right gaze (Table 35–1).

The Extraocular Muscles Are Controlled by Three Cranial Nerves

The extraocular muscles are innervated by groups of motor neurons whose cell bodies are clustered in the three oculomotor nuclei in the brain stem (Figure 35–3).

Table 35–1 Vertical Muscle Action in Adduction and Abduction

Muscle	Action in adduction	Action in abduction
Superior rectus	Intorsion	Elevation
Inferior rectus	Extorsion	Depression
Superior oblique	Depression	Intorsion
Inferior oblique	Elevation	Extorsion

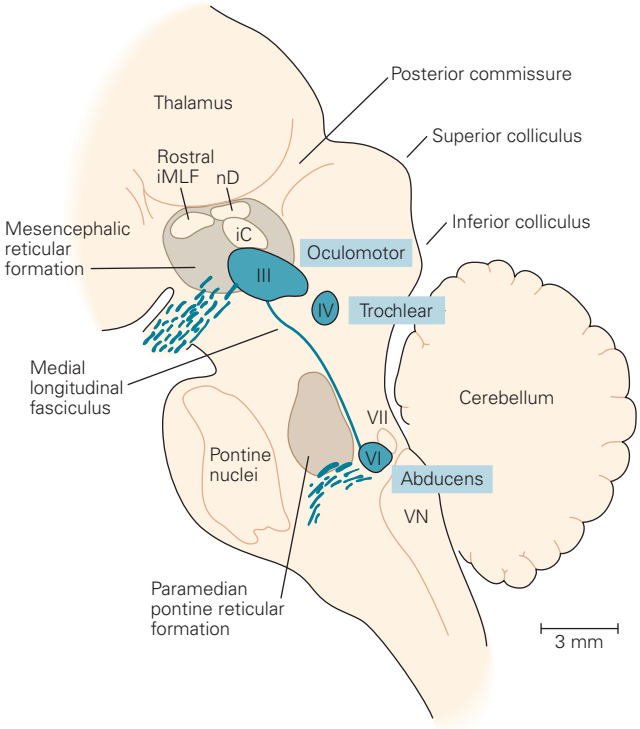

Figure 35–3 The oculomotor nuclei in the brain stem. The nuclei are shown in a parasagittal section through the thalamus, pons, midbrain, and cerebellum of a rhesus monkey. The oculomotor nucleus (cranial nerve III) lies in the midbrain at the level of the mesencephalic reticular formation; the trochlear nucleus (nerve IV) is slightly caudal; and the abducens nucleus (nerve VI) lies in the pons at the level of the paramedian pontine reticular formation, adjacent to the fasciculus of the facial nerve (VII). Compare with Figure 40–5. (Abbreviations: **iC**, interstitial nucleus of Cajal; **iMLF**, interstitial nucleus of the medial longitudinal fasciculus; **nD**, nucleus of Darkshevich; **VN**, vestibular nuclei.) (Adapted from Henn, Hepp, and Büttner-Ennever 1982.)

The lateral rectus is innervated by the abducens nerve (cranial nerve VI), whose nucleus lies in the pons in the floor of the fourth ventricle. The superior oblique muscle is innervated by the trochlear nerve (cranial nerve IV), whose nucleus is located in the contralateral midbrain at the level of the inferior colliculus. (The trochlear nerve gets its name from the trochlea, the bony pulley through which the superior oblique muscle travels.)

All the other extraocular muscles—the medial, inferior, and superior recti, and the inferior oblique—are innervated by the oculomotor nerve (cranial nerve III), whose nucleus lies in the midbrain at the level of the superior colliculus. Superior rectus axons cross the midline and join the contralateral oculomotor nerve. Thus, both superior rectus and superior oblique motor neurons innervate their respective muscles on the opposite side. The oculomotor nerve also contains fibers that innervate the levator muscle of the upper eyelid. Cell bodies of axons innervating both eyelids are located in the central caudal nucleus, a single midline structure within the oculomotor complex. Finally, traveling with the oculomotor nerve are parasympathetic fibers that innervate the iris sphincter muscle, which constricts the pupil, and the ciliary muscles that adjust the curvature of the lens to focus the eye during vergence movements from far to near, the process of accomodation.

The pupil and eyelid also have sympathetic innervation, which originates in the intermediolateral cell column of the ipsilateral upper thoracic spinal cord. Fibers of these neurons synapse on cells in the superior cervical ganglion in the upper neck. Axons of these postganglionic cells travel along the carotid artery to the cavernous sinus and then into the orbit. Sympathetic pupillary fibers innervate the iris dilator muscle, causing the pupil to dilate and thus providing the pupillary component of the so-called "fight or flight" response. Sympathetic fibers also innervate Müller's muscle, a secondary elevator of the upper eyelid. The sympathetic control of pupillary dilatation and lid elevation is responsible for the "wide-eyed" look of excitement and sympathetic overload.

The best way to understand the actions of the extraocular muscles is to consider the eye movements that remain after a lesion of a specific nerve (Box 35–1).

The force generated by an extraocular muscle is determined both by the firing rate of the motor neurons and the number of motor units recruited. Like the motor units for skeletal muscle (Chapter 31), eye motor units are recruited in a fixed sequence. For example, as the eye moves laterally, the number of active abducens neurons and their individual firing rates both increase, thereby increasing the strength of lateral rectus contraction.

Box 35–1 Extraocular Muscle or Nerve Lesions

Patients with lesions of the extraocular muscles or their nerves complain of double vision (diplopia) because the images of the object of gaze no longer fall on the corresponding retinal locations in both eyes. Lesions of each nerve produce characteristic symptoms that depend on which extraocular muscles are affected. In general, double vision increases when the patient tries to look in the direction of the weak muscle.

Abducens Nerve

A lesion of the abducens nerve (VI) causes weakness of the lateral rectus. When the lesion is complete, the eye cannot abduct beyond the midline, such that a horizontal diplopia increases when the subject looks in the direction of the affected eye.

Trochlear Nerve

A left trochlear nerve (IV) lesion affects both torsional and vertical eye movements by weakening the superior oblique muscle (Figure 35–4). Vertical misalignment in superior oblique paresis is also affected by the position of the head. A tilt to one side, such that the ear moves toward the shoulder, induces a small torsion of the eye in the opposite direction, known as ocular counter-roll. For example, when the head tilts to the left, the left eye is ordinarily intorted by the left superior rectus and left superior oblique, while the right eye is extorted by the right inferior rectus and right inferior oblique. In the left eye, the elevation action of the superior rectus is canceled by the depression action of the superior oblique, so the eye only rotates about the line of sight. When the head tilts to the right, the inferior oblique and inferior rectus extort the left eye and the superior oblique and the superior rectus relax.

With paresis of the left superior oblique, the elevating action of the superior rectus is unopposed when the head tilts to the left such that the left eye moves further upward. In contrast, tilting the head to the right relaxes the superior rectus and superior oblique (Figure 35–4D). Thus, patients with trochlear nerve lesions often prefer to keep their heads tilted away from the affected eye because this reduces the misalignment and can eliminate diplopia.

Oculomotor Nerve

A lesion of the oculomotor nerve (III) has complex effects because this nerve innervates multiple muscles. A complete lesion spares only the lateral rectus and superior oblique muscles. Thus, the paretic eye is typically deviated downward and abducted at rest and cannot move medially or upward. Downward movement is also affected because the inferior rectus muscle is weak; because the eye is abducted, the primary action of the intact superior oblique is intorsion rather than depression.

Because the fibers that control lid elevation, accommodation, and pupillary constriction travel in the oculomotor nerve, damage to this nerve also results in drooping of the eyelid (ptosis), blurred vision for near objects, and pupillary dilation (mydriasis). Although sympathetic innervation is still intact with an oculomotor nerve lesion, the ptosis is essentially complete, since Müller's muscle contributes less to elevation of the upper eyelid than does the levator muscle of the upper eyelid.

Sympathetic Oculomotor Nerves

Sympathetic fibers innervating the eye arise from the thoracic spinal cord, traverse the apex of the lung, and ascend to the eye on the outside of the carotid artery. Interruption of the sympathetic pathways to the eye leads to Horner syndrome, which includes a partial ipsilateral ptosis owing to weakness of Müller's muscle and a relative constriction (miosis) of the ipsilateral pupil. The pupillary asymmetry is most pronounced in low light because the normal pupil is able to dilate but the pupil affected by Horner syndrome is not.

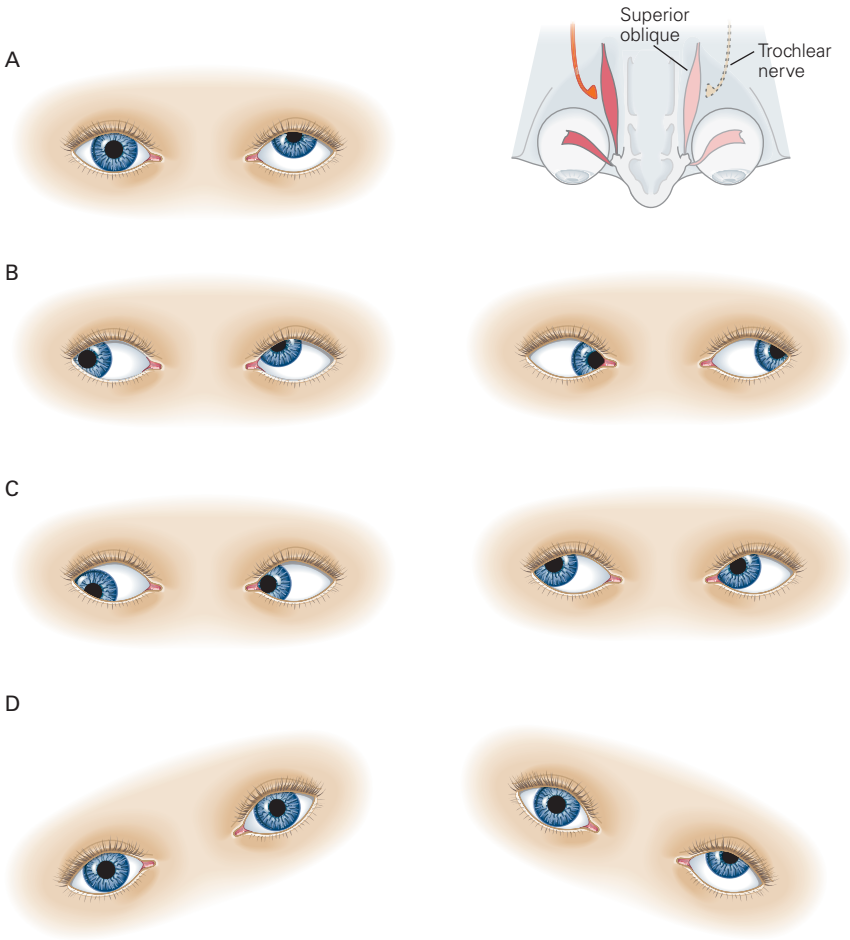

Figure 35–4 Effect of a left trochlear nerve palsy. The trochlear nerve innervates the superior oblique muscle, which inserts behind the equator of the eye. It depresses the eye when it is adducted and intorts the eye when it is abducted.

A. Hypertropia, a permanent upward deviation of the eye, can be seen when a patient is looking straight ahead. The right eye is in the center of the orbit, but the affected left eye is slightly above the right eye.

B. The hypertropia is worse when the eye is adducted because the unopposed inferior oblique pushes the eye higher (*left*). The condition is improved when the eye is abducted (*right*) because the superior oblique contributes less to depression than to intorsion.

C. When the patient looks to the right, the hypertropia is worse on downward gaze (*left*) than it is on upward gaze (*right*).

D. The hypertropia is improved by head tilt to the right (*left*) and worsened by tilt to the left (*right*). The ocular counter-rolling reflex induces intorsion of the left eye on leftward head tilt and extorsion of the eye on rightward head tilt (Chapter 27). With leftward head tilt, intorsion requires increased activity of the superior rectus, whose elevating activity is unopposed by the weak superior oblique, causing increased hypertropia. With rightward head tilt and extorsion of the left eye, the unopposed superior rectus muscle is less active, and the hypertropia decreases.

Six Neuronal Control Systems Keep the Eyes on Target

The oculomotor nuclei are the final common targets for all types of eye movements generated by higher brain networks. Hermann Helmholtz and other 19th-century psychophysicists appreciated that analysis of eye movements was essential for understanding visual perception, but they assumed that all eye movements were smooth. In 1890, Edwin Landott discovered that during reading the eyes do not move smoothly along a line of text but make fast intermittent movements called saccades (French, jerks), each followed by a short pause.

By 1902, Raymond Dodge outlined five distinct types of eye movement that direct the fovea to a visual target and keep it there. All of these eye movements share an effector pathway originating in the three oculomotor nuclei in the brain stem.

- Saccadic eye movements shift the fovea rapidly to a new visual target.
- Smooth-pursuit movements keep the image of a moving target on the fovea.
- Vergence movements move the eyes in opposite directions so that the image of an object of interest is positioned on both foveae regardless of its distance.
- Vestibulo-ocular reflexes stabilize images on the retina during brief head movements.
- Optokinetic movements stabilize images during sustained head rotation or translation.

A sixth system, the fixation system, holds the eye stationary during intent gaze when the head is not moving by actively suppressing eye movement. The optokinetic and vestibular systems are discussed in Chapter 27. We consider the other four systems here.

An Active Fixation System Holds the Fovea on a Stationary Target

Vision is most accurate when the eyes are still. The gaze system actively prevents the eyes from moving when we examine an object of interest. It is not as active in suppressing movement when we are doing something that does not require vision, such as mental arithmetic. Patients with disorders of the fixation system—for example, patients with irrepressible saccadic eye movements (opsoclonus)—have poor vision not because their visual acuity is deficient but because they cannot hold their eyes still enough for the visual system to work correctly.

The Saccadic System Points the Fovea Toward Objects of Interest

Our eyes explore the world in a series of very quick saccades that move the fovea from one fixation point to another (Chapter 25) (Figure 35–5). Saccades allow us to scan the environment quickly and to read. Highly stereotyped, they have a standard waveform with a single smooth increase and decrease of eye velocity. Saccades are also extremely fast, occurring within a fraction of a second at angular speeds up to 900° per second (Figure 35–6A). The velocity of a saccade is determined only by its size. We can voluntarily change

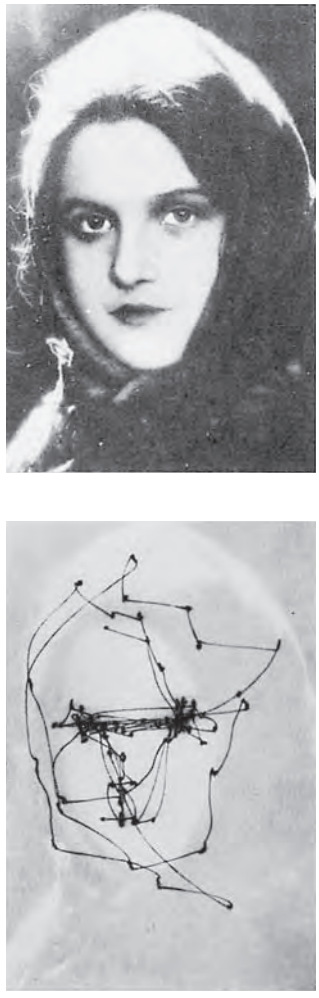

Figure 35–5 Eye movements track the outline of an object of attention. An observer looks at a picture of a woman for 1 minute. The resulting eye positions are then superimposed on the picture. As shown here, the observer concentrated on certain features of the face, lingering over the woman's eyes and mouth (*fixations*) and spending less time over intermediate positions. The rapid movements between fixation points are ***saccades.*** (Reproduced, with permission, from Yarbus 1967.)

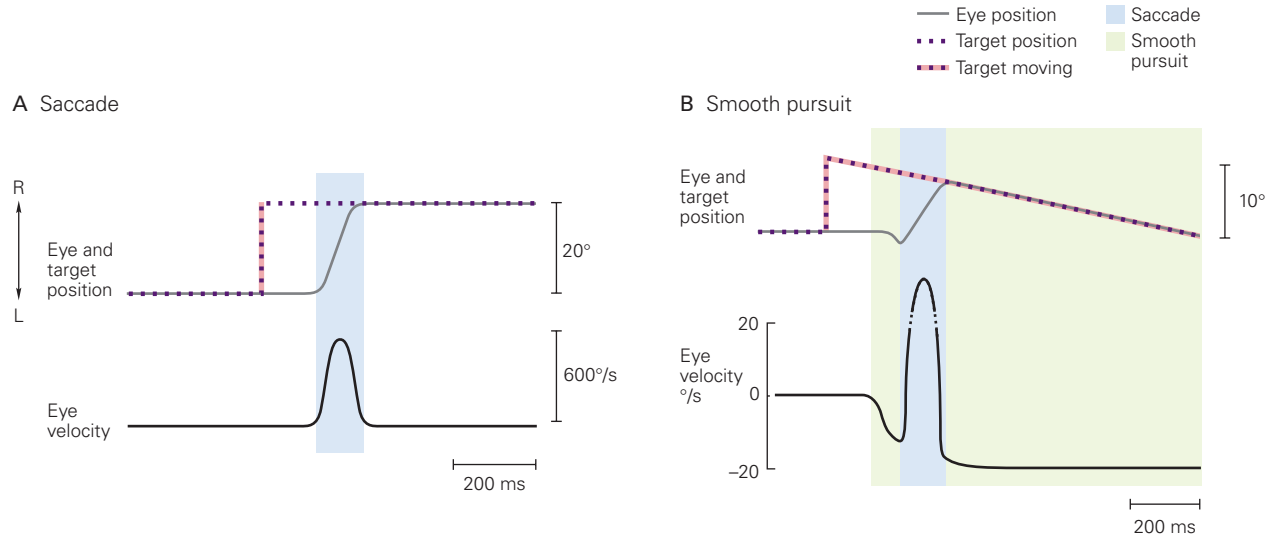

Figure 35–6 Saccadic and smooth-pursuit eye movements. Eye position, target position, and eye velocity are plotted against time.

A. *The human saccade*. At the beginning of the plot, the eye is on the target (the traces representing eye and target positions are superimposed). Suddenly, the target jumps to the right, and within 200 ms, the eye moves to bring the target back to the fovea. Note the smooth, symmetric velocity profile. Because eye movements are rotations of the eye in the orbit, they are described by the angle of rotation. Similarly, objects in the visual field are described by the angle of arc they subtend at the eye. Viewed at arm's length, a thumb subtends an angle of approximately 1°. A saccade from one edge of the thumb to the other therefore traverses 1° of arc. (Abbreviations: **L**, left; **R**, right.)

B. *Human smooth pursuit*. In this example, the subject is asked to make a saccade to a target that jumps away from the center of gaze and then slowly moves back to center. The first movement seen in the position and velocity traces is a smooth-pursuit movement in the same direction as the target movement. The eye briefly moves *away* from the target before a saccade is initiated because the latency of the pursuit system is shorter than that of the saccade system. The smooth-pursuit system is activated by the target moving back toward the center of gaze, the saccade adjusts the eye's position to catch the target, and thereafter, smooth pursuit keeps the eye on the target. The recording of saccade velocity is clipped so that the movement can be shown on the scale of the pursuit movement, an order of magnitude slower than the saccade.

the amplitude and direction of saccades but not their speed, although fatigue, drugs, or pathological states can slow saccades.

Ordinarily, there is no time for visual feedback to modify the course of a saccade as it is being made; instead, corrections to the direction and/or amplitude of movement are made over the course of successive saccades. Accurate saccades can be made not only to visual targets but also to sounds, tactile stimuli, memories of locations in space, and even verbal commands (eg, "look left").

When a saccade is made, the activity of neurons in higher brain centers that control gaze specify only a desired change in eye position (eg, 20° to the right of current gaze, usually based on a target location in the visual field). For the eye movement to be made, this location signal must be transformed into signals for the eye muscles that execute the desired velocity and change in eye position. We can illustrate how the gaze system generates eye movements by considering the activity of an oculomotor neuron during a saccade (Figure 35–7A). To move the eye quickly to a new position in the orbit and keep it there, two passive forces must be overcome: the elastic force of the orbital tissues, which tends to restore the eye to a central position, and a velocity-dependent viscous force that opposes rapid movement. Thus, the motor signal for an eye movement must include both a position component to counter the elastic force and a velocity component to overcome orbital viscosity and move the eye quickly to the new position.

This eye position and velocity information are coded by the discharge frequencies of oculomotor neurons. When a saccade is made, the firing rate of a neuron rises rapidly as eye velocity increases; this is called the *saccadic pulse* (Figure 35–7B). The frequency of this pulse determines the speed of the saccade, whereas the length of the pulse controls the duration of the saccade and thus its amplitude. When the saccade is completed and the eye has reached its goal, there must be a new level of tonic input to the eye muscles that is appropriate for the elastic restoring force at that orbital position. This difference in the tonic firing rate between before and after the saccade is called the *saccadic step* (Figure 35–7B). If the size of the step is not properly matched to

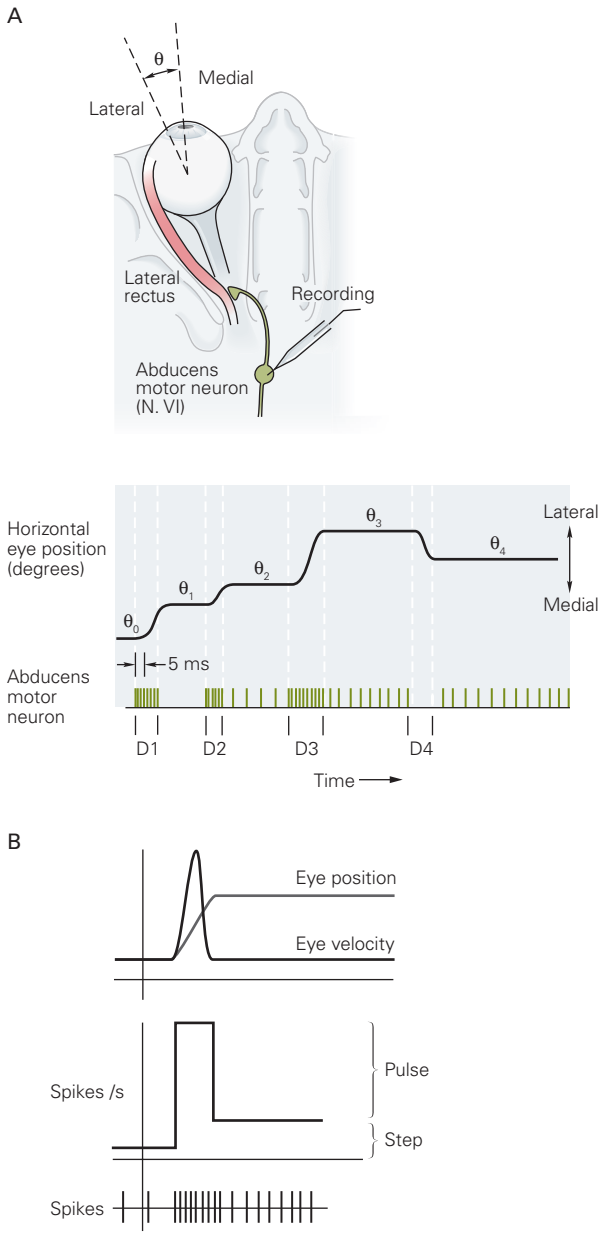

Figure 35–7 Oculomotor neurons signal eye position and velocity.

A. The record is from an abducens neuron of a monkey. When the eye is positioned in the medial side of the orbit, the cell is silent (**position** θ_0). As the monkey makes a lateral saccade, there is a burst of firing (**D1**), but in the new position (θ_1), the eye is still too far medial for the cell to discharge continually. During the next saccade, there is a burst (**D2**), and at the new position (θ_2), there is a tonic position-related discharge. Before and during the next saccade (**D3**), there is again a pulse of activity and a higher tonic discharge when the eye is at the new position (θ_3). When the eye makes a medial movement, there is a period of silence during the saccade (**D4**) even though the eye ends up at a position (θ_4) associated with a tonic discharge. (Adapted from Fuchs and Luschei 1970.)

B. Saccades are associated with a step of activity, which signals the change in eye position, and a pulse of activity, which signals eye velocity. The neural activity corresponding to eye position and velocity is illustrated both as a train of individual spikes and as an estimate of the instantaneous firing rate (spikes per second).

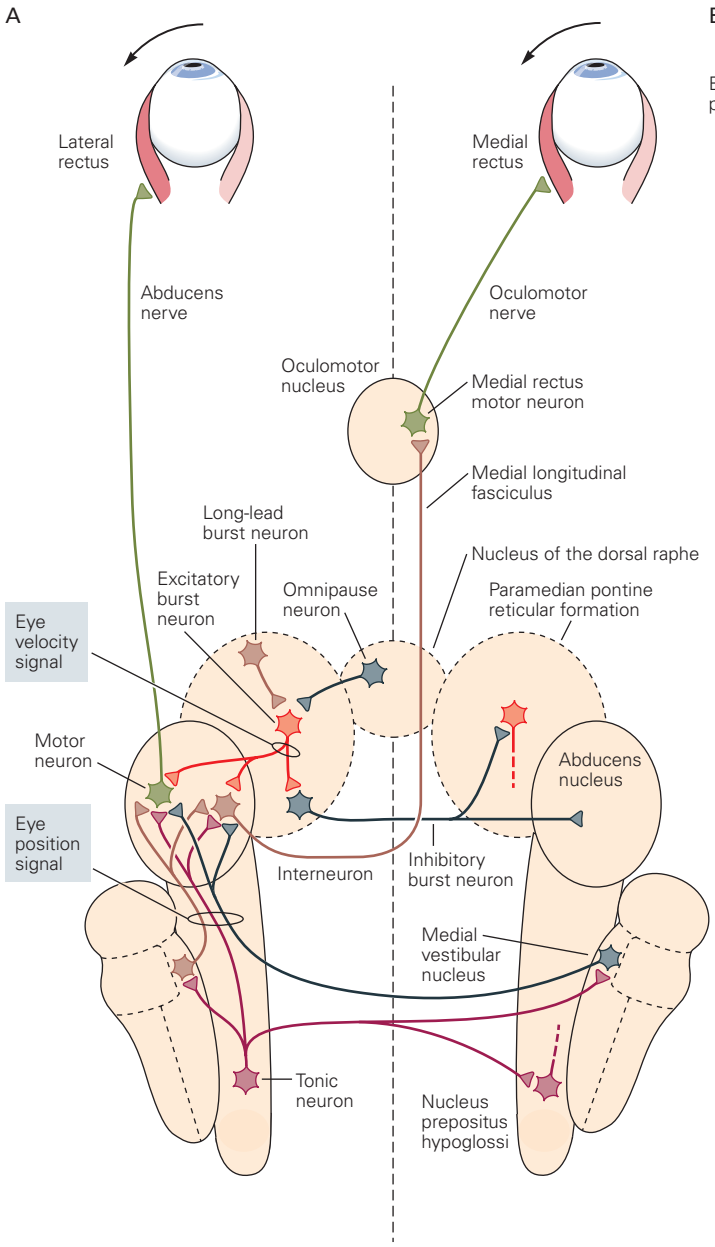
the pulse, then the eye drifts away from the target after the saccade. As described later, the pulse and step are generated by different brain stem structures.

The Motor Circuits for Saccades Lie in the Brain Stem

Horizontal Saccades Are Generated in the Pontine Reticular Formation

The neuronal signal for horizontal saccades originates in the paramedian pontine reticular formation, adjacent to the abducens nucleus to which it projects (Figure 35–8A). The paramedian pontine reticular formation contains a family of *burst neurons* that gives rise to the saccadic pulse. These cells fire at a high frequency just before and during ipsiversive saccades (toward the same side as the discharging neurons), and their activity resembles the pulse component of oculomotor neuron discharge (Figure 35–7B).

There are several types of burst neurons (Figure 35–8B). Medium-lead excitatory burst neurons make direct excitatory connections to motor neurons and interneurons in the ipsilateral abducens nucleus.



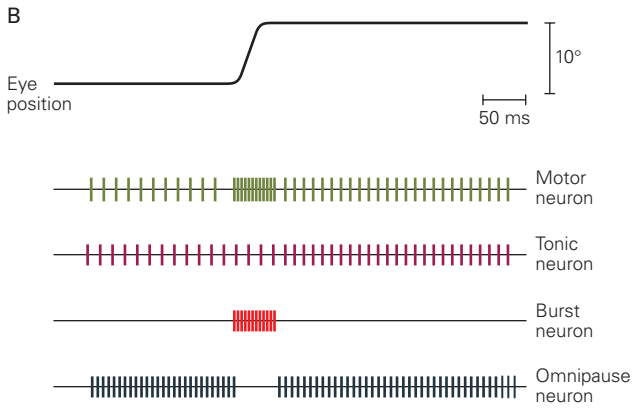


Figure 35–8 The brain stem motor circuit for horizontal saccades.

A. *Eye velocity component.* Long-lead burst neurons relay signals from higher centers to the excitatory burst neurons. The eye velocity component arises from excitatory burst neurons in the paramedian pontine reticular formation that synapse on motor neurons and interneurons in the abducens nucleus. The abducens motor neurons project to the ipsilateral lateral rectus muscles, while the interneurons project to the contralateral medial rectus motor neurons by axons that cross the midline and ascend in the medial longitudinal fasciculus. Excitatory burst neurons also drive ipsilateral inhibitory burst neurons that inhibit contralateral abducens motor neurons and excitatory burst neurons.

Eye position component. This component arises from a neural integrator comprising neurons distributed throughout the medial vestibular nuclei and nucleus prepositus hypoglossi on both sides of the brain stem. These neurons receive velocity signals from excitatory burst neurons and integrate this velocity signal to a position signal. The position signal excites the ipsilateral abducens neurons and inhibits the contralateral abducens neurons. (**Gray** neurons are inhibitory; all other neurons are excitatory. The vertical **dashed line** indicates the midline of the brain stem.)

B. Different neurons provide different information for a horizontal saccade. The motor neuron provides both position and velocity signals. The tonic neuron (nucleus prepositus hypoglossi) signals only eye position. The excitatory burst neuron (paramedian pontine reticular formation) signals only eye velocity. The omnipause neuron discharges at a high rate except immediately before, during, and just after the saccade.

Long-lead burst neurons drive the medium-lead burst cells and receive excitatory input from higher centers. Inhibitory burst neurons suppress the activity of contralateral abducens neurons and contralateral excitatory burst neurons and are themselves excited by medium-lead burst neurons.

A second class of pontine cells, *omnipause neurons*, fires continuously except around the time of a saccade; firing ceases shortly before and during all saccades (Figure 35–8B). Omnipause neurons are located in the nucleus of the dorsal raphe in the midline (Figure 35–8A). They are GABAergic (γ-aminobutyric acid) inhibitory neurons that project to contralateral pontine and mesencephalic burst neurons. Electrical stimulation of omnipause neurons arrests a saccade, which resumes when the stimulation stops. Making a saccade requires simultaneous excitation of burst neurons and inhibition of omnipause cells; this provides the system

with additional stability, such that unwanted saccades are infrequent.

If the motor neurons received signals from only the burst cells, the eyes would drift back to the starting position after a saccade, because there would be no new position signal to hold the eyes against elastic restorative forces. The appropriate tonic innervation is required to keep the eye at the new orbital position. This tonic position signal, the saccadic step, can be generated from the velocity burst signal by the neural equivalent of the mathematical process of integration. Velocity can be computed by differentiating position with respect to time; conversely, position can be computed by integrating velocity with respect to time.

For horizontal eye movements, neural integration of the velocity signal is performed by the medial vestibular nucleus and nucleus prepositus hypoglossi (Figure 35–8A) in conjunction with the flocculus of the cerebellum. As expected, animals with lesions of these areas make normal horizontal saccades, but the eyes drift back to a middle position after a saccade. Moreover, integration of the horizontal saccadic burst requires coordination of the bilateral nuclei prepositi hypoglossi and medial vestibular nuclei through commissural connections. Thus, a midline lesion of these connections also causes failure of the neural integrator.

Medium-lead burst neurons in the paramedian pontine reticular formation and neurons of the medial vestibular nucleus and nucleus prepositus hypoglossi project to the ipsilateral abducens nucleus and deliver respectively the pulse and step components of the motor signal. Two populations of neurons in the abducens nucleus receive this signal. One is a group of motor neurons that innervate the ipsilateral lateral rectus muscle. The second group consists of interneurons whose axons cross the midline and ascend in the medial longitudinal fasciculus to the motor neurons for the contralateral medial rectus, which lie in the oculomotor nucleus (Figure 35–8A).

Thus, medial rectus motor neurons do not receive the pulse and step signals directly. This arrangement allows for precise coordination of corresponding movements of both eyes during horizontal saccades and other conjugate eye movements. The susceptibility of the medial longitudinal fasciculus to strokes and multiple sclerosis make it clinically important.

Several cerebellar structures play an important role in the calibration of the saccade motor signal. First, the oculomotor portion of the dorsal vermis, acting through the caudal fastigial nucleus, controls the duration of the pulse and thus the accuracy of the saccade. The fastigial nucleus increases saccade velocity at the beginning of contraversive saccades and contributes to braking ipsiversive saccades to end the saccade. Second, the flocculus and paraflocculus of the vestibulocerebellum calibrate the neural integrator to ensure that the step is properly matched to the pulse, in order to hold the eyes at the new position after each saccade.

Vertical Saccades Are Generated in the Mesencephalic Reticular Formation

The burst neurons responsible for vertical saccades are found in the rostral interstitial nucleus of the medial longitudinal fasciculus in the mesencephalic reticular formation (Figure 35–3). Vertical and torsional neural integration are performed in the nearby interstitial nucleus of Cajal. The pontine and mesencephalic systems participate together in the generation of oblique saccades, which have both horizontal and vertical components.

Purely vertical saccades require activity on both sides of the mesencephalic reticular formation, and communication between the two sides occurs via the posterior commissure. There are not separate omnipause neurons for horizontal and vertical saccades; pontine omnipause cells inhibit both pontine and mesencephalic burst neurons.

Brain Stem Lesions Result in Characteristic Deficits in Eye Movements

We can now understand how different brain stem lesions cause characteristic syndromes. Lesions that include the paramedian pontine reticular formation result in paralysis of ipsiversive horizontal gaze of both eyes but spare contraversive and vertical saccades. A lesion of the abducens nucleus has a similar effect, as both abducens motor neurons and interneurons are affected. Lesions that include the midbrain gaze centers cause paralysis of vertical gaze. Certain neurological disorders cause degeneration of burst neurons and impair their function, leading to a progressive slowing of saccades.

Lesions of the medial longitudinal fasciculus disconnect the medial rectus motor neurons from the abducens interneurons (Figure 35–8A). Thus, during conjugate horizontal eye movements, such as saccades and pursuit, the abducting eye moves normally but adduction of the other eye is impeded. Despite this paralysis in version movements, the medial rectus typically acts normally in vergence movements because the motor neurons for vergence lie in the midbrain, as will be discussed later. This syndrome, called an *internuclear ophthalmoplegia*, is a consequence of a brain stem stroke or demyelinating diseases such as multiple sclerosis.

A lesion of the cerebellar fastigial nucleus causes ipsiversive saccades to overshoot their targets (*hypermetric* saccades), due to failure of normal termination of the saccadic burst. Contraversive saccades undershoot their targets (*hypometric* saccades). Correspondingly, damage to the oculomotor vermis disinhibits the fastigial nucleus and causes hypometric ipsiversive saccades. This may be due to an additional failure to compensate for the position-dependent passive forces of the orbital tissues.

Saccades Are Controlled by the Cerebral Cortex Through the Superior Colliculus

The pontine and mesencephalic burst circuits provide the motor signals necessary to drive the extraocular muscles for saccades. However, among higher mammals, eye movements are ultimately driven by cognitive behavior. The decision of when and where to make a saccade that is behaviorally important is usually made in the cerebral cortex. A network of cortical and subcortical areas controls the saccadic system through the superior colliculus (Figure 35–9).

The Superior Colliculus Integrates Visual and Motor Information into Oculomotor Signals for the Brain Stem

The superior colliculus in the midbrain is a major visuomotor integration region, the mammalian homolog of the optic tectum in nonmammalian vertebrates. It can be divided into two functional regions: the superficial layers and the intermediate and deep layers.

The three superficial layers receive both direct input from the retina and a projection from the striate

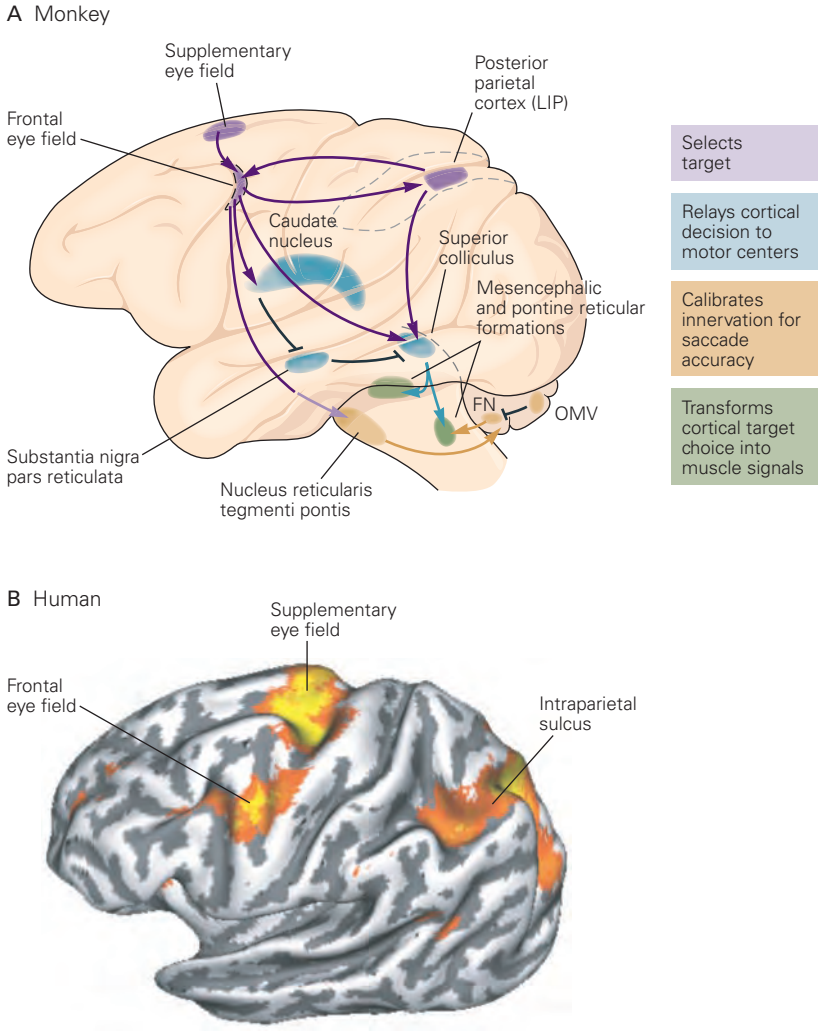

Figure 35–9 Cortical pathways for saccades.

A. In the monkey, the saccade generator in the brain stem receives a command from the superior colliculus. That command is relayed through the pontine and mesencephalic burst circuits, providing the motor signals that drive the extraocular muscles for saccades. The colliculus receives direct excitatory projections from the frontal eye fields and the lateral intraparietal area (**LIP**) and an inhibitory projection from the substantia nigra. The substantia nigra is suppressed by the caudate nucleus, which in turn is excited by the frontal eye fields. Thus, the frontal eye fields directly excite the colliculus and indirectly release it from suppression by the substantia nigra by exciting the caudate nucleus, which inhibits the substantia nigra. The oculomotor vermis (**OMV**) of the cerebellum, acting through the fastigial nucleus (**FN**), calibrates the burst to keep saccades accurate.

B. This lateral scan of a human brain shows areas of cortex activated during saccades. (Adapted from Curtis and Connolly 2008.)

cortex representing the entire contralateral visual hemifield. Neurons in the superficial layers respond to visual stimuli. In monkeys, the responses of half of these vision-related neurons are quantitatively enhanced when an animal prepares to make a saccade to a stimulus in the cell's receptive field. This enhancement is specific for saccades. If the monkey attends to the stimulus without making a saccade to it—for example, by making a hand movement in response to a brightness change—the neuron's response is not augmented. Neurons in the superficial layers of the superior colliculus are functionally arranged in a retinotopic map of the visual field in which representation of the visual field closest to the fovea occupies the largest area (Figure 35–10).

Neuronal activity in the two intermediate and deep layers is primarily related to oculomotor actions. The movement-related neurons in these layers receive visual information from the prestriate, middle temporal, and parietal cortices and motor information from the frontal eye field. The intermediate and deep layers also contain somatotopic, tonotopic, and retinotopic maps of sensory inputs, all in register with one another. For example, the image of a bird will excite a vision-related neuron, whereas the bird's chirp will excite an adjacent audition-related neuron, and both will excite a bimodal neuron. Polymodal spatial maps enable us to shift our eyes toward auditory or somatosensory stimuli as well as visual ones.

Much of the early research describing the sensory responsiveness of neurons in the intermediate layer was done in anesthetized animals. To understand how the brain generates movement, however, the activity of neurons needs to be studied in alert, active animals. Edward Evarts pioneered this approach in studies of the skeletomotor system, after which it was extended to the oculomotor system.

One of the earliest cellular studies in active animals revealed that individual movement-related neurons in the superior colliculus selectively discharge before saccades of specific amplitudes and directions, just as individual vision-related neurons in the superior colliculus respond to stimuli at specific distances and directions from the fovea (Figure 35–11A). The movement-related neurons form a map of potential eye movements that is in register with the visuotopic and tonotopic arrays of sensory inputs, so that the neurons that control eye movements to a particular target are found in the same region as the cells excited by the sounds and image of that target. Each movement-related neuron in the superior colliculus has a *movement field*, a region of the visual field that is the target for saccades controlled by that neuron. There is a map of movement fields in the intermediate layers that is in register with the map of visual receptive fields in the overlying superficial layers. Each movement neuron discharges before a saccade to the center of the overlying visual receptive field. A map of saccades evoked by electrical stimulation of the intermediate layers resembles the visual map.

Movement fields are large, so each superior colliculus cell fires before a wide range of saccades, although each cell fires most intensely before saccades of a specific direction and amplitude. A large population of cells is thus active before each saccade, and eye movement is encoded by the entire ensemble of these broadly tuned cells. Because each cell makes only a small contribution to the direction and amplitude of the movement, any variability or noise in the discharge of a given cell is minimized. Similar population coding is found in many sensory systems (Chapter 17) and the skeletal motor system (Chapter 34).

Activity in the superficial and intermediate layers of the superior colliculus can occur independently: Sensory activity in the superficial layers does not always lead to motor output, and motor output can occur without sensory activity in the superficial layers. In fact, the neurons in the superficial layers do not provide a large projection directly to the intermediate

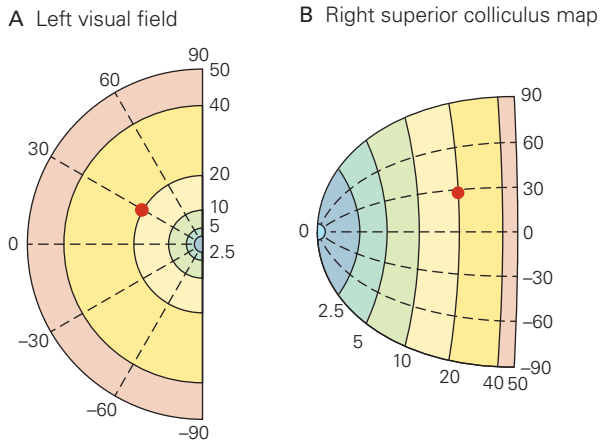

Figure 35–10 Neurons in the superior colliculus are organized in a retinotopic map.

A. Map of the left visual field in polar coordinates. **Dashed lines** represent the angle and **solid lines** the eccentricity.

B. Spatial map of neurons in the superior colliculus represented in polar coordinates of the visual field. In the nucleus, more neurons represent the part of the visual field close to the fovea and fewer neurons represent the periphery. For example, a stimulus appearing at 20° eccentricity and 30° elevation in the visual field (**red dot**) will excite neurons at the location of the red dot on the collicular map. (Reproduced, with permission, from Quaia et al. 1998.)

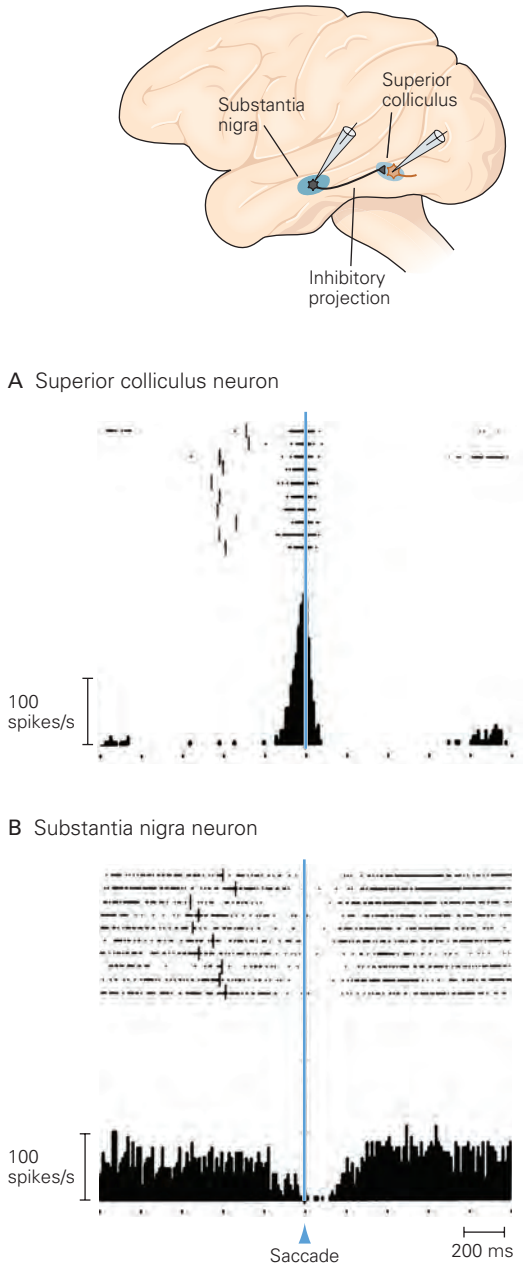

Figure 35–11 Neurons in the superior colliculus and substantia nigra are active around the time of a saccade. (Reproduced, with permission, from Hikosaka and Wurtz 1989.)

A. A neuron recorded from the region in the superior colliculus from which the neuron in B could be excited antidromically fires in a burst immediately before the saccade. Raster plots of activity in successive trials of the same task are summed to form the histogram below. The small vertical lines in the raster indicate target appearance. The trials are aligned at the beginning of the saccade (**blue line**).

B. A neuron in the substantia nigra pars reticulata is tonically active, becomes quiet just before the saccade, and resumes activity after the saccade. This type of neuron inhibits neurons in the intermediate layers of the superior colliculus.

layers. Instead, their axons terminate on neurons in the pulvinar and lateral posterior nuclei of the thalamus, which relay the signals from the superficial layers of the superior colliculus to cortical regions that project back to the intermediate layers.

Lesions of a small part of the colliculus affect the latency, accuracy, and velocity of saccades. Destruction of the entire colliculus renders a monkey unable to make any contraversive saccades, although with time, this ability is recovered.

The Rostral Superior Colliculus Facilitates Visual Fixation

The most rostral portion of the superior colliculus receives inputs from the fovea and the foveal representation in primary visual cortex (V1). Neurons in the intermediate layers in this region discharge strongly during active visual fixation and before small saccades to the contralateral visual field. Because the neurons are active during visual fixation, this area of the superior colliculus is often called the fixation zone.

Neurons here inhibit the movement-related neurons in the more caudal parts of the colliculus and also project directly to the nucleus of the dorsal raphe, where they inhibit saccade generation by exciting the omnipause neurons. With lesions in the fixation zone, an animal is more likely to make saccades to distracting stimuli.

The Basal Ganglia and Two Regions of Cerebral Cortex Control the Superior Colliculus

The superior colliculus receives a powerful GABAergic inhibitory projection from neurons in the substantia nigra, which fire spontaneously with high frequency. This discharge is suppressed at the time of voluntary eye movements to the contralateral visual field (Figure 35–11B) by inhibitory input from neurons in the caudate nucleus, which fire before saccades to the contralateral visual field.

The superior colliculus is controlled by two regions of the cerebral cortex that have overlapping but distinct functions: the lateral intraparietal area of the posterior parietal cortex (part of Brodmann's area 7) and the frontal eye field (part of Brodmann's area 8). Each of these areas contributes to the generation of saccades and the control of visual attention.

Perception of attended objects in the visual field is better than perception of unattended objects, as measured either by a subject's reaction time to an object suddenly appearing in the visual field or by the subject's ability to perceive a stimulus that is just barely

noticeable. Saccadic eye movements and visual attention are closely intertwined (Figure 35–5).

The lateral intraparietal area in the monkey is important in the generation of both visual attention and saccades. The role of this area in the processing of eye movements is best illustrated by a memory-guided saccade. To demonstrate this saccade, a monkey first fixates a spot of light. An object (the stimulus) appears in the receptive field of a neuron and then disappears; then the spot of light is extinguished. After a delay, the monkey must make a saccade to the former location of the vanished object. Neurons in the lateral intraparietal area respond from the moment the object appears and continue firing after the object has vanished and throughout the delay until the saccade begins (Figure 35–12A), but their activity can be also dissociated from saccade planning. If the monkey is planning a saccade to a target outside the receptive field of a neuron and a distractor appears in the field during the delay period, the neuron responds as vigorously to the distractor as it does to the target of a saccade (Figure 35–12B).

Lesioning of a monkey's posterior parietal cortex, which includes the lateral intraparietal area, increases the latency of saccades and reduces their accuracy. Such a lesion also produces selective neglect: A monkey with a unilateral parietal lesion preferentially attends to stimuli in the ipsilateral visual hemifield. In humans as well, parietal lesions—especially right parietal lesions—initially cause dramatic attentional deficits. Patients act as if the objects in the neglected field do not exist, and they have difficulty making eye movements into that field (Chapter 59).

Patients with Balint syndrome, which is usually the result of bilateral lesions of the posterior parietal

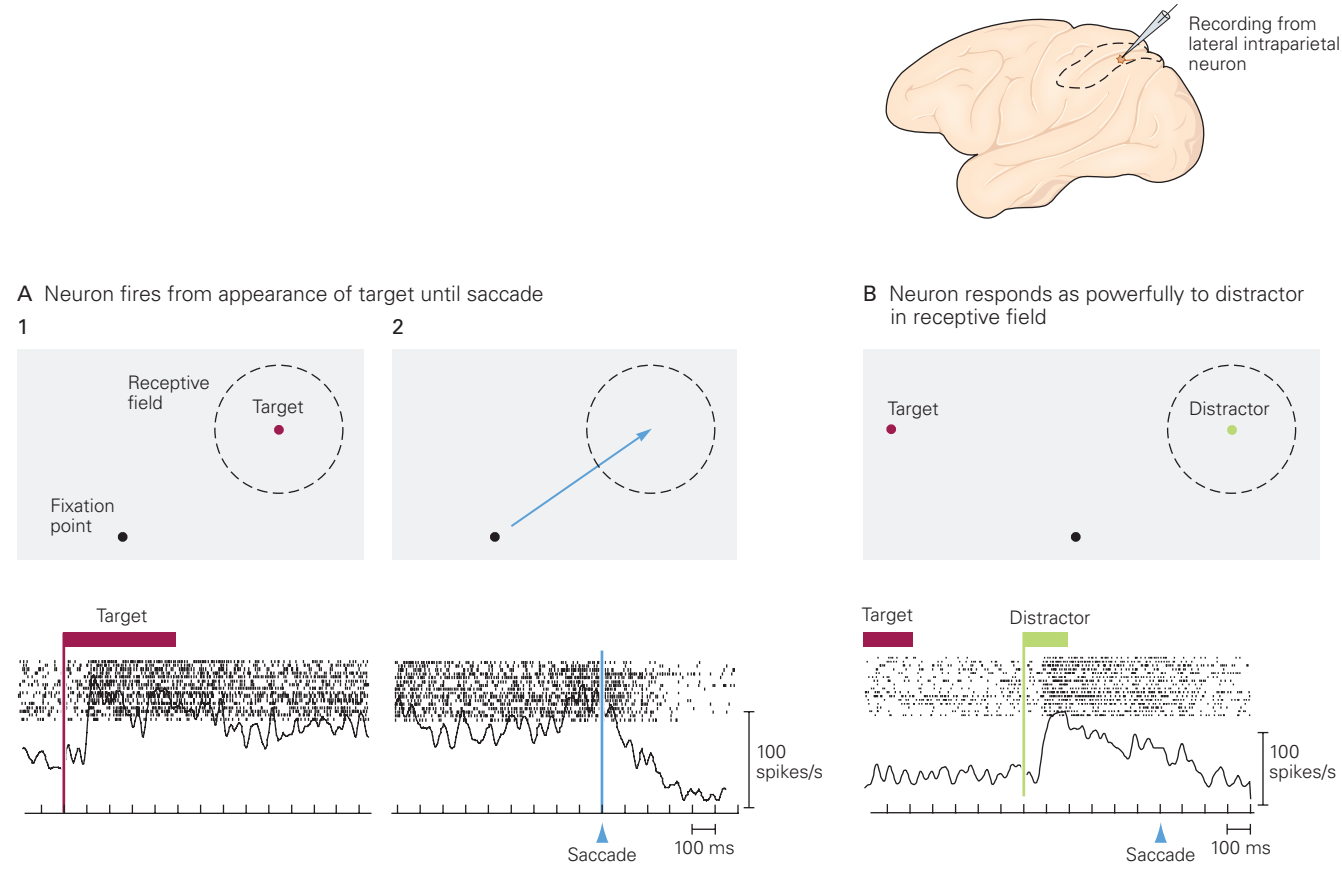

Figure 35–12 A parietal neuron is active before memory-guided saccades. Traces are aligned at events indicated by vertical lines. (Adapted, with permission, from Powell and Goldberg 2000.)

A. The monkey plans a saccade from a fixation point to a target in the receptive field of a neuron in the lateral intraparietal cortex. The neuron responds to the appearance of the target (**1**). It continues to fire after the target has disappeared but before the signal to make the saccade and stops firing after the onset of the saccade (**2**).

B. The monkey plans a saccade to a target outside the receptive field. The neuron responds initially to a distractor in the receptive field as strongly as it did to the target of a saccade.

and prestriate cortex, tend to see and describe only one object at a time in their visual environment. These patients make few saccades, as if they are unable to shift the focus of their attention from the fovea, and can therefore describe only a foveal target. Even after these patients have recovered from most of their deficits, their saccades are delayed and inaccurate.

Compared to the neurons in the parietal cortex, neurons in the frontal eye field are more closely associated with saccades. Three different types of neurons in the frontal eye field discharge before saccades.

Visual neurons respond to visual stimuli, and half of these neurons respond more vigorously to stimuli that are the targets of saccades (Figure 35–13A). Activity in these cells is not enhanced when an animal responds to the stimulus without making a saccade to it. Likewise, these cells are not activated before saccades that are made without visual targets; monkeys can be trained to make saccades of a specific direction and amplitude in total darkness.

Movement-related neurons fire before and during saccades to their movement fields. Unlike the movement-related cells in the superior colliculus, which fire before all saccades, movement-related neurons of the frontal eye field fire only before saccades that are relevant to the monkey's behavior (Figure 35–13B). These neurons, especially those whose receptive fields lie in the visual periphery, project more strongly to the superior colliculus than do the visual neurons.

Visuomovement neurons have both visual and movement-related activity and discharge most strongly before visually guided saccades. Electrical stimulation of the frontal eye field evokes saccades to the movement fields of the stimulated cells. Bilateral stimulation of the frontal eye field evokes vertical saccades.

Movement-related neurons in frontal eye field control the superior colliculus through two pathways. They excite the superior colliculus directly and they release it from the inhibitory influence of the substantia nigra by exciting the caudate nucleus, which in turn inhibits the nigra (Figure 35–9A). The frontal eye field also projects to the pontine and mesencephalic reticular formations, although not directly to the burst cells.

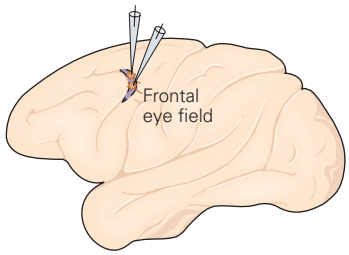
Two other cortical regions besides LIP that have inputs to the frontal eye field are thought to be important in the cognitive aspects of saccades. The supplementary eye field at the most rostral part of the supplementary motor area contains neurons that encode spatial information other than the direction of the desired eye movement. For example, a neuron in the left supplementary eye field that ordinarily fires before rightward eye movements will fire before a leftward saccade if that saccade is to the right side of the target. The dorsolateral prefrontal cortex has neurons that discharge when a monkey makes a saccade to a remembered target. The activity commences with the appearance of the stimulus and continues throughout the interval during which the monkey must remember the location of the target.

We can now understand the effects of lesions of these regions on the generation of saccades. Lesions of the superior colliculus in monkeys produce only transient damage to the saccade system because the projection from the frontal eye field to the brain stem remains intact. Animals can likewise recover from cortical lesions if the superior colliculus is intact. However, when both the frontal eye field and the colliculus are damaged, the ability to make saccades is permanently compromised. The predominant effect of a parietal lesion is an attentional deficit. After recovery, however, the system can function normally because the frontal eye field signals are sufficient to suppress the substantia nigra and stimulate the colliculus.

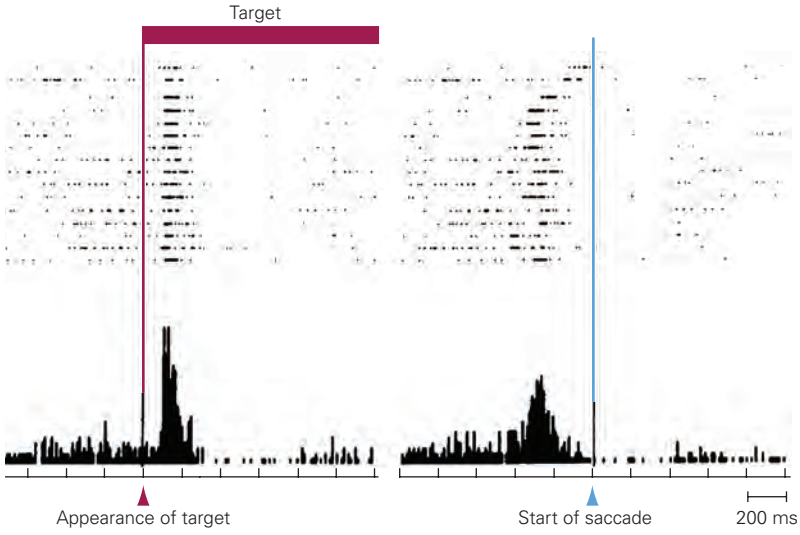
Damage to the frontal eye field alone causes more subtle deficits. Lesions of the frontal eye field in monkeys cause transient contralateral neglect and paresis of contraversive gaze, which recover rapidly. The latter deficit may reflect the loss of frontal eye field control of the substantia nigra; this loss of control means that the constant inhibitory input from the substantia nigra to the colliculus does not get suppressed, and the colliculus is unable to generate any saccades. Eventually the system adapts, and the colliculus responds to the remaining parietal signal. After recovery, the animals have no trouble producing saccades to targets in the visual field but have great difficulty with memory-guided saccades. Bilateral lesions of both the frontal eye fields and the superior colliculus render monkeys unable to make saccades at all.

Humans with lesions of the frontal cortex have difficulty suppressing unwanted saccades to attended stimuli. This is easily shown by asking subjects to make an eye movement away from a stimulus, the "anti-saccades task." For example, if a stimulus appears on the left, the subject should make a saccade of the same size to the right. To do this, the subject must attend to the stimulus, without turning the eyes toward it, and use its location to calculate the desired saccade to the opposite direction. Patients with frontal lesions have great difficulty suppressing the unwanted saccade to the stimulus.

As we have seen, neurons in the lateral intraparietal area of monkeys are active when the animal attends to a visual stimulus whether or not the animal makes a saccade to the stimulus. In the absence of frontal eye field signals, this undifferentiated signal is the only one to reach the superior colliculus. In humans, the failure to suppress a saccade is therefore to be expected



A Visual neuron responds to the stimulus and not to movement



B Movement-related neuron responds before movement but not to stimulus

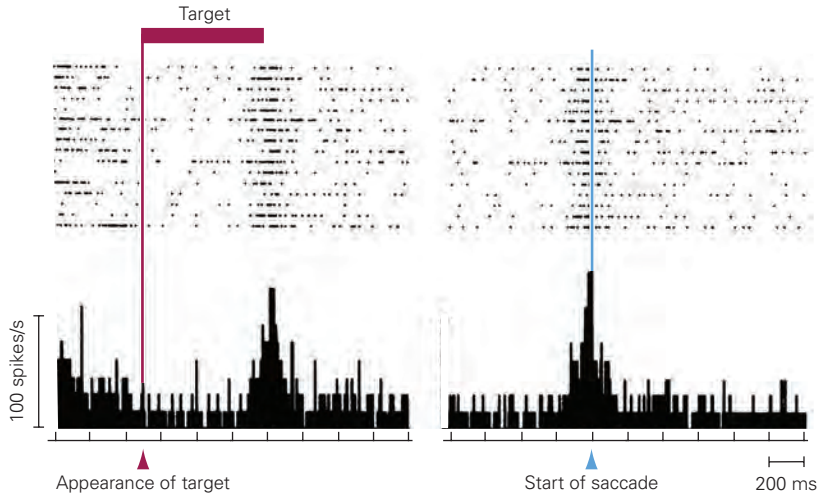


Figure 35–13 Visual and movement-related neurons in the frontal eye field. (Reproduced, with permission, from Bruce and Goldberg 1985.)

A. Activity of a visual neuron in the frontal eye field as a monkey makes a saccade to a target in its visual field. Raster plots of activity in successive trials of the same task are summed to form the histogram below. In the record on the left, the individual trials are aligned at the appearance of the stimulus. A burst of firing is closely time-locked to the stimulus. In the record on the right, the trials are aligned at the beginning of the saccade. Activity is not well aligned with the beginning of the saccade and stops before the saccade itself commences.

B. Activity of a movement-related neuron in the frontal eye field. The records of each trial are aligned as in part **A**. The cell does not respond to appearance of the saccade target (*left*) but is active at the time of the saccade (*right*).

if the superior colliculus responds to a parietal signal that generates attention to the stimulus without the frontal-nigral control that normally prevents saccades in response to parietal signals.

The Control of Saccades Can Be Modified by Experience

Quantitative study of the neural control of movement is possible because the discharge rate of a motor neuron has a predictable effect on a movement. For example, a certain frequency of firing in the abducens motor neuron has a predictable effect on eye position and velocity.

This relationship can change if disease damages an oculomotor nerve or causes an eye muscle to become weak, although the brain can compensate to some degree for such changes. Guntram Kommerell described a case that dramatically illustrates this point. A diabetic patient had an acute partial abducens nerve lesion affecting one eye and a retinal hemorrhage in the other. Because of the poor vision in the eye with a normal abducens nerve, he ordinarily used the eye with the newly weakened lateral rectus muscle. After a few days, the eye recovered the ability to make fairly accurate eye movements. When the weak eye was patched and the subject attempted to make a saccade with the visually poor eye, the saccade overshot the target. This implies that in order to compensate for the weakness of the visually normal eye the brain increased the neural signal to both eyes, resulting in too large a signal to the eye with normal motor input. This change in the motor response depends on the fastigial nucleus and vermis of the cerebellum (Figure 35–9A) and results from the visual system signaling that the preceding eye movement was inaccurate.

Some Rapid Gaze Shifts Require Coordinated Head and Eye Movements

So far, we have described how the eyes are moved when the head is still. When we look around, however, our head is moving as well. Head and eye movements must be coordinated to direct the fovea to a target.

Because the head has a much greater inertia than the eyes, a small shift in gaze drives the fovea to its target before the head begins to move. A small gaze shift usually consists of a saccade followed by a small head movement during which the vestibulo-ocular reflex moves the eyes back to the center of the orbit in the new head position (Figure 35–14). For larger gaze shifts, the eyes and the head move simultaneously in the same direction. Because the vestibulo-ocular reflex ordinarily moves the eyes in the direction opposite that of the head, the reflex must be temporarily suppressed.

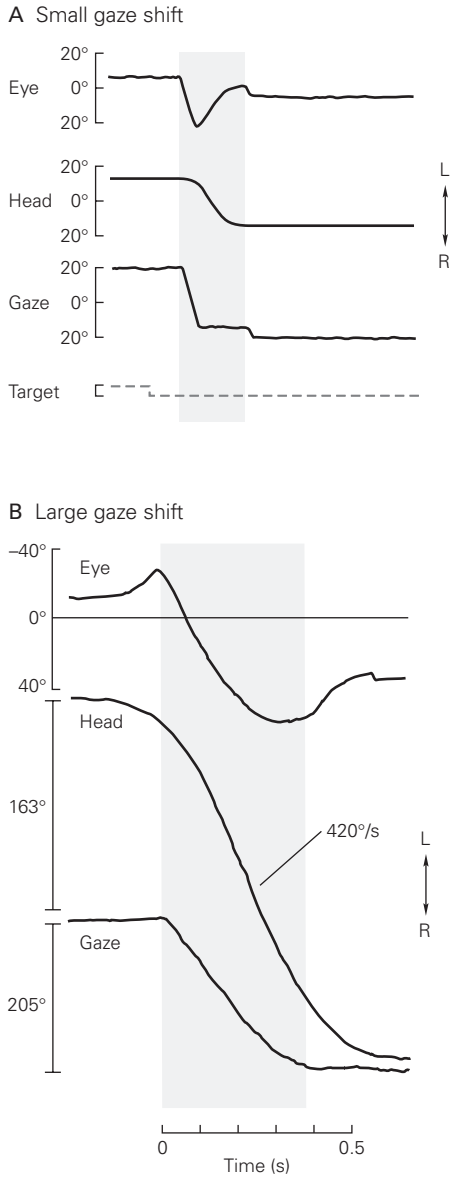

Figure 35–14 Directing the fovea to an object when the head is moving requires coordinated head and eye movements.

A. For a small gaze shift, the eye and head move in sequence. The eye begins to move 300 ms after the target appears. Near the end of the eye movement, the head begins to move as well. The eye then rotates back to the center of the orbit to compensate for the head movement. The gaze record is the sum of eye and head movements. (Abbreviations: **L**, left; **R**, right.) (Reproduced, with permission, from Zee 1977.)

B. For a large gaze shift, the eye and head move in the same direction simultaneously. Near the end of the gaze shift, the vestibulo-ocular reflex returns, the eye begins to compensate for head movement as in part **A**, and gaze becomes still. (Reproduced, with permission, from Laurutis and Robinson 1986.)

The Smooth-Pursuit System Keeps Moving Targets on the Fovea

The smooth-pursuit system holds the image of a moving target on the fovea by calculating how fast the target is moving and moving the eyes at the same speed. Smooth-pursuit movements have a maximum angular velocity of approximately 100° per second, much slower than saccades. Drugs, fatigue, alcohol, and even distraction degrade the quality of these movements.

Smooth pursuit and saccades have very different central control systems. This is best seen when a target jumps away from the center of gaze and then slowly moves back toward it. A smooth-pursuit movement is initiated first because the smooth-pursuit system has a shorter latency and responds to target motion on the peripheral retina as well as on the fovea. The task of the smooth-pursuit system differs from that of the saccade system. Instead of driving the eyes as rapidly as possible to a point in space, it must match the velocity of the eyes to that of a target in space. Therefore, as the target moves back toward the center of gaze, the smooth-pursuit system briefly moves the eye away from the target before the saccade is initiated (Figure 35–6B). The subsequent saccade then brings the eye to the target. Neurons that signal eye velocity for smooth pursuit are found in the medial vestibular nucleus and the nucleus prepositus hypoglossi. They receive projections from the flocculus of the cerebellum and project to the abducens nucleus as well as the oculomotor nuclei in the midbrain.

Neurons in both the flocculus and vermis transmit an eye-velocity signal that correlates with smooth pursuit. These areas receive signals from the cerebral cortex relayed by the dorsolateral pontine nucleus (Figure 35–15). Thus, lesions in the dorsolateral pons disrupt ipsiversive smooth pursuit.

There are two major cortical inputs to the smooth-pursuit system in monkeys. One arises from motion-sensitive regions in the superior temporal sulcus and the middle temporal and medial superior temporal areas. The other arises from the frontal eye field.

The middle temporal and medial superior temporal areas were named because of their position in sulcus-free cortex of the owl monkey, a New World monkey. In humans and Old World monkeys, these areas lie in the superior temporal sulcus, at the junction between the occipital and parietal lobes. Neurons in both the middle temporal and medial superior temporal areas calculate the velocity of the target. When the eye accelerates to match the target's speed, the rate of the target's motion across the retina decreases. As the speed of the retinal image decreases, neurons in the middle temporal area, whose activity signals retinal-image motion, stop firing, even though the target continues to move in space. Neurons in the medial superior temporal area continue to fire even if the target disappears briefly. These neurons have access to a process that adds the speeds of the moving eye and the target moving on the retina to compute the speed of the target in space.

Lesions of either the middle temporal or medial superior temporal area disrupt the ability of a subject to respond to targets moving in regions of the visual field represented in the damaged cortical area. Lesions of the latter area also diminish smooth-pursuit movements toward the side of the lesion, no matter where the target lies on the retina.

The two motion-selective areas provide the sensory information to guide pursuit movements but may not be able to initiate them. Electrical stimulation of either area does not initiate smooth pursuit but can affect pursuit movement, accelerating ipsiversive pursuit and slowing contraversive pursuit. The frontal eye field may

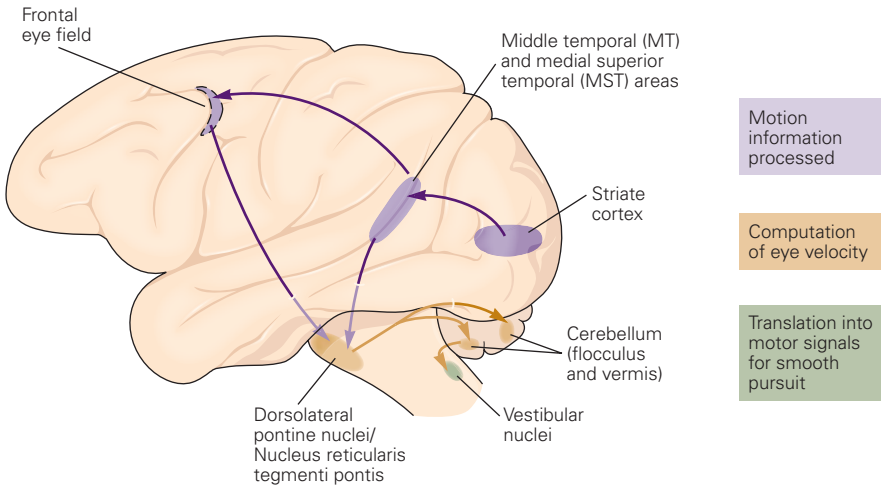

Figure 35–15 Cortical pathways for smooth-pursuit eye movements in the monkey. The cerebral cortex processes information about motion in the visual field and sends it to the oculomotor neurons via the dorsolateral pontine nuclei, the vermis and flocculus of the cerebellum, and the vestibular nuclei. The initiation signal for smooth pursuit may originate in part from the frontal eye field.

be more important for initiating pursuit. This area has neurons that fire in association with ipsiversive smooth pursuit. Electrical stimulation of the frontal eye field initiates ipsiversive pursuit, whereas lesions of this area diminish but do not eliminate smooth pursuit.

In humans, disruption of the pursuit pathway anywhere along its course, including lesions at the level of cortical, cerebellar, and brain stem areas, prevents adequate smooth-pursuit eye movements. Instead, moving targets are tracked using a combination of defective smooth-pursuit movements (the velocity is less than that of the target) and small saccades. Patients with brain stem and cerebellar lesions cannot pursue targets moving toward the side of the lesion.

Patients with parietal deficits that include the motion-sensitive areas have two different types of deficit. The first is a directional deficit that resembles that of monkeys with lesions of the medial superior temporal area: targets moving toward the side of the lesion cannot be tracked. The second is a retinotopic deficit that resembles the deficit of monkeys with lesions of the middle temporal area: There is an impairment of smooth pursuit of a stimulus limited to the visual hemifield opposite the lesion, regardless of the direction of motion.

The Vergence System Aligns the Eyes to Look at Targets at Different Depths

The smooth-pursuit and saccade systems produce conjugate eye movements: Both eyes move in the same direction and at the same speed. In contrast, the vergence system produces disconjugate movements of the eyes. When we look at an object that is close to us, our eyes *converge* or rotate toward each other; when we look at an object that is farther away, they *diverge* or rotate away from each other (Figure 35–16). These disconjugate movements ensure that the image of the object falls on the foveae of both retinas. Whereas the visual system uses slight differences in left and right retinal positions, or *retinal disparity*, to create a

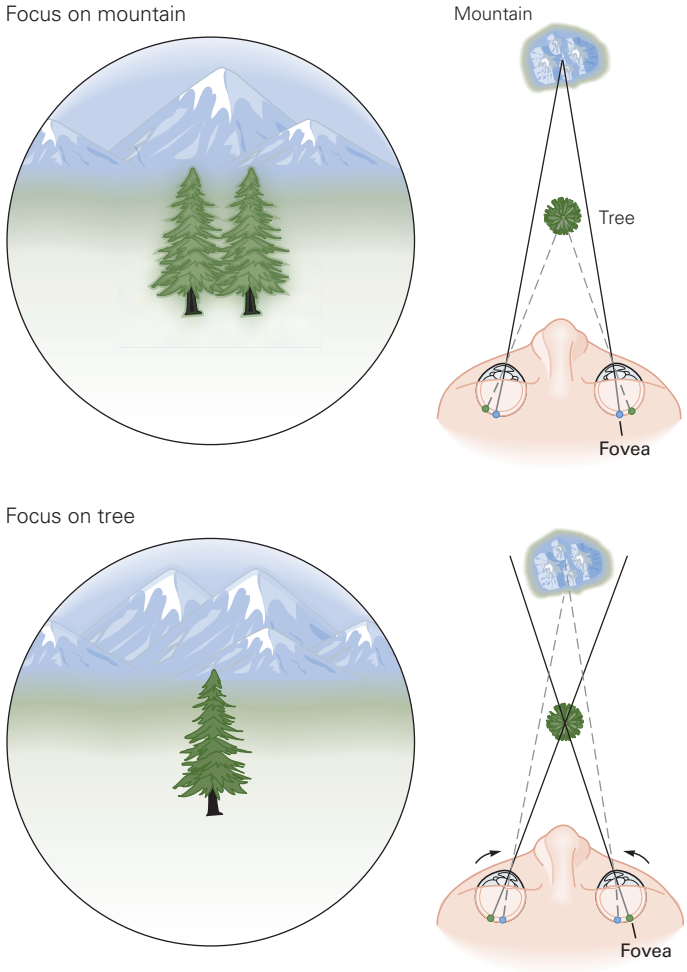

Figure 35–16 Vergence movements. When the eyes focus on a distant mountain, images of the mountain lie on the foveae, while those of the tree in the forefront occupy different retinal positions, yielding the percept of a double image. When the viewer looks instead at the tree, the vergence system must rotate each eye inward. Now the tree's image occupies similar positions on both foveae and is seen as one object, but the mountain's images occupy different locations on the retinas and appear double. (Reproduced, with permission, from F.A. Miles.)

sense of depth, vergence movements eliminate retinal disparity at the fovea.

Vergence is a function of the horizontal rectus muscles only, because the two eyes are horizontally, not vertically, displaced. Convergence of the eyes for near-field viewing is accomplished by simultaneously increasing the tone of the medial recti muscles and decreasing the tone of the lateral recti muscles to converge the eyes. Conversely, distance viewing is accomplished by reducing the tone of the medial rectus and increasing the tone of the lateral rectus.

At any given time, the entire visual field is not in focus on the retina. When we look at something nearby, distant objects are blurred. When we look at something far away, near objects are blurred. When we wish to focus on an object in a closer plane in the visual field, the oculomotor system contracts the ciliary muscle, thereby changing the radius of curvature of the lens. This process is called *accommodation.* With age, accommodation declines owing to increased rigidity of the lens; reading glasses are then needed to focus images at short distances.

Accommodation and vergence are linked. Accommodation is elicited by the blurring of an image, and whenever accommodation occurs, the eyes also converge. Conversely, retinal disparity induces vergence, and whenever the eyes converge, accommodation also takes place. At the same time, the pupils transiently constrict to increase the depth of field of the focus. The linked phenomena of accommodation, vergence, and pupillary constriction comprise the *near response.* Accommodation and vergence are controlled by midbrain neurons in the region of the oculomotor nucleus. Neurons in this region discharge during vergence, accommodation, or both.

Highlights

1. The oculomotor system provides a valuable window into the nervous system for both the clinician and the scientist. Patients with oculomotor deficits may experience alarming symptoms such as double vision that quickly send them to seek medical help. A physician with a thorough knowledge of the oculomotor system can describe and diagnose most oculomotor deficits at the bedside and localize the site of the lesion within the brain based on the neuroanatomy and neurophysiology of eye movements.
2. The purpose of eye movements is to rotate the eye in the orbit in order to direct the fovea, the area of the retina with best acuity, to the point of greatest interest in the visual scene and then to keep the image steady.
3. Six muscles work together to move each eye. These eye muscles are yoked in three pairs. The lateral rectus abducts the eye horizontally, and the medial rectus adducts it. The cyclovertical eye muscles move the eye both vertically and torsionally.
4. Motor neurons for the extraocular muscles lie in three brainstem nuclei. The abducens nucleus in the pons contains the neurons for the lateral rectus. The other oculomotor neurons are in the midbrain: The trochlear nucleus contains superior oblique neurons, and the oculomotor nucleus has the motor neurons for the medial, superior, and inferior rectus muscles and the inferior oblique muscle. Neurons that constrict the pupil and those that elevate the eyelid also lie in the oculomotor nucleus.
5. There are six different types of eye movements, with different control systems: (1) Saccades shift the fovea rapidly to a new visual target. (2) Smooth-pursuit movements keep the image of a moving object on the fovea. (3) Vergence movements rotate the eyes in opposite directions so that the image of an object of interest is positioned on both foveae regardless of its distance. (4) Vestibulo-ocular reflexes hold images still on the retina during brief, rapid head movements. (5) Optokinetic movements hold images stationary during sustained or slow head movements. (6) Fixation is an active process that keeps the eye still during intent gaze when the head is not moving.
6. The firing pattern of eye muscle neurons combines independent signals that code eye position and velocity. The neurons that generate the velocity signal for horizontal saccades lie in the paramedian pontine reticular formation, and this velocity signal is integrated in the medial vestibular nucleus and nucleus prepositus hypoglossi to provide the position signal.
7. The mesencephalic reticular formation provides the position and velocity signals for vertical and torsional eye movements as well as vergence eye movements.
8. Presaccadic burst neurons in the superior colliculus project a desired displacement signal to the reticular formation. These neurons are inhibited by a GABAergic projection from the substantia nigra and excited by projections from the frontal eye field and the posterior parietal cortex. A motor signal from the frontal eye field excites the caudate nucleus, which then inhibits the substantia nigra, allowing a saccade to occur.
9. The posterior parietal cortex projects an attentional signal to the superior colliculus that does not distinguish between attention and movement.

10. Most large gaze shifts involve head movements as well as eye movements. Because the eye moves faster than the head, it typically reaches the target first. The vestibulo-ocular reflex maintains the eye on target by driving the eye with a velocity opposite to that of the head movement.
11. The cerebellum calibrates eye movements based on visual feedback and mediates the learning process that keeps them accurate over time.
12. Smooth pursuit is driven by a network that includes the medial vestibular nucleus, the flocculus of the cerebellum, the dorsolateral pontine nucleus, and two motion-selective areas that are found in the superior temporal sulcus of some monkeys—the middle temporal and medial superior temporal areas. Homologous areas in the human brain are located at the parieto-occipital junction. The pursuit area of the frontal eye fields initiates smooth-pursuit movements.
13. Although the motor programming of eye movements is well understood, the great bulk of physiological research in this field was done with a monkey making a directed saccade to a spot of light. The neural mechanisms underlying the free choice of saccade targets as we explore the visual world are poorly understood. This question, lying at the intersection of cognition and motor control, is one of the great unknowns in neuroscience and will be at the center of oculomotor research in the future.

Posture

The control of posture involves two interrelated goals, equilibrium (balance) and orientation, crucial for most tasks of daily living. Balance control maintains the body in stable equilibrium to avoid falls. Orientation aligns the body segments with respect to each other and to the world, such as maintaining the head vertical. Both balance and orientation use several different types of control: automatic postural responses, anticipatory postural adjustments, postural sway in stance, sensory integration for a body schema, orientation to vertical, and dynamic stability during gait.

To appreciate the complexity of maintaining balance and orientation, imagine that you are waiting tables on a tour boat. You have a tray full of drinks to be delivered to a table on the other side of the rolling deck. Even as your mind is occupied with remembering customer orders, unconscious but complex sensorimotor processes for controlling postural orientation and balance allow you to move about in an efficient and coordinated manner without falling. As you cross the rolling deck, your brain rapidly integrates and interprets sensory information and adjusts motor output to maintain your balance and the upright orientation of your head and trunk, as well as stabilize the arm supporting the tray of full glasses. Sudden

unexpected motions of the boat evoke automatic postural responses that prevent falls. Before you reach out to place a glass on the table, your nervous system makes anticipatory postural adjustments to maintain your balance.

Somatosensory, vestibular, and visual information are integrated to provide a coherent sense of the position and velocity of the body in space with respect to the support surface, gravity, and visual environment. Since the surface is unstable and vision is not providing earth-stable information, your dependence on vestibular information is greater than usual. Your head is kept stable while your trunk motions and walking pattern adjust for disequilibrium caused by the moving surface. You notice that both your voluntary tasks and your balance control deteriorate when trying to attend to both goals.

Equilibrium and Orientation Underlie Posture Control

Postural equilibrium refers to the ability to actively stabilize the upper body by resisting external forces acting on the body. Although the dominant external force affecting equilibrium on earth is gravity, other inertial forces and external perturbations must also be resisted. Depending on the particular task or behavior, different sets of muscles are activated in response to or in anticipation of disturbance to equilibrium.

Postural orientation refers to the ability to actively align body segments, such as the trunk and head, with respect to each other and to the environment. Depending on the particular task or behavior, body segments may be aligned with respect to gravitational vertical, visual vertical, or the support surface. For example, when skiing downhill, the head may be oriented to gravitational and inertial vertical, but not to the visual or support surface references that are inclined.

The biomechanical requirements of postural control depend on anatomy and postural orientation and thus vary among species. Nevertheless, in a variety of species, the control mechanisms for postural equilibrium and orientation have many common features. The sensorimotor mechanisms for postural control are quite similar in humans and quadrupedal mammals even though their habitual stance is different.

Postural Equilibrium Controls the Body's Center of Mass

With many segments linked by joints, the body is mechanically unstable. To maintain balance, the nervous system must control the position and motion of the body's *center of mass* as well as the body's rotation about it. The center of mass is a point that represents the average position of the body's total mass. In the standing adult, for example, the center of mass is located about 2 cm in front of the second lumbar vertebra; in a young child, it is higher. The location of the center of mass is not fixed but depends on postural orientation. For example, when you flex at the hips while standing, the center of mass moves from a location inside the body to a position outside the body.

Although gravity pulls on all body segments, the net effect on body equilibrium acts through the body's center of mass. The force due to gravity is opposed by the forces between the feet and the ground. Each point on the surface will generate a force on the foot. All the forces acting between the foot and the ground can be summed to yield a single force vector termed the *ground reaction force*. This origin of the ground reaction force vector on the surface is the point at which the rotational effect of all the forces on the feet are balanced and is termed the *center of pressure* (Box 36–1).

Maintaining balance while standing requires keeping the downward projection of the center of mass within the base of support, an imaginary area defined by those parts of the body in contact with the environment. For example, the two feet or one foot of a standing human define a *base of support* (Box 36–1). However, when a standing person leans against a wall or is supported by crutches, the base of support extends from the ground under the feet to the contact point between the body and the wall or crutches. Because the body is always in motion, even during stable stance, the body's center of mass continually moves about with respect to the base of support. Postural instability is determined by how fast the center of mass is accelerating toward and beyond the boundary of its base of support and how close the downward projection of the body's center of mass is to the boundary.

Upright stance requires two actions: (1) maintaining support against gravity by keeping the center of mass at some height and joints stable and (2) maintaining balance by controlling the trajectory of the center of mass in the horizontal plane. Balance and antigravity support are controlled separately by the nervous system and may be differentially affected in certain pathological conditions. For example, antigravity support can be excessive when spasticity is present after a stroke or insufficient in the hypotonia of cerebral palsy, although balance control may be preserved. Alternatively, in vestibular disorders, antigravity support can be normal, although balance control is disordered.

Box 36–1 Center of Pressure

The center of pressure (CoP) is defined as the origin of the *ground reaction force* vector on the support surface. For the body to be in static equilibrium, that is, to remain motionless, the force caused by gravity and the ground reaction force must be equal and opposite, and the CoP must be directly under the center of mass (CoM) (Figure 36–1A). Misalignment of the CoM and CoP causes motion of the CoM. For example, if the CoM projection onto the base of support is to the right of the CoP, the body will sway to the right until the CoP moves to the right to move the CoM back over the base of support.

However, standing is never truly static. While the body is in motion (postural sway), CoM and CoP are not aligned and dynamic equilibrium must maintain balance (Figure 36–1B). In fact, when the body is unsupported, CoP and CoM are continually in motion and are rarely aligned, although when averaged over time during quiet stance, they are coincident. The sway of the body during quiet stance can be described by the trajectory of either CoM or CoP over time, such as sway path, area, velocity, and frequency.

In more dynamic situations like walking, running, turning, and jumping, stability can be achieved even when the CoM briefly goes outside the base of support. For example, when standing on one leg or on a narrow beam, momentum from rotating the hips, arms, and other body parts or movement of the CoP can be used to change the direction of the ground reaction force to return the body CoM over its base of support to maintain stability (Figure 36–1B). If the CoM is outside the base of support and heading away from it, subjects may need to take a step or grab a stable object to change the base of support and avoid a fall.

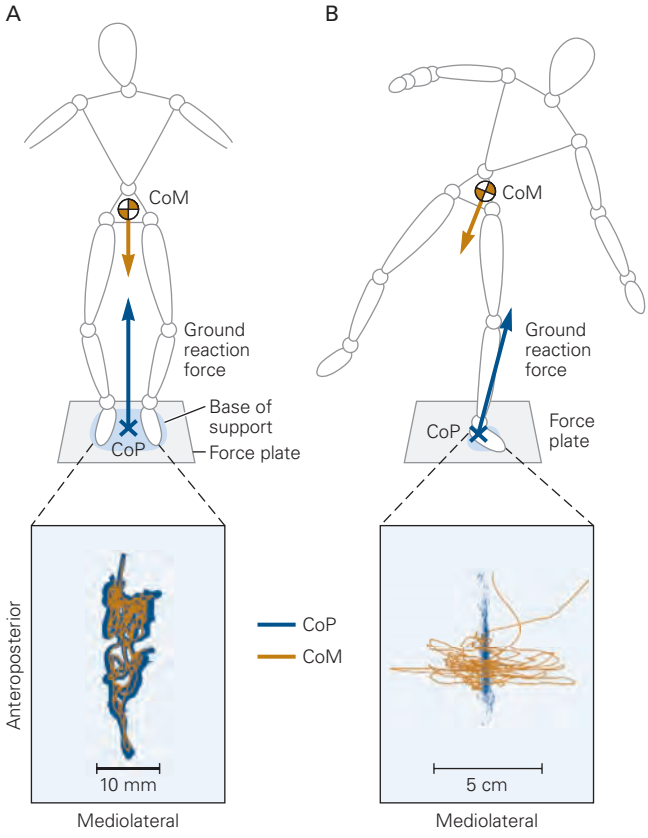

Figure 36–1 The center of mass is controlled by moving the center of pressure.

A. The force caused by gravity passes through the center of mass (**CoM**) in the trunk. The surface exerts an upward force against each foot, such that the ground reaction force vector originates at the center of pressure (**CoP**) on the support surface. **Below:** Even when the feet remain in place, the CoP (**blue displacement**) and CoM (**gold displacement**) are always in motion as we sway. During normal standing on two feet, the projection of the CoM of the body remains within the base of support (**light blue rectangle** around the feet in contact with the ground) for equilibrium. The base of support of the standing human is defined by contact of the feet on the support surface.

B. In a dynamic situation, such as standing on one leg on a narrow beam, equilibrium can be maintained even when the body CoM displacements (**gold displacements**) go outside of the base of support for brief periods. Strategies such as counter-rotation of the lower and upper body can tilt the ground reaction force so that it accelerates the body CoM back over its base of support. Antigravity support, or "postural tone," is provided by the tonic activation of muscles that generate force against the ground to keep the trunk and limbs extended and the center of mass at the appropriate height. In humans, much of the support against gravity is provided by passive bone-on-bone forces in joints such as the knees, which can be fully extended during stance, and in stretched ligaments such as those at the front of the hips. Nevertheless, antigravity support in humans also requires active tonic muscle contraction, for example, in ankle, trunk, and neck extensors. Postural tone, however, should not be considered a static state of muscle activation, as can be seen in pathologies such as decerebrate rigidity or the rigidity of parkinsonism. Normal postural tone is constantly changing, as a "wave" or "reed in the wind," to accommodate changes in postural alignment, voluntary movements, and task requirements.

Postural tone is not sufficient, however, for maintaining balance. Both bipeds and quadrupeds are inherently unstable, and their bodies sway during quiet stance. Actively contracted muscles exhibit a spring-like stiffness that helps to resist body sway, but muscle stiffness alone is insufficient for maintaining balance. Even stiffening of the limbs through muscle cocontraction is not sufficient for balance control. Instead, complex patterns of muscle activation produce direction-specific forces to control the body's center of mass. Body sway caused by even subtle movements, such as the motion of the chest during breathing, is actively counteracted by alterations in postural tone.

Postural Orientation Anticipates Disturbances to Balance

Postural orientation is the manner in which body parts are aligned with respect to each other and to the environment. Animals arrange their bodies to accomplish specific tasks efficiently. Although this postural orientation interacts with balance control, the two systems can act independently. For example, soccer goalies may orient their body to intercept a ball by sacrificing the goal of maintaining balance. In contrast, a patient with Parkinson disease or thoracic kyphosis may use an inefficient, flexed postural alignment to maintain effective control of balance while standing.

The energy needed to maintain body position over a period of time can influence postural orientation. In humans, for example, the upright orientation of the trunk with respect to gravity minimizes the forces and thus the energy required to hold the body's center of mass over the base of support. Task requirements also affect postural orientation. For some tasks, it is important to stabilize the arrangement of the body in space, whereas for others, it is necessary to stabilize one body part with respect to another. When walking while carrying a full glass, for example, it is important to stabilize the hand against gravity to prevent spillage. In contrast, when walking while reading a cell phone, the hand must be stabilized with respect to the head and eyes to maintain visual acuity.

Subjects may adopt a particular postural orientation to optimize the accuracy of sensory signals regarding body motion. For example, when standing and walking inside a ship, in which the surface and visual references may be unstable, information about earth vertical is derived primarily from vestibular inputs. A person often aligns his head with respect to gravitational vertical when balancing on an unstable surface because the perception of vertical is most accurate when the head is upright and stable.

Anticipatory alterations of habitual body orientation can minimize the effect of a possible disturbance. For example, people often lean in the direction of an anticipated external force, or they flex their knees, widen their stance, and extend their arms when anticipating that stability will be compromised.

Postural Responses and Anticipatory Postural Adjustments Use Stereotyped Strategies and Synergies

When a sudden disturbance causes the body to sway, various postural motor strategies are used to maintain the center of mass within the base of support. In one strategy, the base of support remains fixed relative to the support surface: While the feet remain in place, the body rotates about the ankles back to the upright position (Figure 36–2A). In other strategies, the base of support is moved or enlarged, for example, by taking a step or by grabbing a support with the hand (Figure 36–2B).

Older views of motor control focused on trunk and proximal limb muscles as the main postural effectors. Recent behavioral studies show that any group of muscles from the neck and trunk, legs and arms, or feet and hands can act as postural muscles depending on the body parts in contact with the environment and the biomechanical requirements of equilibrium.

When studying the posture control system, scientists disrupt balance in a controlled manner to determine the subject's automatic postural response. This response is described by the ground reaction force vector, the motion of the center of pressure, and movements of parts of the body. The electrical activity

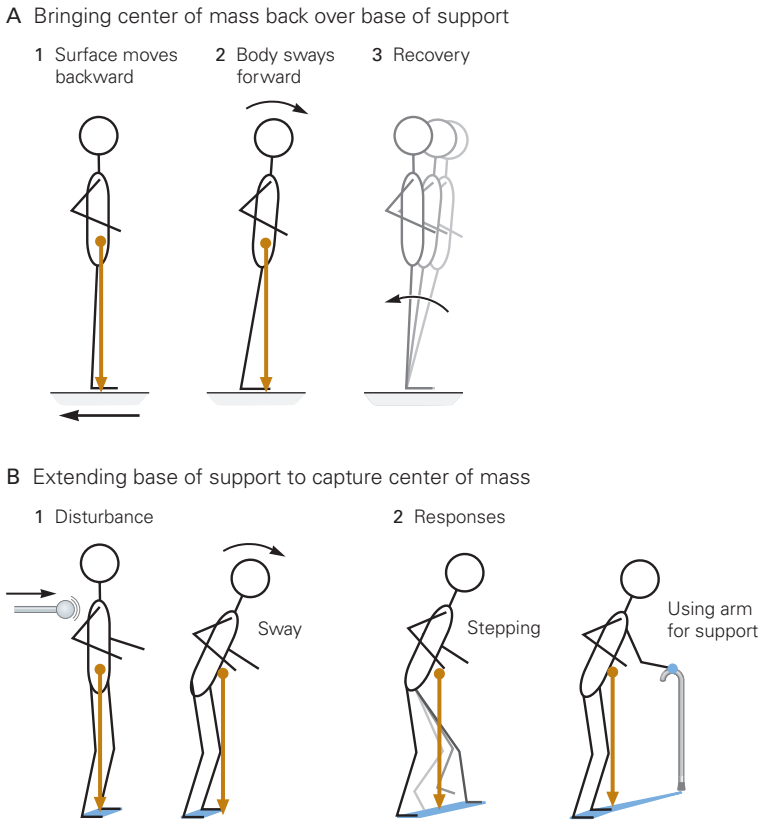

Figure 36–2 Automatic postural responses keep the center of mass within the base of support.

A. One postural strategy for regaining balance is to bring the center of mass back to its origin over the base of support. When the platform on which a subject is standing is suddenly moved backward, the body sways forward and the projection of the center of mass moves toward the toes. During recovery, the body actively exerts force into the surface about the ankles, bringing the center of mass back to the original position over the feet.

B. An alternative postural strategy enlarges the base of support to keep the center of mass within the base. A disturbance causes the subject to sway forward and the center of mass moves toward the boundary of the base of support (**blue area** on the ground). The base can be enlarged in two ways: taking a step and placing the foot in front of the center of mass to decelerate the body's motion, or grabbing a support and thereby extending the base to include the contact point between the hand and support.

of many muscles is recorded by electromyography (EMG), which reflects the firing of alpha motor neurons that innervate skeletal muscle and thus provides a window into the nervous system's output for balance control. The combination of all these measurements allows investigators to infer the active neural processes underlying balance control.

Automatic Postural Responses Compensate for Sudden Disturbances

An automatic postural response to a sudden disturbance is not a simple stretch reflex but rather the synergistic activation of a group of muscles in a characteristic sequence with the goal of maintaining equilibrium. That is, the recruitment of a muscle for a postural response serves the requirements of equilibrium and is not a reflexive change in the muscle's length caused by the disturbance. For example, when the surface under a person is rotated in the toes-up direction, the ankle extensor (gastrocnemius) is lengthened and a small stretch reflex may occur. However, the postural response for balance recruits the antagonist ankle flexor (tibialis anterior), which itself is shortened by the surface rotation, while suppressing the stretch response in the gastrocnemius. In contrast, when the platform is moved backward, the gastrocnemius is again lengthened but now it is recruited for the postural response, as evidenced by a second burst of EMG activity after the stretch reflex. Thus, the initial change in length of a muscle induced by perturbation does not determine whether that muscle is recruited for postural control, and stretch reflexes are not the basis for postural control. In fact, monosynaptic stretch reflexes are too weak to move the body center of mass effectively, and very often, the postural muscles activated to recover equilibrium have not been stretched.

Automatic postural responses to sudden disturbances have characteristic temporal and spatial features. A postural response in muscles must be recruited rapidly following the onset of a disturbance. Sudden movement of the support surface under a standing cat evokes EMG activity within 40 to 60 ms (Figure 36–3). Humans have longer latencies of postural response (90–120 ms in the ankle muscles); the increased delay is attributed to the larger body size of humans and thus

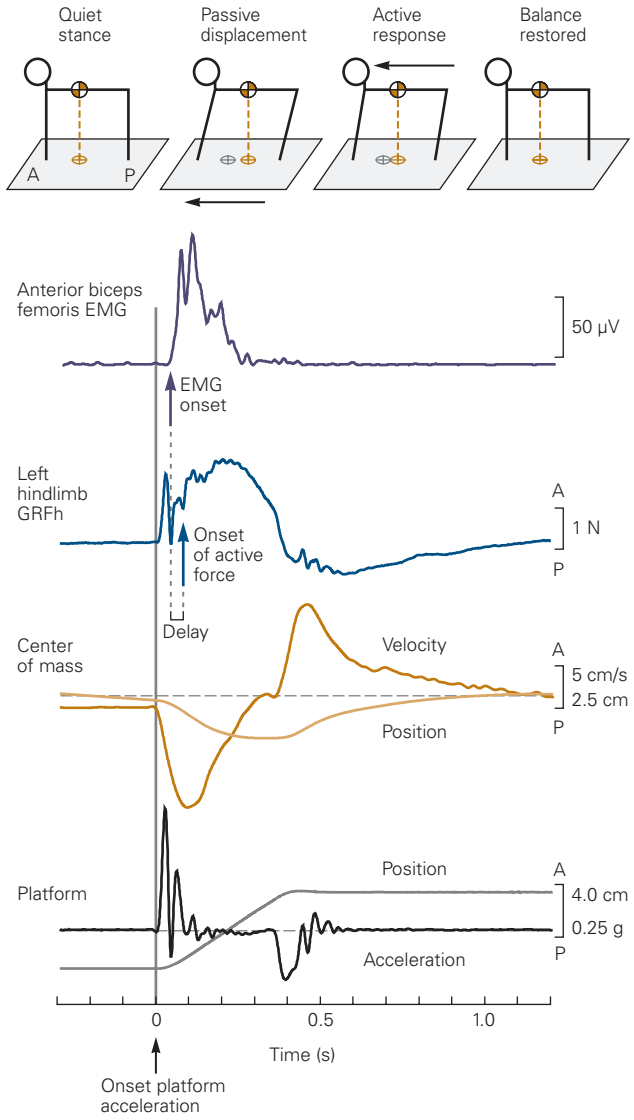

Figure 36–3 **Automatic postural responses have stereotypical temporal characteristics.** Electromyographic (**EMG**) activity has a characteristic latency. Anterior motion of the platform evokes an EMG response in the hip extensor muscle (anterior biceps femoris) of a cat approximately 40 ms after the onset of platform acceleration (100 ms in a human). This latency is stereotyped and repeatable across subjects and is approximately four times as long as that of the monosynaptic stretch reflex. As the platform moves, the paws are carried forward and the trunk remains behind owing to inertia, causing the center of mass to move backward with increasing velocity with respect to the platform. The velocity of the center of mass peaks and then decreases as the horizontal component of the ground reaction force (**GRFh**) increases following muscle activation. The delay of approximately 30 ms between the onset of EMG activity and the onset of the active response reflects excitation–contraction coupling and musculoskeletal compliance. The automatic postural response extends the hind limb, propelling the trunk forward and restoring the position of the center of mass with respect to the paws. (Abbreviations: **A**, anterior; **P**, posterior.) (Data from J. Macpherson.)

the greater signal conduction distances from sensory receptors to the central nervous system and thence to leg muscles. The latency of automatic postural responses is shorter than voluntary reaction time but longer than the monosynaptic stretch reflex.

Postural responses involving a change in support base, such as stepping, have even longer latencies than those that occur when the feet remain in place. The longer time presumably affords greater flexibility in the commands transmitted by long loops through the cortex; for example, the choice of foot to begin the step, the direction of the step, and the path of the step around obstacles.

Activation of postural muscles results in contraction and the development of force in the muscles, leading to torque (rotational force) at the joints. The net result is an active response, the ground reaction force (Box 36–1), that restores the center of mass to its original position over the base of support (Figure 36–3). The delay between EMG activation and the active response, approximately 30 ms in the cat and 50 ms in humans, reflects the excitation–contraction coupling time of each muscle as well as the compliance of the musculoskeletal system.

The amplitude of EMG activity in a particular muscle depends on both the speed and direction of postural disturbance. The amplitude increases as the speed of a movable platform under a standing human or cat increases, and it varies in a monotonic fashion as the direction of platform motion is varied systematically. Each muscle responds to a limited set of perturbation directions with a characteristic tuning curve (Figure 36–4).

Although individual muscles have unique directional tuning curves, muscles are not activated independently but instead are activated together in *synergies*, with characteristic time delays. The muscles within a synergy receive a common command signal during postural responses. In this way, the many muscles of the body are controlled by just a few signals, reducing the time needed to compute the appropriate postural response (Box 36–2).

The set of muscles recruited in a postural response to a disturbance depends on the body's initial stance. The same disturbance elicits very different postural responses in someone standing unaided, standing while grasping a stable support, or crouching on all four limbs. For example, forward sway activates muscles in the back of the legs and trunk during upright free stance. When the subject is holding onto a stable support, muscles of the arms rather than those of the legs are activated first. When the subject is crouched on toes and fingers, like a cat, muscles in the front of the legs and in the arms are activated (Figure 36–6A).

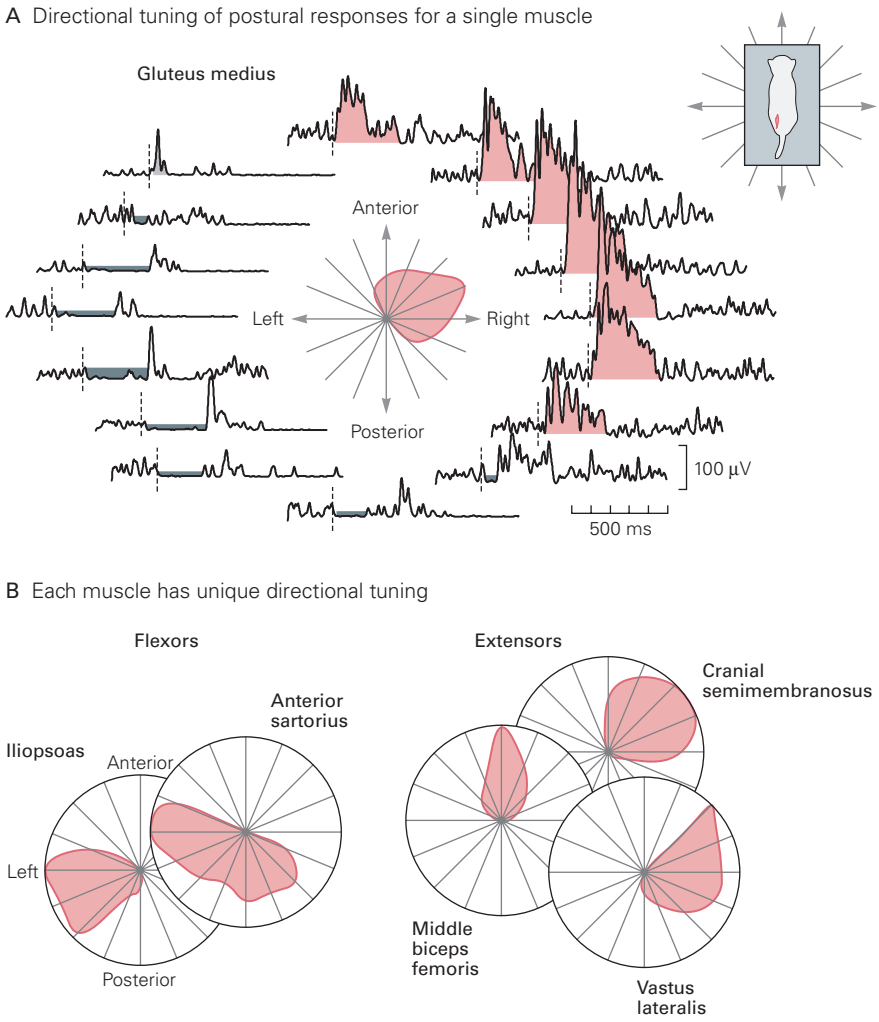

Figure 36–4 Automatic postural responses have stereotypical directional characteristics. (Adapted from Macpherson 1988.)

A. The gluteus medius muscle in the cat, a hip extensor and abductor, responds to a range of directions of motion in the horizontal plane. The electromyographic (EMG) records shown here are from a cat standing on a platform that was moved in the horizontal plane in each of 16 evenly spaced directions. The gluteus medius muscle of the left hind limb was activated by motion in several directions (**pink**) and inhibited in the remaining directions (**gray**). The **dashed vertical lines** indicate the onset of platform acceleration. In the center is a polar plot of the amplitude of EMG activity versus the direction of motion during the automatic postural response; it represents a directional tuning curve for the muscle. EMG amplitude was computed from the area under the curve during the first 80 ms of the response.

B. Every muscle has a characteristic directional tuning curve that differs from that of other muscles, even if they have similar actions. The middle biceps femoris and cranial semimembranosus, for example, are both extensors of the hip.

Because postural responses are influenced by recent experience, they adapt only gradually to new biomechanical conditions. When forward sway is induced by backward motion of a platform on which a subject is standing, the posterior muscles of the ankle, knee, and hip are activated in sequence beginning 90 ms after the platform starts moving. This postural response, the *ankle strategy*, restores balance primarily by rotating the body about the ankle joints. However, when forward sway is induced by backward motion of a narrow beam, it is impossible to use surface torque alone to recover equilibrium and the anterior muscles of the hip and trunk are activated. This postural response, the *hip strategy*, restores the body's center of mass by bending forward at the hip joints and counterrotating at the ankles (Figure 36–6B).

When a subject moves from standing on a wide platform to a narrow beam, she or he persists in using the ankle strategy in the first few trials. This strategy does not work when standing on the beam, and the subject falls. Over several trials, the subject will gradually switch to using the hip strategy. Similarly, moving from the beam back to the platform requires several trials to adapt the postural response back to the ankle strategy (Figure 36–6C).

Although sensory stimulation changes immediately after subjects move from the beam to the floor, the postural response adjusts gradually as it is tuned for optimal behavior by trial and error. If postural responses were simple reflexes, they would change immediately upon a change in sensory drive. Trial-to-trial changes in postural behavior generally occur at the subconscious level (implicit learning) and involve updating of the body schema and internal model of the world within the right parietal cortex. This body schema is dynamic, as it is constantly updated based on experience.

Postural responses not only improve with practice, but the improvements are retained, a sign of motor

Box 36–2 Synergistic Activation of Muscles

Coordinated movements require precise control of the many joints and muscles in the body. Maintaining control is biomechanically complex, in part because different combinations of joint rotations and muscle activations can achieve the same goal. Such redundancy confers great flexibility, for example, in modifying stepping patterns to negotiate obstacles in our path, but comes at the cost of increased complexity in the brain's computation of movement trajectories and forces.

Many factors must be included in the computation of movement commands, including the effect of external forces such as gravity and the forces that one body segment exerts on another during motion. All these factors come into play when the brain computes postural responses to sudden disturbances, but with the added constraint of a time limit on computation: Responses must occur within a certain time or balance will be lost.

It has long been believed that the brain simplifies the control of movement by grouping control variables, for example, activating several muscles together. Using mathematical techniques that parse complex data into a small number of components, one can determine that only four synergies are needed to account for the vast majority of activation patterns of 13 muscles of the human leg and trunk during automatic postural responses to many directions of platform motion (Figure 36–5). Activation of each synergy produces a unique direction of force against the ground, suggesting that postural control is based on task-related variables such as the force between foot and ground rather than the contraction force of individual muscles.

Like the arrangement of notes in a musical chord, each muscle synergy specifies the timing and amplitude of activation for a particular muscle together with others. Just as one note belongs to several different chords, each muscle belongs to more than one synergy. When several chords are played simultaneously, the chord structure is no longer evident in the multitude of notes. Similarly, when several synergies are activated concurrently, the observed muscle pattern gives the appearance of unstructured complexity, but a particular muscle's activation is the result of the systematic addition of synergy commands. Concurrent activation of synergies simplifies the neural command signals for movement as only a few central commands are required instead of a separate command for each muscle, while allowing flexibility and adaptability to postural control.

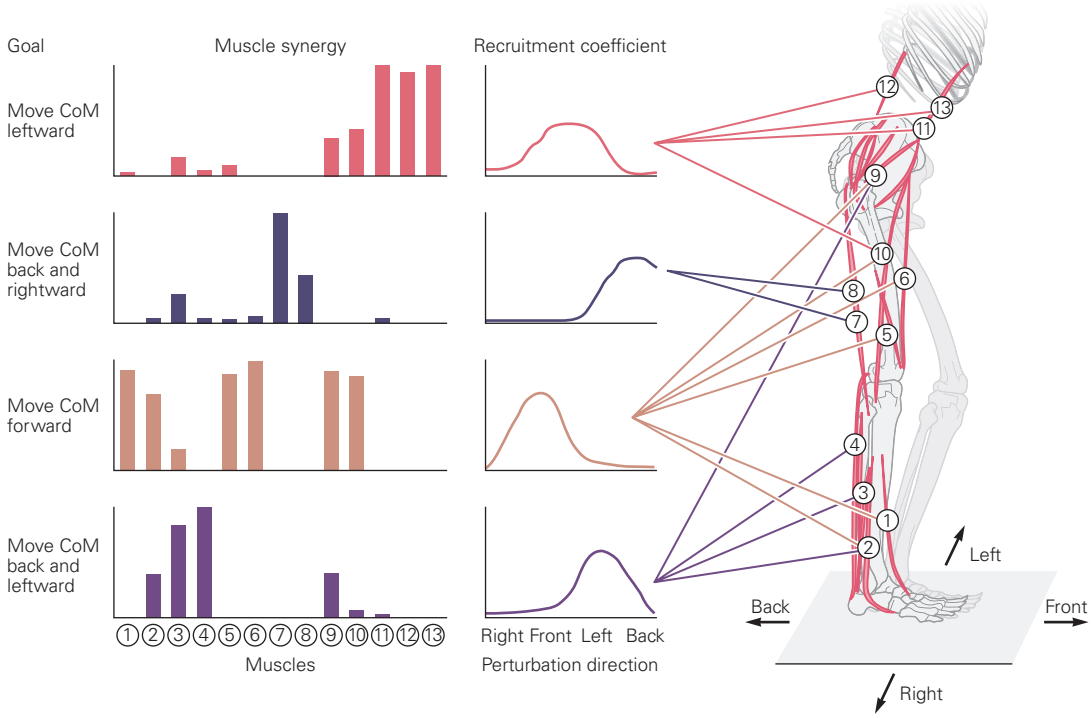

Figure 36–5 Postural commands activate synergies rather than individual muscles. Synergistic activation of several muscles allows movement goals to be translated into specific muscle activity patterns. Each muscle synergy activates a group of muscles in a fixed proportion (**colored bars**) to produce the mechanical output needed to achieve a postural goal. The height of each bar represents the relative amount of activation, or weighting, for each muscle (1–13). Each synergy is activated more or less at particular times during a behavior driven by central commands and sensory drive (recruitment function). For example, different postural synergies are activated for different directions of falling. (Abbreviation: **CoM**, center of mass.) (Reproduced, with permission, from L. Ting.)

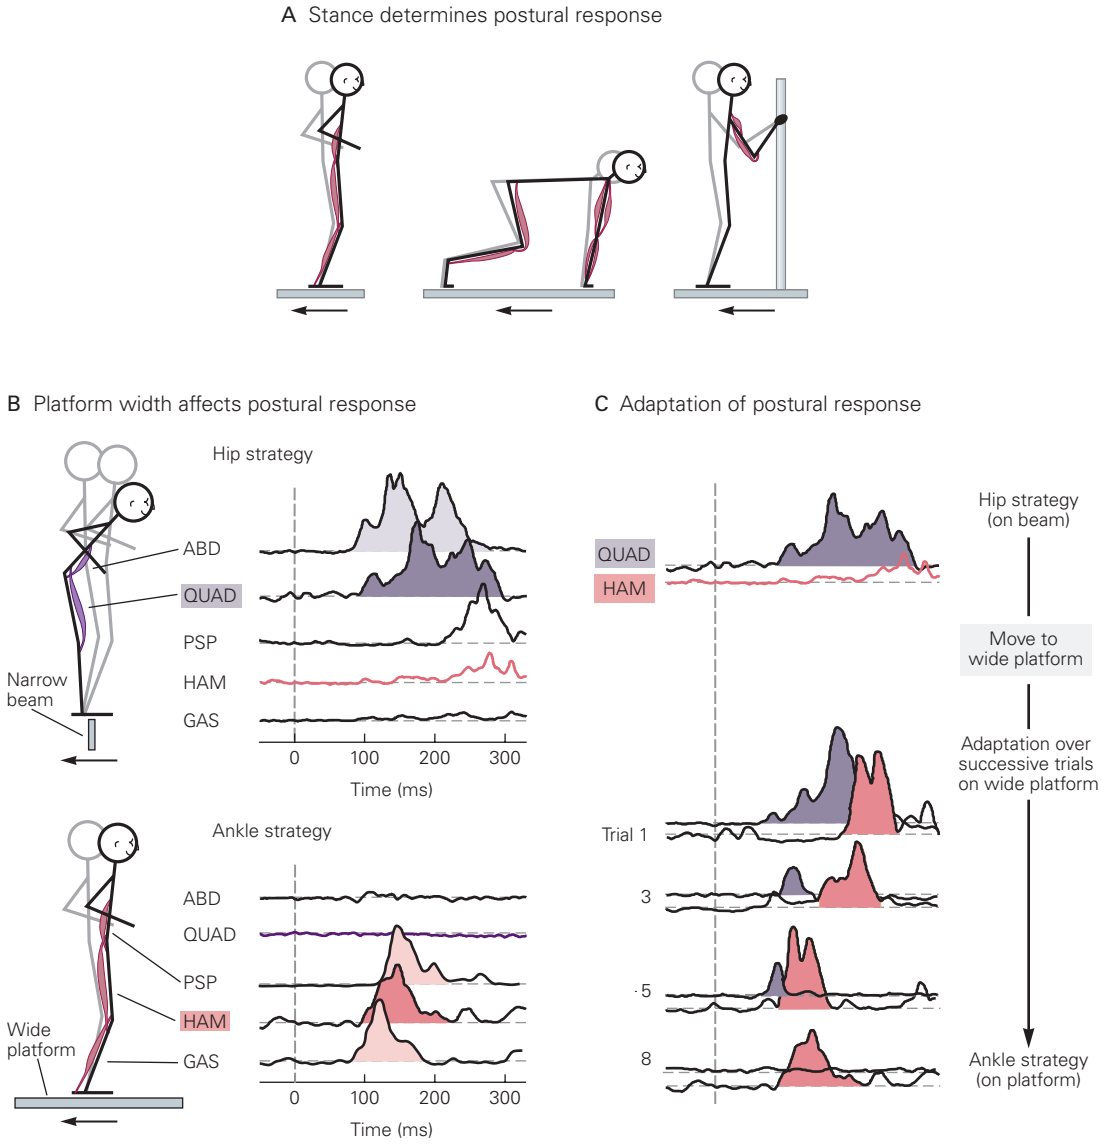

Figure 36–6 Automatic postural responses change with biomechanical conditions.

A. The backward movement of a platform activates different groups of muscles depending on initial stance. **Gray stick figures** show initial positions (upright unsupported, quadrupedal, or upright supported). The muscles activated in each postural response are shown in **red**. (Adapted, with permission, from Dunbar et al. 1986.)

B. When a subject stands on a narrow beam that is abruptly moved backward, the anterior muscles—abdominals (**ABD**) and quadriceps (**QUAD**)—are recruited to flex the trunk and extend the ankles, moving the hips backward (the hip strategy). When the subject instead stands on a wide platform that is moved backward, his posterior muscles—paraspinals (**PSP**), hamstrings (**HAM**), and gastrocnemius (**GAS**)—are activated to bring the body back to the erect position by rotating at the ankles (the ankle strategy). Muscles representative of different postural responses are highlighted in color. **Dashed vertical lines** in the plots indicate onset of platform (or beam) acceleration.

C. Postural strategy adapts after the subject moves from the narrow beam onto the wide platform. On the beam, the quadriceps are activated and the hamstrings are silent; after adaptation to the wide platform, the reverse is observed. The transition from quadriceps to hamstrings activation occurs over a series of trials; the activity in the quadriceps gradually decreases in amplitude, whereas the hamstrings are activated earlier and earlier until, by trial 8, quadriceps activity disappears altogether. Ankle and trunk muscles show similar patterns of adaptation. (B. and C, adapted, with permission, from Horak and Nashner 1986.)

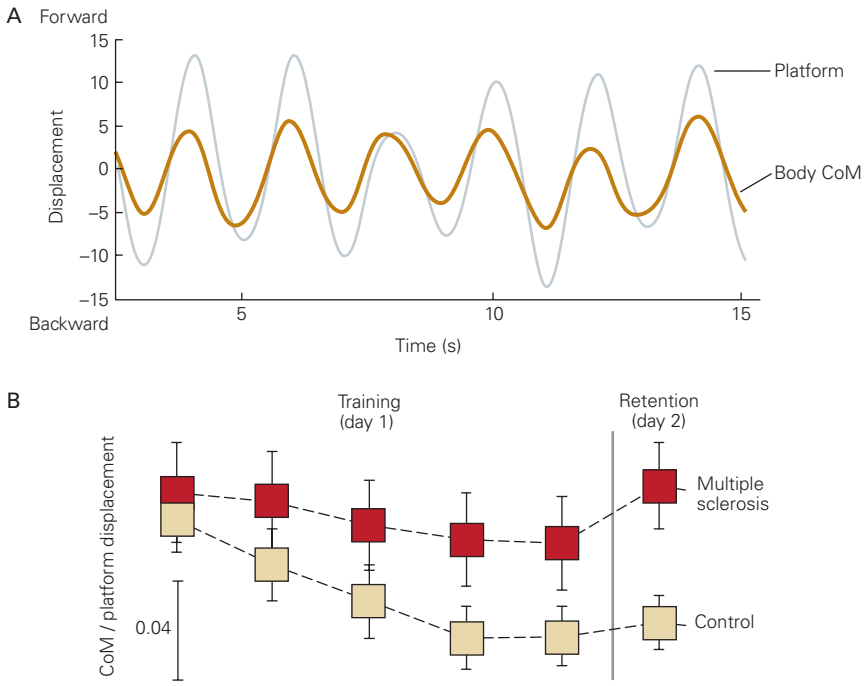

Figure 36–7 Postural responses can be learned and retained with practice.

A. Displacement of body center mass (**CoM**, **gold oscillation**) in response to forward and backward platform oscillations of varying amplitudes (**gray**) as a healthy subject learns to reduce postural instability.

B. Displacement of the body CoM by forward–backward surface oscillations is reduced across training sessions on day 1, and this improvement is retained on day 2 in healthy control subjects. People with multiple sclerosis also learn to reduce CoM displacements but do not retain this improvement the next day. The mean and standard error of group changes in gain (CoM/surface displacement) are compared. (Adapted, with permission, from Gera et al. 2016.)

learning. For example, when subjects practice standing on an oscillating surface, they gradually learn to decrease the extent of the displacement of their center of mass, and much of this improvement is retained the next day (Figure 36–7). Patients with neurological disorders, such as multiple sclerosis or Parkinson disease, who have significantly impaired postural responses can often learn to improve their postural control with practice, although they may need more practice than normal to retain the improvements (Figure 36–7).

Anticipatory Postural Adjustments Compensate for Voluntary Movement

Voluntary movements can also destabilize postural orientation and equilibrium. For example, rapidly lifting the arms forward while standing produces forces that extend the hips, flex the knees, and dorsiflex the ankles, moving the body's center of mass forward relative to the feet. The nervous system has advance knowledge of the effects of voluntary movement on postural alignment and stability and activates anticipatory postural adjustments, often in advance of the primary movement (Figure 36–8A).

Anticipatory postural adjustments are specific to biomechanical conditions. When a freely standing subject rapidly pulls on a handle fixed to the wall, the leg muscles (gastrocnemius and hamstrings) are activated before the arm muscles (Figure 36–8B). When the subject performs the same pull while his shoulders are propped against a rigid bar, no anticipatory leg muscle activity occurs because the nervous system relies on the support of the bar to prevent the body from moving forward. When the handle is pulled in response to an external cue, the arm muscles are activated faster in the supported condition than in the freestanding condition. Thus, voluntary arm muscle activation is normally delayed when the task requires active postural stability.

Another common preparatory postural adjustment occurs when one begins to walk. The center of mass is accelerated forward and laterally by the unweighting of one leg. This postural adjustment appears to be independent of the stepping program that underlies ongoing locomotion (Chapter 33). Similarly, a forward shift of the center of mass precedes the act of standing on the toes. A subject is unable to remain standing on his toes if he simply activates the calf muscles without moving his center of mass forward; he rises onto his toes only momentarily before gravity restores a flat-footed stance. Moving the center of mass forward over the toes before activating the calf muscles aligns it over the anticipated base of support and thus stabilizes the toe stance.

Postural equilibrium during voluntary movement requires control not only of the position and motion of the body's center of mass but also of the angular momentum about the center of mass. A diver can

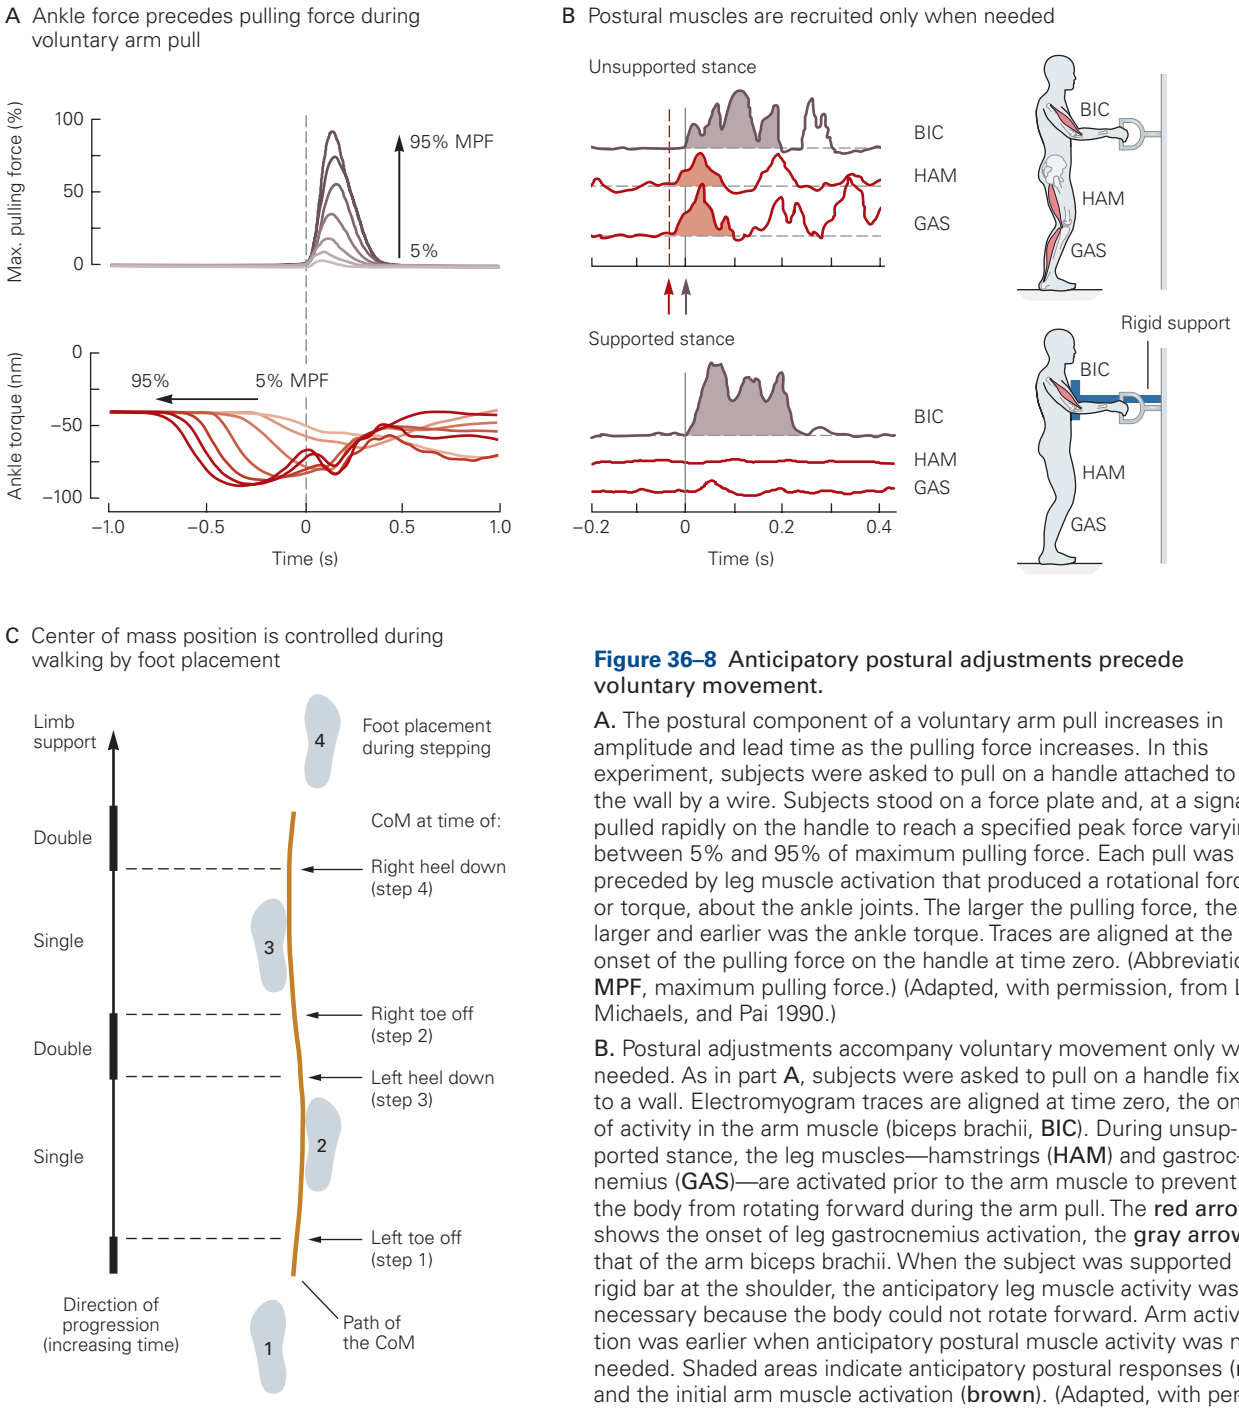

Figure 36–8 Anticipatory postural adjustments precede voluntary movement.

A. The postural component of a voluntary arm pull increases in amplitude and lead time as the pulling force increases. In this experiment, subjects were asked to pull on a handle attached to the wall by a wire. Subjects stood on a force plate and, at a signal, pulled rapidly on the handle to reach a specified peak force varying between 5% and 95% of maximum pulling force. Each pull was preceded by leg muscle activation that produced a rotational force, or torque, about the ankle joints. The larger the pulling force, the larger and earlier was the ankle torque. Traces are aligned at the onset of the pulling force on the handle at time zero. (Abbreviation: **MPF**, maximum pulling force.) (Adapted, with permission, from Lee, Michaels, and Pai 1990.)

B. Postural adjustments accompany voluntary movement only when needed. As in part **A**, subjects were asked to pull on a handle fixed to a wall. Electromyogram traces are aligned at time zero, the onset of activity in the arm muscle (biceps brachii, **BIC**). During unsupported stance, the leg muscles—hamstrings (**HAM**) and gastrocnemius (**GAS**)—are activated prior to the arm muscle to prevent the body from rotating forward during the arm pull. The **red arrow** shows the onset of leg gastrocnemius activation, the **gray arrow** that of the arm biceps brachii. When the subject was supported by a rigid bar at the shoulder, the anticipatory leg muscle activity was not necessary because the body could not rotate forward. Arm activation was earlier when anticipatory postural muscle activity was not needed. Shaded areas indicate anticipatory postural responses (**red**) and the initial arm muscle activation (**brown**). (Adapted, with permission, from Cordo and Nashner 1982.)

C. During walking, the trajectory of the center of mass (CoM) is controlled by foot placement. The body's center of mass is between the feet, moving forward and from side to side as the subject walks forward. When the body is supported by only one leg (single support phase), the CoM is outside the base of support and moves toward the lifting limb. People do not fall while walking because the placement of the foot on the next step decelerates the CoM and propels it back toward the midline. (Adapted from MacKinnon and Winter 1993.)

perform elaborate rolls and twists of the body about the center of mass while airborne, although the trajectory of his center of mass is fixed once he leaves the board. During voluntary movements, postural adjustments control the body's angular momentum by anticipating rotational forces.

Posture Control Is Integrated With Locomotion

During walking and running, the body is in a constant state of falling as the center of mass moves forward and laterally toward the leg that is in the swing phase (Figure 36–8C). During walking, the center of mass is within the base of support only when both feet are on the ground, the double stance phase, which is only one-third of a gait cycle. When one foot is supporting the body, the center of mass moves forward in front of the foot, always medial to the base of support.

Falling is prevented during walking and running by moving the base of support forward and laterally under the falling center of mass. Postural equilibrium during gait relies on the placement of each step to control the speed and trajectory of the center of mass. The nervous system plans foot placement several steps in advance using visual information about the terrain and surrounding environment.

The main postural challenge during walking is controlling the center of mass of the upper body over the moving legs, especially in the lateral direction. Excessive lateral displacement of the trunk and excessive lateral foot placement variability are signs of postural instability during locomotion. Patients with abnormal postural stability during gait may nevertheless exhibit normal automatic and anticipatory postural adjustments, postural sway in stance under different sensory conditions, and orientation to vertical, suggesting that postural control and gait have different nervous system circuits.

Somatosensory, Vestibular, and Visual Information Must Be Integrated and Interpreted to Maintain Posture

Because information about motion from any one sensory system may be ambiguous, multiple modalities must be integrated in postural centers to determine what orientation and motion of the body are appropriate. The influence of any one modality on the postural control system varies according to the task and biomechanical conditions.

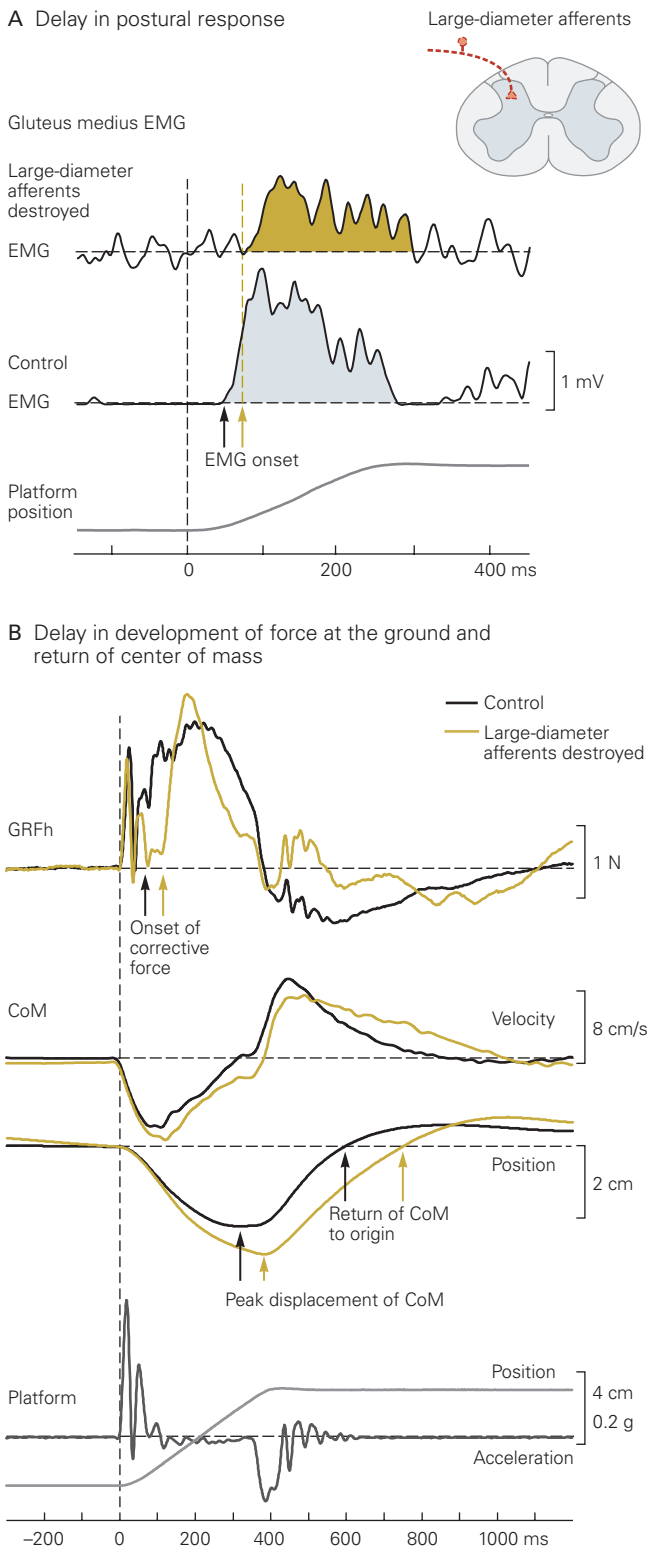
According to prevailing theory, sensory modalities are integrated to form an internal representation of the body housed within the parietal cortex that the nervous system uses to plan and execute motor behaviors. Over time, this internal representation must adapt to changes associated with early development, aging, and injury.

Somatosensory Signals Are Important for Timing and Direction of Automatic Postural Responses

Many types of somatosensory fibers trigger and shape the automatic postural response. The largest fibers, those in group I (12–20 μm in diameter), appear to be essential for normal response latencies. The longer latency, slower rise time, and lower amplitude of the EMG response following destruction of the group I fibers reflect a loss of acceleration information encoded by muscle spindle primary receptors (Figure 36–9A). The largest and most rapidly conducting sensory fibers are the Ia afferents from muscle spindles and Ib afferents from Golgi tendon organs, as well as some fibers from cutaneous mechanoreceptors (Chapter 18). Group I fibers provide rapid information about the biomechanics of the body including responses to muscle stretch, muscle force, and directionally specific pressure on the foot soles. However, group II fibers from muscle spindles and cutaneous receptors may also play a role in shaping automatic postural responses. Although they may be too slow to generate the earliest part of the response, they likely encode center of mass velocity and position.

Both proprioceptive and cutaneous inputs provide cues about postural orientation. During upright stance, for example, muscles lengthen and shorten as the body sways under the force of gravity, generating proprioceptive signals related to load, muscle length, and velocity of stretch. Joint receptors may detect compressive forces on the joints, whereas cutaneous receptors in the sole of the foot respond to motion of the center of pressure and to changes in ground reaction force angle as the body sways. Pressure receptors near the kidneys are sensitive to gravity (somatic graviception) and are used by the nervous system to help detect upright or tilted postures. All of these signals contribute to the neural map of the position of body segments with respect to each other and the platform surface and may contribute to the neural computation of center of mass motion.

The large-diameter, fast somatosensory fibers from muscle spindles are critical for maintaining balance during stance. When these axons die, as occurs in some forms of peripheral neuropathy, automatic postural responses to movement of a platform are delayed, retarding the ground reaction force. As a



result, the center of mass moves faster and farther from the initial position and takes longer to return (Figure 36–9). Because it is more likely that the center of mass will move outside the base of support, balance is precarious and a fall may occur. Accordingly, individuals with large-fiber peripheral neuropathy in the legs experience ataxia and difficulties with balance.

Vestibular Information Is Important for Balance on Unstable Surfaces and During Head Movements

The otolithic organs of the vestibular apparatus provide information about the direction of gravity, whereas the semicircular canals measure the velocity of head rotation (Chapter 27). Vestibular information thus informs the nervous system about how much the body is tilted with respect to gravity as well as whether it is swaying forward, backward, or sideways.

Somatosensory and vestibular information about the gravitational angle of the body is combined to orient the body with respect to gravity and other inertial forces. To maintain balance while riding a bike in a circular path at high speed, for example, the body and bike must be oriented with respect to a combination of gravitational and centripetal forces (Figure 36–10A).

Unlike somatosensory inputs, vestibular signals are not essential for the normal timing of balance reactions. Instead, they influence the directional tuning of a postural response by providing information about the orientation of the body relative to gravity. In humans and experimental animals lacking functional vestibular afferent pathways, the postural response to *angular* motion or tilt of the support surface is opposite to the

Figure 36–9 (Left) **Loss of large-diameter somatosensory fibers delays automatic postural responses.** Electromyograms (**EMGs**) of postural responses to horizontal motion of a moveable platform were recorded in a cat before and after destruction of the large-diameter (group I) somatosensory fibers throughout the body by vitamin B_6 intoxication. Motor neurons and muscle strength are not affected by the loss of the somatosensory fibers, but afferent information about muscle length and force is diminished. (Reproduced, with permission, from J. Macpherson.)

A. The postural response in the gluteus medius evoked by horizontal motion of the support platform is significantly delayed after destruction of group I fibers. This delay of approximately 20 ms induces ataxia and difficulty in maintaining balance.

B. Destruction of group I fibers delays activation of the hind limb. This delay slows the restoration of the center of mass (**CoM**) and the recovery of balance following platform displacement. The delay in onset of the horizontal component of the ground reaction force (**GRFh**) results in a greater peak displacement of the CoM and a delay in its return to its origin relative to the paws.

A Orienting to gravito-inertial force

B Orienting to rotating visual field

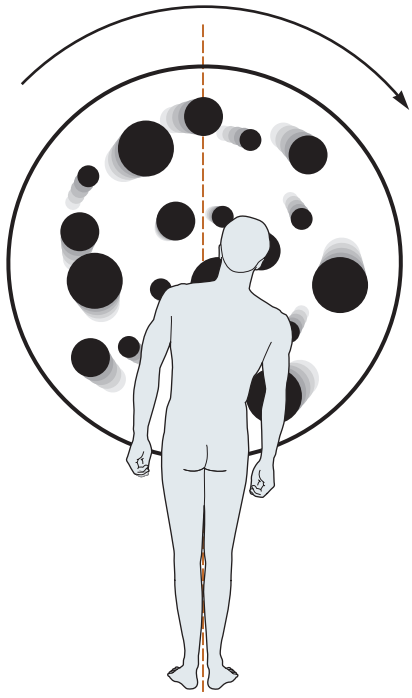


Figure 36–10 The postural system orients the body to various external reference frames.

A. When traveling at high speed along a curved path, a cyclist orients to the gravito-inertial force (angle A), the vector sum of the force caused by gravity and the centripetal force caused by acceleration along the curved path. (Used, with permission, from Joseph Daniel, Story Arts Media, LLC. Previously published in McMahon and Bonner 1983.)

B. The postural system can interpret rightward rotation of objects occupying a large region of the visual field as the body tilting to the left. In compensation for this illusion of motion, the subject tilts to the right, adopting a new postural vertical orientation that is driven by the visual system. The **red dashed line** indicates gravitational vertical. (Adapted, with permission, from Brandt, Paulus, and Straube 1986.)

normal response. Rather than resisting the tilt, subjects lacking vestibular signals do the opposite and accentuate the tilt through their own muscular activity. In contrast, the response to horizontal translation motion of a platform has the appropriate directional tuning and latency, even in the acute stage prior to vestibular compensation.

Why does the absence of vestibular signals cause difficulty with tilt but not with linear motion? The answer lies in how the nervous system determines the direction of vertical. Gravity is the main force that causes the body to fall. As the support surface tilts, healthy subjects orient to gravity using vestibular information to remain upright. In contrast, subjects without vestibular function use somatosensory inputs to orient themselves to the support surface and consequently fall downhill as the surface tilts. During linear motion, however, gravitational and surface vertical are collinear, and somatosensory signals are sufficient to compute the correct postural response. Although visual inputs also provide a vertical reference, visual processing is too slow to participate in the automatic postural response to rapid tilt, especially soon after the loss of vestibular function.

Without vestibular information, the response to linear motion of the support surface is larger than normal (*hypermetria*), leading to overbalancing and instability. Hypermetria is a major cause of ataxia when vestibular information is lost. Vestibular hypermetria may result from reduced cerebellar inhibition of the motor system, for the loss of vestibular inputs reduces the drive to the inhibitory Purkinje cells.

Humans and cats are quite ataxic immediately after loss of the vestibular apparatus. The head and trunk show marked instability, stance and gait are broad-based, and walking follows a weaving path with frequent falling. Instability is especially great on turning the head, probably because trunk motion cannot be distinguished from head motion using somatosensory information alone. Cats and humans lacking vestibular inputs produce motor output that results in them actively pushing themselves toward the side of

a voluntary head turn, likely because somatosensory inputs that encode trunk and head motion are misinterpreted in the absence of vestibular inputs. The postural system erroneously senses that the body is falling to the side away from the head tilt and generates a response in the opposite direction, resulting in imbalance.

Immediately following vestibular loss, neck muscles are abnormally activated during ordinary movements and often the head and trunk are moved together as a unit. After several months, routine movement becomes more normal through vestibular compensation, which may involve greater reliance on the remaining sensory information. However, more challenging tasks are hampered by a residual hypermetria, stiffness in head–trunk control, and instability, especially when visual and somatosensory information is unavailable for postural orientation. Vestibular information is critical for balance when visual information is reduced and the support surface is not stable, for example, at night on a sandy beach or on a boat deck.

Visual Inputs Provide the Postural System With Orientation and Motion Information

Vision reduces body sway when standing still and provides stabilizing cues, especially when a new balancing task is attempted or balance is precarious. Skaters and dancers maintain stability while spinning by fixing their gaze on a point in the visual field. However, visual processing is too slow to significantly affect the postural response to a sudden and unexpected disturbance of balance. Vision does play an important role in anticipatory postural adjustments during voluntary movements, such as planning where to place the feet when walking over obstacles.

Vision can have a powerful influence on postural orientation, evident when watching a movie scene filmed from the perspective of a moving viewer and projected on a large screen. Simulated rides in a roller coaster or airplane can induce strong sensations of motion along with activation of postural muscles. An illusion of movement is induced when sufficiently large regions of the visual field are stimulated, as when a large disk in front of a standing subject is rotated. The subject responds to this illusion by tilting his body; clockwise rotation of the visual field is interpreted by the postural system as the body falling to the left, to which the subject compensates by leaning to the right (Figure 36–10B). The rate and direction of optic flow—the flow of images across the retina as people move about—provide clues about body orientation and movement.

Information From a Single Sensory Modality Can Be Ambiguous

Any one sensory modality alone may provide ambiguous information about postural orientation and body motion. The visual system, for example, cannot distinguish self-motion from object motion. We have all experienced the fleeting sensation while sitting in a stationary vehicle of not knowing whether we are moving or the adjacent vehicle is moving.

Vestibular information can also be ambiguous for two reasons. First, vestibular receptors are located in the head and therefore provide information about acceleration of the head but not about the rest of the body. The postural control system cannot use vestibular information alone to distinguish between the head tilting on a stationary trunk and the whole body tilting by rotation at the ankles, both of which activate the semicircular canals and otolith organs. Additional information from somatosensory receptors is required to resolve this ambiguity. The otolith organs also cannot distinguish between acceleration owing to gravity and linear acceleration of the head. Tilting to the left, for example, can produce the same otolithic stimulation as acceleration of the body to the right (Figure 36–11).

Studies suggest that there are neural circuits that can disambiguate the head-tilt component of a linear acceleration by using a combination of canal and otolith inputs. Output from this circuit may allow the postural system to determine the orientation of gravity relative to the head regardless of head position and motion. The distinction between tilt and linear motion is especially important while standing on an unstable or a tilting surface.

Somatosensory inputs may also provide ambiguous information about body orientation and motion. When we stand upright, mechanoreceptors in the soles of our feet and proprioceptors in muscles and joints signal the motion of our body relative to the support surface. But somatosensory inputs alone cannot distinguish between body and surface motion, for example, whether ankle flexion stems from forward body sway or tilting of the surface. Our common experience is that the ground beneath us is stable and that somatosensory inputs reflect movements of the body's center of mass as we sway. But surfaces may move relative to the earth, such as a boat's deck, or may be pliant under our weight, like a soft or spongy surface. Therefore, somatosensory information must be integrated with vestibular and visual inputs to give the nervous system an accurate picture of the stability and inclination of the support surface and of our body's relationship to earth vertical.

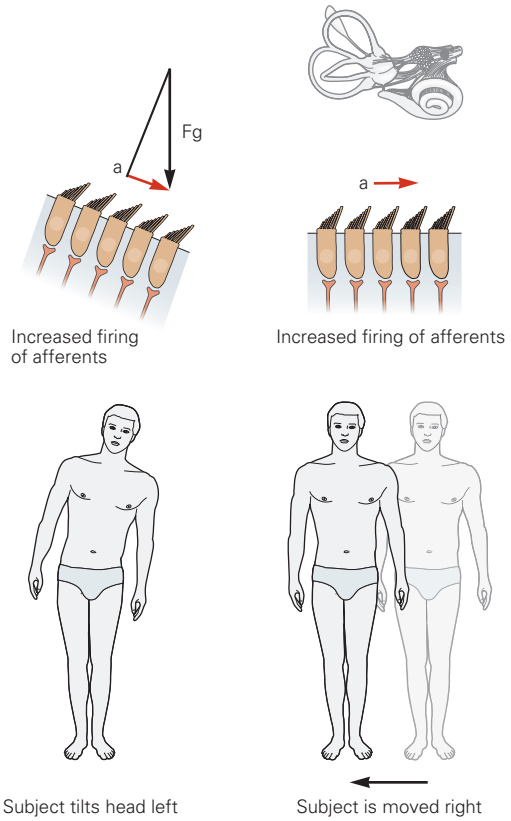

Figure 36–11 Vestibular inputs regarding body posture and motion can be ambiguous. The postural system cannot distinguish between tilt and linear acceleration of the body based on otolith inputs alone. The mechanoreceptors of the vestibular system are hair bundles that bend in response to shearing forces, thus changing the firing rate of the tonically active sensory afferents. The same shearing force can result from tilting of the head (*left*), which exposes the hair cells to a portion of the acceleration (**a**) owing to gravity (**Fg**), or from horizontal linear acceleration of the body (*right*).

The Postural Control System Uses a Body Schema That Incorporates Internal Models for Balance

Because of the mechanical complexity of the body, with its many skeletal segments and muscles, the nervous system requires a detailed representation of the body and its interaction with the environment. To execute the simple movement of raising your hand and touching your nose with your index finger while your eyes are closed, your nervous system must know the characteristics (length, mass, and connections) of each segment of the arm, the shoulder, and head as well as the orientation of your arm with respect to the gravity vector and your nose. Thus, information from multiple sensory systems is integrated into a central representation of the body, often called the body schema.

The body schema for postural control, as developed by Viktor Gurfinkel, is not simply a sensory map like the somatotopic representation of the skin in primary sensory cortex. Instead, it incorporates internal models of the body's relationship with the environment. The body schema is used to compute appropriate anticipatory and automatic postural reactions to maintain balance and postural orientation. A simplified example of such an internal model is one in which the body is represented as a single segment hinged at the foot (Figure 36–12A). The internal model generates an estimate of the orientation of the foot in space, which also serves as an estimate of the orientation of the support surface, a variable that cannot be directly sensed.

Henry Head, a neurologist working in the early part of the 20th century, described the body schema as a dynamic system in which both spatial and temporal features are continually updated, a concept that remains current. To allow adequate planning of movement strategies, the body schema must incorporate not only the relationship of body segments to space and to each other but also the mass and inertia of each segment and an estimate of the external forces acting on the body including gravity.

The body schema integrates sensory information from the somatosensory, vestibular, and visual systems to orient the body to vertical. Even in the dark, people can accurately reorient a projected line to a vertical position (visual vertical) and they can reorient themselves to vertical when sitting on a tilting swing (gravitational vertical). Visual vertical and gravitational vertical are independent of each other. Patients with asymmetrical vestibular function show abnormal visual vertical but normal gravitational vertical, whereas patients with hemi-neglect from stroke show abnormal gravitational vertical but normal visual vertical.

Another component of the body schema is a model of the sensory information expected as a result of a movement. Disorientation or motion sickness may result when the actual sensory information received by the nervous system does not match the expected sensory information, as in the microgravity environment of space flight. With continued exposure to the new environment, however, the model is gradually updated until expected and actual sensory information agree and the person is no longer spatially disoriented.

The internal model for balance control must be continually updated, both in the short term, as we use experience to improve our balance strategies, and in the long term, as we age and our bodies change in shape and size. One way the body schema is updated is by changing the relative sensitivity or weighting of each sensory system.

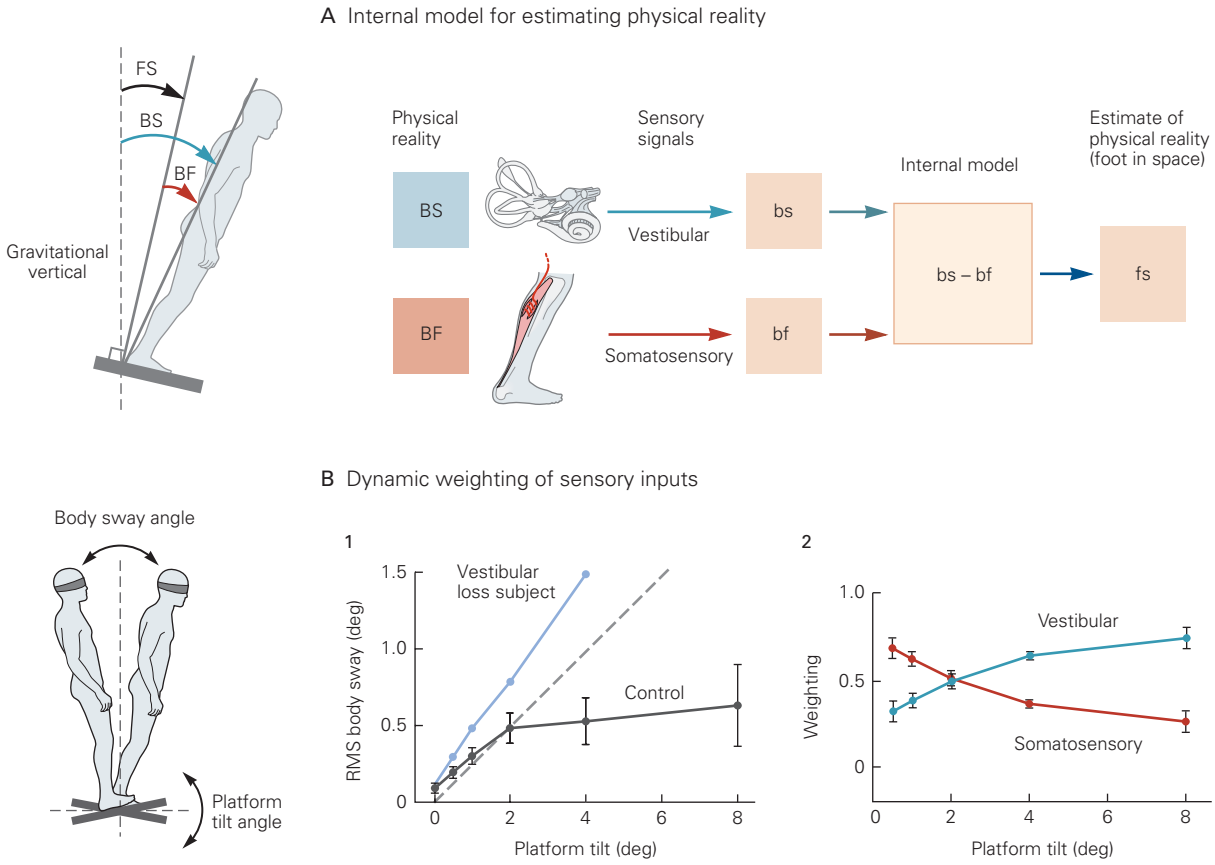

Figure 36–12 Many types of sensory signals are integrated and weighted in an internal model that optimizes balance and orientation. (Adapted from Peterka 2002.)

A. The simple example of a person standing on a tilted surface illustrates how the nervous system might estimate physical variables that are not sensed directly. The physical variables are body tilt with respect to earth vertical or body-in-space (**BS**), and body angle relative to the foot (**BF**). The angle of the foot in space (**FS**) is simply the difference BS – BF. The neural estimate of body in space (**bs**) comes from vestibular and other receptors that detect tilt of the body relative to gravity. The neural estimate of body angle to foot (**bf**) comes from somatosensory signals related to ankle joint angle. The internal model for estimating physical reality, bs – bf, produces a neural estimate of the foot in space (**fs**). Such estimates of the physical world are continually updated based on experience.

B. Sensory information is weighted dynamically to maintain balance and orientation under varying conditions. The figure illustrates findings from an experiment in which human subjects stood blindfolded on a platform that slowly rotated continuously in the toes-up or toes-down direction at amplitudes of up to 8° (peak to peak). **1.** Comparison of body sway during surface oscillations in a subject with loss of vestibular function and a group of control subjects. Body-sway angle is measured relative to gravitational vertical during platform tilt and expressed as root mean square (**RMS**) sway in degrees. The **dashed line** represents equal platform and body sway; for example, for a platform tilt of 4°, an equal amount of body sway is 1° RMS. In control subjects, the body and platform sway are equal for small platform tilts up to 2°, suggesting that people normally use somatosensory signals to remain perpendicular to the platform (minimizing changes in ankle angle). With larger platform tilts, body sway does not increase much beyond 0.5° RMS. In contrast, subjects with vestibular loss sway even more than the platform (1.5° RMS of body tilt at 4° of platform tilt) and cannot remain standing at platform tilts above 4°. Thus, when both vestibular and visual signals are absent, a person attempts to maintain his position only relative to the support surface and has difficulty maintaining balance as that surface moves. **2.** In control subjects, as platform tilt increases, the influence of somatosensory input decreases with increasing platform tilt while the influence of vestibular input increases. At larger tilt angles, the greater influence of vestibular input minimizes the degree of body sway away from gravitational vertical.

Control of Posture Is Task Dependent

The senses and muscles used to control posture vary, depending on task constraints and requirements. For example, when vestibular and somatosensory information is altered while working on a space station, vision is used to orient the body to tasks, and the goal of postural equilibrium changes from preventing falls due to gravity to preventing unintended collision with objects due to inertia. A healthy nervous system very quickly adapts to changing tasks, goals, and environments by modifying its relative dependence upon different sensory information and by using different sets of muscles to optimize achieving the goals of both posture control and voluntary movements.

Task Requirements Determine the Role of Each Sensory System in Postural Equilibrium and Orientation

The postural control system must be able to change the weighting of different sensory modalities to accommodate changes in the environment and movement goals. Subjects standing on a firm stable surface tend to rely primarily on somatosensory information for postural orientation. When the support surface is unstable, subjects depend more on vestibular and visual information. However, even when the support surface is not stable, light touch with a fingertip on a stable object is more effective than vision in maintaining postural orientation and balance. Vestibular information is particularly critical when visual and somatosensory information is ambiguous or absent, such as when skiing downhill or walking below deck on a ship.

The changeable weighting of individual sensory modalities was demonstrated in an experiment in which subjects were blindfolded and asked to stand quietly on a surface with a tilt that slowly oscillated by varying amounts, up to 8° in magnitude. For tilts of less than 2°, all subjects sway with the platform, suggesting that they use somatosensory information to orient their body to the support surface (Figure 36–12B). At larger tilts, healthy subjects attenuate their sway and orient their posture more with respect to gravitational vertical than to the surface, as they rely more on vestibular information so they stop increasing body sway. Thus, relative sensory weighting changes in control subjects such that somatosensory weight is highest with a stable platform and vestibular weight is highest when standing on an unstable surface, such as with large surface tilts (Figure 36–12B2). In contrast, patients who have lost vestibular function persist in swaying along with the platform and subsequently fall during large surface tilts. This behavior is consistent with the patients' inappropriate automatic postural response to platform tilts.

Studies such as these suggest that when people are standing on moving or unstable surfaces, the weighting of vestibular and visual information increases, whereas that of somatosensory information decreases. Any sensory modality may dominate at a particular time, depending on the conditions of postural support and the specific motor behavior to be performed.

Control of Posture Is Distributed in the Nervous System

Postural orientation and balance are achieved through the dynamic and context-dependent interplay among all levels of the central nervous system, from the spinal cord to cerebral cortex. The major areas of the brain involved in postural control are shown in Figure 36–13. Signals from specific areas in all lobes of the cerebral cortex converge and are integrated to determine appropriate outputs from motor cortical areas to subcortical structures. The basal ganglia, cerebellum, and pedunculopontine nucleus then send outputs to the brain stem. Ultimately, inputs from these varied sources result in activation of the reticulospinal and vestibulospinal pathways, which descend to the spinal cord where they contact interneurons and spinal motor neurons for postural control.

Afferent inputs from visual, vestibular, and somatosensory sources are integrated along the neuraxis, including the vestibular nuclei and right parietal cortex, to inform the internal model of body orientation and balance. This internal model is continually updated by the cerebellum based on error signals between expected and actual sensory feedback following motor commands.

Spinal Cord Circuits Are Sufficient for Maintaining Antigravity Support but Not Balance

Adult cats with complete spinal transection at the thoracic level can, with experience, support the weight of their hindquarters with fairly normal hind limb and trunk postural orientation, but they have little control of balance. These animals do not exhibit normal postural responses in their hind limbs when the support surface moves. Their response to horizontal motion consists of small, random, and highly variable bursts of activity in extensor muscles, and postural activity in flexor muscles is completely absent. Active balance is absent despite the fact that extensors and flexors can

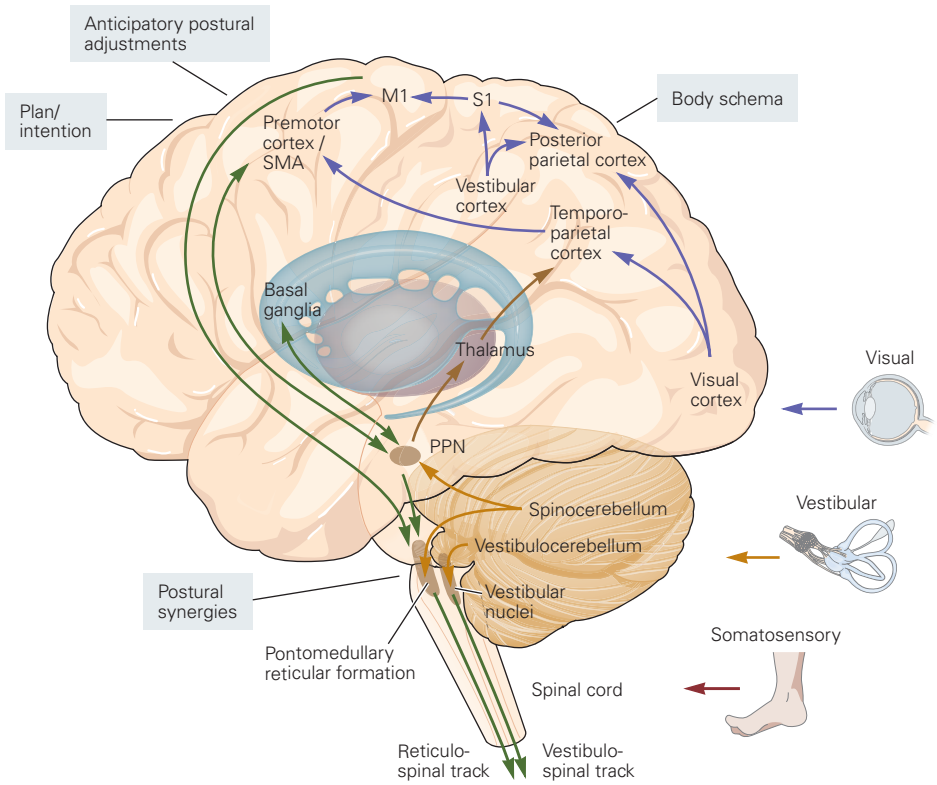

Figure 36–13 Many parts of the nervous system control posture. Areas of frontal, parietal, temporal, and occipital cortex, as well as the basal ganglia, cerebellum, and pendunculopontine nucleus (**PPN**), provide inputs to the recticulospinal and vestibulospinal pathways descending to spinal motor neurons. Afferent inputs from the visual, vestibular, and somatosensory systems are integrated in the brainstem and cortex to update the body schema and inform future postural commands. (Abbreviations: **M1**, primary motor cortex; **S1**, primary somatosensory cortex; **SMA**, supplementary motor area.) (Adapted from Beristain 2016.)

be recruited for other movements such as stepping on a treadmill, suggesting that unlike locomotion, postural muscle activation requires supraspinal control.

An adult cat with a spinal transection can stand independently for only short periods of time and within a narrow range of stability; head turns in particular cause the animal to lose balance. What stability there is likely results from the broad base of support afforded by quadrupedal stance, the stiffness of the tonically contracting hind limb extensors that support the weight of the hindquarters, and active compensation by forelimbs that continue to produce postural responses. Humans with spinal cord injuries have various amounts of antigravity muscle tonus but lack automatic postural responses below the level of the lesion. These results emphasize that antigravity support and balance control are distinct mechanisms and that the control of balance requires the involvement of supraspinal circuits.

The Brain Stem and Cerebellum Integrate Sensory Signals for Posture

If spinal circuits alone are not capable of producing automatic postural responses, what supraspinal centers are responsible for these responses? Although the answer to this question remains unknown, good candidates include the brain stem and cerebellum, which are highly interconnected and work together to modulate the descending commands to spinal motor centers of the limbs and trunk. These regions have the input–output structure that would be expected of centers for postural control.

Muscle synergies for automatic postural responses may be organized in the brain stem, perhaps the reticular formation. However, adaptation of postural synergies to changes in the environment and task demands may require the cerebellum.

Two regions of the cerebellum influence orientation and balance: the vestibulocerebellum (nodulus, uvula, and fastigial nucleus) and the spinocerebellum (anterior lobe and interpositus nucleus). These regions are interconnected with the vestibular nuclei and reticular formation of the pons and medulla (see Figure 37–4). Lesions of the brain stem and vestibulocerebellum produce a variety of deficits in head and trunk control including a tendency to tilt from vertical, even with eyes open, suggesting a deficit in the internal representation of postural orientation. Lesions of the spinocerebellum result in excessive postural sway that is worse with the eyes closed, ataxia during walking, and hypermetric postural responses, suggesting

deficits in balance corrections. Certain regions in the pons and medulla facilitate or depress extensor tonus and could be involved in antigravity support.

The brain stem and cerebellum are sites of integration of sensory inputs, perhaps generating the internal model of body orientation and balance. Vestibular and visual inputs are distributed to brain stem centers (Chapters 25 and 27) and the vestibulocerebellum. The spinocerebellum receives signals from rapidly conducting proprioceptive and cutaneous fibers. More slowly conducting somatosensory fibers project to the vestibular nuclei and reticular formation.

Two major descending systems carry signals from the brain stem and cerebellum to the spinal cord and could trigger automatic postural responses for balance and orientation. The medial and lateral vestibulospinal tracts originate from the vestibular nuclei, and the medial and lateral reticulospinal tracts originate from the reticular formation of the pons and medulla (see Figure 37–5). Lesions of these tracts result in profound ataxia and postural instability. In contrast, lesions of the corticospinal and rubrospinal tracts have minimal effect on balance even though they produce profound disturbance of voluntary limb movements.

The Spinocerebellum and Basal Ganglia Are Important in Adaptation of Posture

Patients with spinocerebellar disorders such as alcoholic anterior-lobe syndrome and basal ganglia deficits such as Parkinson disease experience postural difficulties. Studies suggest that the spinocerebellum and basal ganglia play complementary roles in adapting postural responses to changing conditions.

The spinocerebellum is where the amplitude of postural responses is adapted based on experience. The basal ganglia are important for quickly adjusting the postural set when conditions suddenly change. Both the spinocerebellum and the basal ganglia regulate muscle tone and force for voluntary postural adjustments. They are not necessary, however, for triggering or constructing the basic postural patterns.

Patients with disorders of the spinocerebellum have difficulty modifying the magnitude of balance adjustments with practice, over the course of repeated trials, but can readily adapt postural responses immediately after a change in conditions based on sensory feedback. For example, a patient standing on a movable platform scales the size of postural responses appropriately when platform velocity is increased with each trial. These postural adjustments rely on velocity information, which is encoded by somatosensory inputs at the beginning of platform movement.

In contrast, patients with cerebellar disorders cannot scale the size of postural responses based on feedforward control using the anticipated amplitude of postural displacements. Because the amplitude of platform movement is not known until the platform has stopped moving, well after the initial postural response is complete, a subject cannot use feedback from the trial at hand to guide the response but must instead use his experience from previous trials to inform his response in a subsequent trial of the same amplitude. Whereas a healthy subject does this quite readily, a patient with spinocerebellar disorders is unable to efficiently adapt his postural responses based on recent experience (Figure 36–14A).

A healthy subject standing on a moveable platform is able to scale muscle activity during sudden backward motion of the platform to counteract the forward sway induced by the perturbation. A subject with spinocerebellar disease always overresponds, although the timing of muscle activation is normal (Figure 36–14B). As a result, this individual returns beyond the upright position and oscillates back and forth. Reminiscent of the hypermetria observed immediately after labyrinthectomy, cerebellar hypermetria may also result from loss of Purkinje cell inhibition on spinal motor centers.

A patient with Parkinson disease can, with sufficient practice, gradually modify his postural responses but has difficulty changing responses when conditions change suddenly. Such postural inflexibility is seen when initial posture changes. For example, when a normal subject switches from standing upright to sitting on a stool on a movable platform, the pattern of his automatic postural response to backward movement of the platform changes immediately. Because leg muscle activity is no longer necessary after the switch from standing to sitting, this component ceases to be recruited.

In contrast, a patient with Parkinson disease employs the same muscle activation pattern for both sitting and standing (Figure 36–15). L-DOPA replacement therapy does not improve the patient's ability to switch postural set. With repetition of trials in the seated posture, however, the leg muscle activity eventually disappears, showing that enough experience permits adaptation of postural responses. A patient with Parkinson disease also has difficulty when instructed to increase or decrease the magnitude of a postural response, a difficulty that is consistent with the inability to change cognitive sets quickly.

Patients with Parkinson disease have problems with postural tone and force generation in addition to

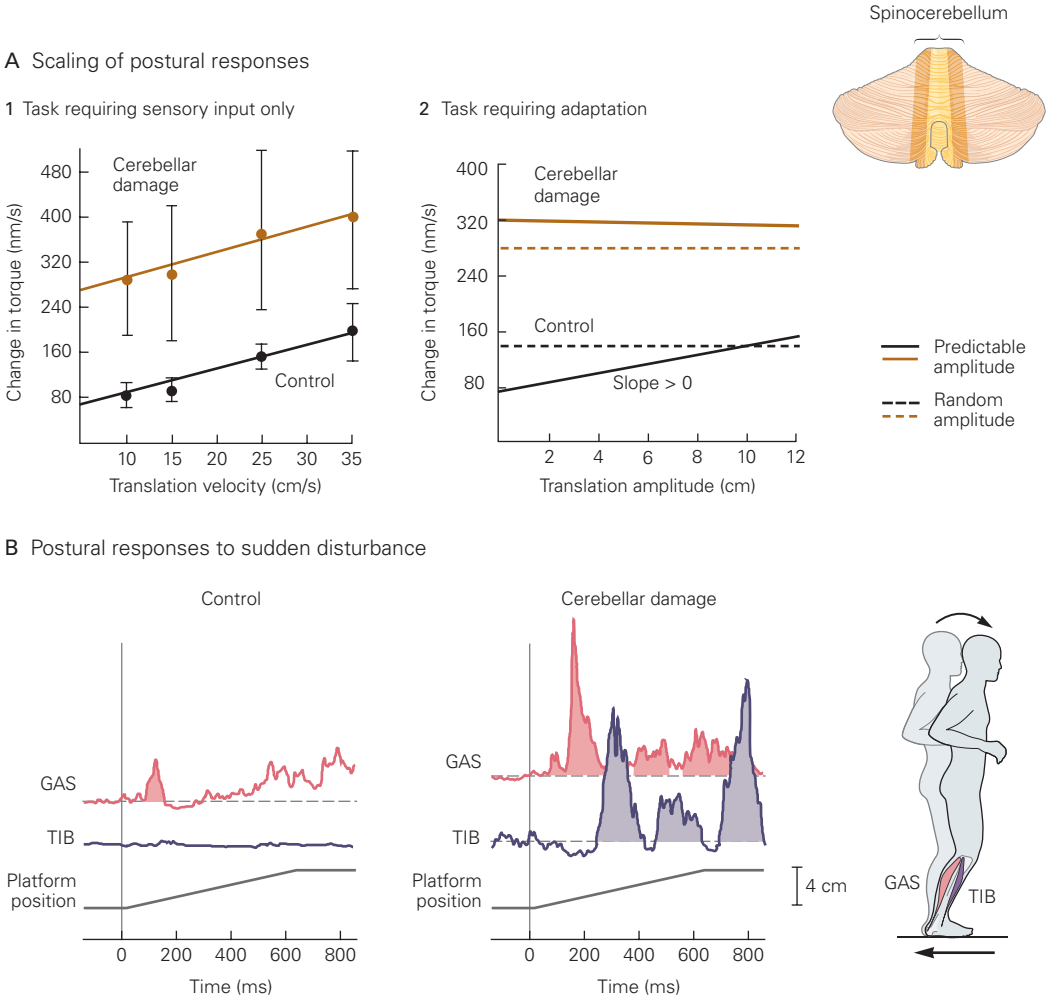

Figure 36–14 **The spinocerebellum has a role in adapting postural responses to changing conditions and in scaling postural responses to anticipated postural disturbances.** The spinocerebellum is important for adapting postural responses based on experience. Patients with a spinocerebellar disorder are able to use immediate sensory input, but not experience, to adjust automatic postural responses. (Adapted, with permission, from Horak and Diener 1994.)

A. 1. In this experiment, subjects stand on a platform that is moved horizontally; the velocity is increased on each trial. Maintaining balance requires scaling responses to the velocity of the platform using sensory feedback. The adjustments in a subject with a spinocerebellar disorder have the same regression coefficient (slope) as those of a control subject, even though in each trial the responses are larger and more variable than those of the control subject. **2.** When subjects are required to anticipate and adapt to platform translation, the postural adjustments in the spinocerebellar subject are compromised. When translation amplitude is random, responses are large, as if the subject expects a large translation. When trials with the same amplitude are repeated, a control subject learns to predict the amplitude of the disturbance and adjust his response. In contrast, a spinocerebellar subject shows no improvement in performance; he cannot use his experience in one trial to adjust his responses in subsequent trials. All responses are large, as if the subject always expects the large translation.

B. In this experiment, subjects stand on a platform that is moved backward (6 cm amplitude at 10 cm/s). In a control subject, the onset of movement evokes a small burst of activity in the gastrocnemius (**GAS**), an ankle extensor. In a subject with damage to the anterior lobe of the cerebellum, the muscle responses are overly large, with bursts of activity alternating between the gastrocnemius and its antagonist, the tibialis anterior (**TIB**).

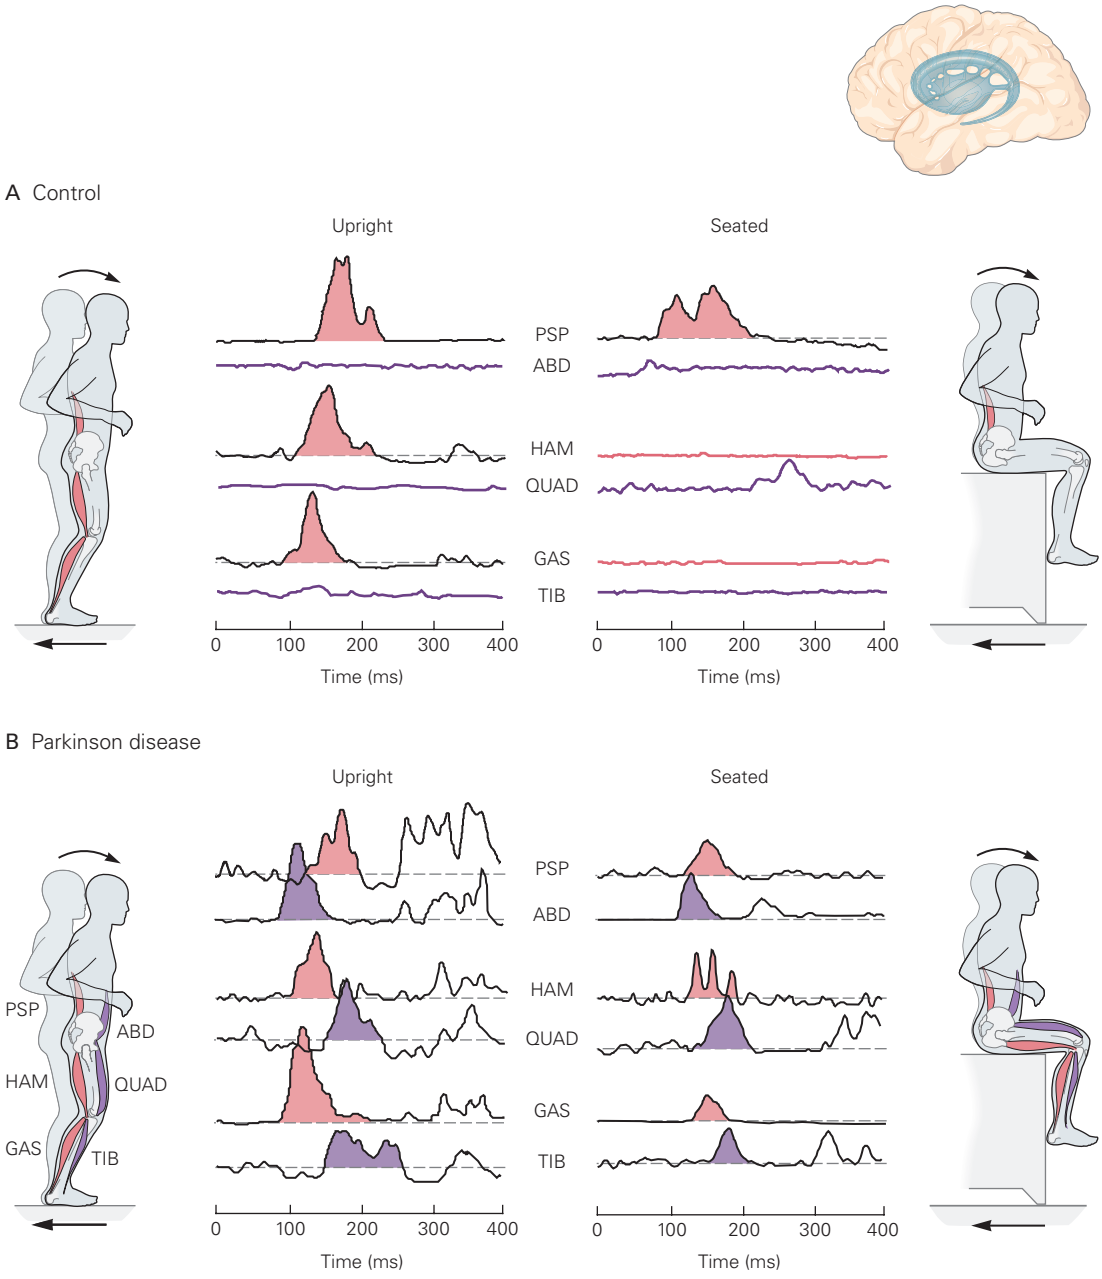

Figure 36–15 **The basal ganglia are important for adapting postural responses to a sudden change in initial conditions.** (Adapted, with permission, from Horak, Nutt, and Nashner 1992.)

A. When a normal subject switches from upright stance to sitting, he immediately modifies his response to backward movement of the support platform. The postural response to movement while seated does not involve the leg muscles—the gastrocnemius (**GAS**) and hamstrings (**HAM**)—but does activate the paraspinal muscles (**PSP**) and with shorter latency than in the response to movement while standing. (Abbreviations: **ABD**, abdominals; **QUAD**, quadriceps; **TIB**, tibialis anterior.)

B. A patient with Parkinson disease does not suppress the leg muscle response in the first trial after switching from standing to sitting. The postural response of this subject is similar for both initial positions: Antagonist muscles (**purple**) are activated along with agonists (**pink**).

an inability to adapt to changing conditions. The disease's bradykinesia (slowness of movement) is reflected in slow development of force in postural responses, and its rigidity is manifested in co-contraction. L-DOPA replacement greatly improves a patient's ability to generate not only forceful voluntary movements but also the accompanying postural adjustments, such as rising onto the toes and gait. However, neither the automatic postural response to an unexpected disturbance nor postural adaptation is improved by L-DOPA, suggesting that these functions involve the nondopaminergic pathways affected by Parkinson disease.

Cerebral Cortex Centers Contribute to Postural Control

Several areas of cerebral cortex influence postural orientation and equilibrium, including both anticipatory and automatic postural responses. Most voluntary movements, which are initiated in the cerebral cortex, require postural adjustments that must be integrated with the primary goal of the movement in both timing and amplitude. Where this integration occurs is not clear.

The cerebral cortex is more involved in anticipatory postural adjustments than in automatic postural reactions. However, recent electroencephalographic studies show that areas of cerebral cortex are activated by anticipation of a postural disturbance before an automatic postural response is initiated. This finding is consistent with the idea that the cortex optimizes balance control as part of motor planning.

The supplementary motor area and temporoparietal cortex have both been implicated in postural control. The supplementary motor area, anterior to the motor cortex, is likely involved with anticipatory postural adjustments that accompany voluntary movements. The temporoparietal cortex appears to integrate sensory information and may comprise internal models for perception of body verticality. Lesions of insular cortex can impair perception of the visual vertical, whereas lesions of superior parietal cortex impair perception of the postural vertical, and either of these defects may impair balance when standing on an unstable support.

Sensorimotor cortex receives somatosensory inputs signaling balance disturbances and postural responses. However, this region is not essential for automatic postural adjustments. Lesioning the motor cortex in cats impairs lifting of the forelimb in response to a light touch during stance but does not abolish the accompanying postural adjustment in the contralateral forelimb. Although the sensorimotor cortex is not responsible for postural adjustments, it may have a role in the process.

Behavioral studies, too, have implicated cortical processes in postural control. Control of posture, like control of voluntary movement, requires attention. When subjects must press a button following a visual or auditory cue while also maintaining balance, their reaction time increases with the difficulty of the task (balancing on one foot versus sitting, for example). Moreover, when subjects try to perform a cognitive task while actively maintaining posture, the performance of either or both can degrade. For example, when a subject is asked to count backward by threes while standing on one foot, both the cognitive task and postural adjustment deteriorate. The timing of automatic postural responses to unexpected disturbances is little affected by cognitive interference.

Balance control is also influenced by emotional state, thus implicating the limbic system in posture control. Fear of falling, for example, can increase postural tone and stiffness, reduce sway area, increase sway velocity, and alter balancing strategies in response to disturbances.

Finally, balance control is also influenced by attentional ability and demands, thus implicating the frontoparietal attention network. There is evidence of competition for central processing resources in dual task conditions, where a person must maintain balance and perform a concurrent cognitive task. Both postural control and cognitive performance may be impaired in dual-task conditions as compared to single-task conditions assessing either postural or cognitive performance in isolation. As cognitive demands increase, responses to postural perturbations are smaller in amplitude and occur at longer latency. However, when necessary, healthy individuals prioritize postural control over the cognitive task and demonstrate decreasing cognitive performance as postural demands increase. In contrast, individuals with nervous system disorders such as Parkinson disease may not prioritize postural control in dual-task situations and may be at increased risk for falls in dual-task situations.

Although the roles of specific areas of cerebral cortex in postural control are largely undefined, there is no doubt that the cortex is important for learning new, complex postural strategies. The cortex must be involved in the amazing improvement in balance and postural orientation of athletes and dancers who use cognitive information and advice from coaches. In fact, the cerebral cortex is involved in postural control each time we consciously maintain our balance while walking across a slippery floor, standing on a moving bus, or waiting tables on a rocking ship.

Highlights

1. The two goals of posture are balance and orientation. Balance control maintains the body in stable equilibrium to avoid falls. Postural orientation aligns the body segments with respect to each other and to the world, such as maintaining the head vertical.
2. A sudden displacement of the body center of mass while standing triggers ankle, hip, and/or stepping strategies to return the center of mass within the base of foot support.
3. Postural responses are fast and automatic, but adapt quickly to changes in environmental context, intention, and conditions. Postural responses can also be improved with practice.
4. Activation of centrally organized muscle synergies is used to control balance. This synergy organization simplifies the neural control so only a few central commands are required, instead of a separate command for each muscle, while allowing flexibility and adaptability for postural control.
5. Somatosensory, vestibular, and visual sensory modalities are integrated to form an internal representation of the body that the nervous system uses for postural orientation and balance control. Somatosensory signals trigger the fastest, largest postural responses and are most critical for control of postural sway in standing. Vestibular signals are particularly critical when standing on an unstable surface, when it is difficult to use somatosensory information for postural orientation. Visual inputs provide spatial orientation and motion information.
6. The body center of mass is often outside of the base of foot support during walking and running so balance is provided by adjusting foot placement and lateral trunk stability to control the center of mass with respect to the changing base of support.
7. The vestibulocerebellum and the spinocerebellum are interconnected with the vestibular nuclei and reticular formation of the brainstem for control of balance and postural orientation.
8. The basal ganglia are important for control of axial postural tone, adapting postural response strategies based on initial conditions, and anticipatory postural control. The cerebellum is important for adapting the magnitude of balance responses with practice, over the course of repeated trials, and for scaling the size of postural responses.
9. Posture control involves many brain areas from the brainstem to the frontal cortex, but the specific circuits involved in different types of posture control (automatic postural responses, anticipatory postural adjustments, body sway in stance, sensory integration for a body schema and verticality) have yet to be determined.

The Cerebellum

The cerebellum constitutes only 10% of the total volume of the brain but contains more than one-half of its neurons. The cerebellar cortex comprises a series of highly regular, repeating units, each of which contains the same basic microcircuit. Different regions of the cerebellum receive projections from distinct brain and spinal structures and then project back to the brain. The similarity of the architecture and physiology in all regions of the cerebellum implies that different regions of the cerebellum perform similar computational operations on different inputs.

The symptoms of cerebellar damage in humans and experimental animals provide compelling evidence that the cerebellum participates in the control of movement. The symptoms, in addition to being diagnostic for clinicians, thus help define the possible roles of the cerebellum in controlling behavior.

Several fundamental principles define our understanding of the physiological function of the cerebellum. First, the cerebellum acts in advance of sensory feedback arising from movement, thus providing feedforward control of muscular contractions. Second, to achieve such control, the cerebellum relies on internal models of the body to process and compare sensory inputs with copies of motor commands. Third, the cerebellum plays a special role in motor and perceptual timing. Fourth, the cerebellum is critical for adapting

and learning motor skills. Finally, the primate cerebellum has extensive connectivity to nonmotor areas of the cerebral cortex, suggesting it performs similar functions in the performance and learning of motor and nonmotor behaviors.

Damage of the Cerebellum Causes Distinctive Symptoms and Signs

Damage Results in Characteristic Abnormalities of Movement and Posture

Disorders that involve the cerebellum typically disrupt normal movement patterns, demonstrating the cerebellum's critical role in movement. Patients describe a loss of the automatic, unconscious nature of most movements. In the early 20th century, Gordon Holmes recorded the self-report of a man with a lesion of his right cerebellar hemisphere: "movements of my left arm are done subconsciously, but I have to think out each movement of the right arm. I come to a dead stop in turning and have to think before I start again."

This has been interpreted as an interruption in the automatic level of processing by cerebellar inputs and outputs. With a malfunctioning cerebellum, it seems that the cerebral cortex needs to play a more active role in programming the details of motor actions. Importantly, individuals with cerebellar damage do not experience the paralysis that can be associated with cerebral cortical damage. Instead, they show characteristic abnormalities in voluntary movement, walking, and posture that have provided important clues about cerebellar function.

The most prominent symptom of cerebellar disorders is *ataxia*, or lack of coordination of movement. Ataxia is a generic term used to describe the collective motor features associated with cerebellar damage. People with cerebellar disorders make movements that qualitatively appear jerky, irregular, and highly variable. *Limb ataxia* during reaching is characterized by curved hand paths that are *dysmetric* in that they over- or undershoot the intended target and oscillate (Figure 37–1A). Patients often break a movement down into components, presumably in an effort to simplify control of multi-joint movements (*decomposition of movement*). Yet this may not be effective. For example, patients often have difficulty holding the shoulder steady while moving the elbow, a deficit thought to be due to poor predictions of how the movement at the elbow mechanically affects the shoulder (Figure 37–1B). If prediction fails, then patients are forced to try to steady the shoulder using time-delayed feedback, which is less effective.

At the end of reaching movements, there can be marked oscillation as the hand approaches the target. This *action* (or *intention*) *tremor* is the result of a series of erroneous, overshooting attempts to correct the movement. It largely disappears when the eyes are shut, suggesting that it is driven by time-delayed visual feedback of the movement. Finally, patients show abnormalities in the rate and regularity of repeated movements, a sign referred to as *dysdiadochokinesia* (Greek, impaired alternating movement) that can be readily demonstrated when a patient attempts to perform rapid alternating movements (Figure 37–1C).

People with cerebellar damage also exhibit *gait ataxia* and poor balance. When walking, they take steps that are irregularly timed and placed. They have difficulty shifting their weight from one foot to the other, which can lead to falling. The trunk oscillates when they are unsupported in sitting, standing, and during walking, particularly as they start, stop, or turn. A wide stepping pattern with feet spread apart is common and is thought to be a compensatory measure to improve stability.

Other signs that are commonly observed with cerebellar dysfunction can also occur with damage to other brain regions. People with cerebellar damage often have slurred speech with irregular timing (dysarthria); repetitive to-and-fro movements of the eyes with a slow and fast phase (nystagmus); and reduced resistance to passive limb displacements (hypotonia), which is thought to be related to so-called "pendular reflexes" often observed in cerebellar patients. In patients with cerebellar disease, the leg may oscillate like a pendulum many times after a knee jerk produced by a tap on the patellar tendon with a reflex hammer, instead of coming to rest immediately.

Damage Affects Specific Sensory and Cognitive Abilities

It is now known that cerebellar damage affects proprioceptive abilities (the sense of limb position and movement), but only during active movement. Proprioceptive acuity—the sense of the position and movement of the limbs—is normally more precise for active movements than for passive movements. Cerebellar patients show normal proprioceptive acuity when they have to judge which of two passive movements is larger. However, their proprioceptive acuity is worse than that of healthy individuals when they move a limb actively. One interpretation of these findings is that the cerebellum normally helps to predict how active movements will unfold, which would be important for movement coordination and for perceiving where the limbs are during active movements.

Damage to the cerebellum also affects cognitive processes, although these deficits are less obvious compared to the pronounced disturbances of sensory–motor function. Some of the earliest studies implicating the cerebellum in a range of cognitive tasks involved functional imaging to study the brain activity during behavior in healthy individuals. For example, in a study using positron emission tomography to image the brain activity of subjects during silent reading, reading aloud, and speech, areas of the cerebellum involved in the control of mouth movements were more active when subjects read aloud than when they read silently. Surprisingly, however, cerebellar activation was more pronounced in a task with greater cognitive load, when subjects were asked to name a verb associated with a noun; a subject might respond with "bark" if he or she saw the word "dog." Compared with simply reading aloud, the word-association task produced a pronounced increase in activity within the right lateral cerebellum. Consistent with this finding, a patient with damage in the right cerebellum could not learn a word-association task.

By now, many studies have revealed clear deficits in executive function, visual spatial cognition, language, and emotional processing after cerebellar damage. There appears to be some regional specificity within the cerebellum for different types of cognitive function. Damage to the midline cerebellum or *vermis* seems to be related to emotional or affective dysregulation, likely due to its interconnectivity with limbic structures. Damage to the right cerebellar hemisphere is related to language and verbal dysfunction, presumably because this hemisphere is interconnected with the left cerebral cortical hemisphere. Likewise, damage to the left cerebellar hemisphere is related to visuospatial dysfunction, probably because this hemisphere is interconnected with the right cerebral cortical hemisphere. Additionally, studies that examine cognitive dysfunction produce variable results; patients perform normally in one study but not another. Some studies show that cognitive deficits are most pronounced when patients are tested shortly after damage to the cerebellum and that compensations at the level of cerebral cortex might gradually make up for

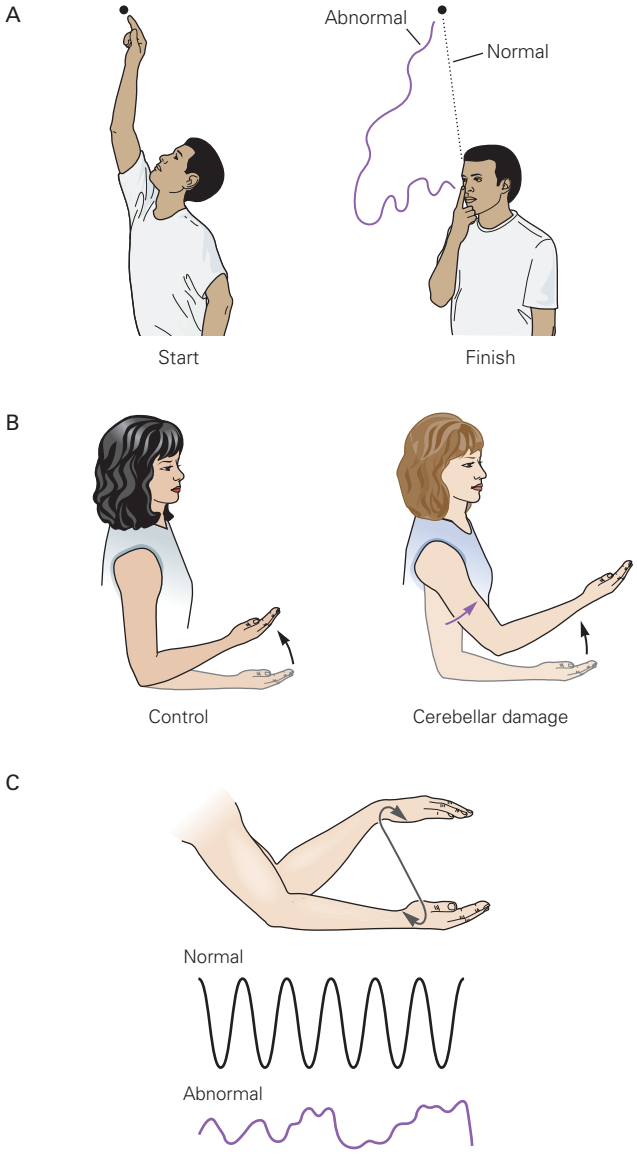

Figure 37–1 (Left) Typical defects observed in cerebellar diseases.

A. A cerebellar patient moving his arm from a raised position to touch the tip of his nose exhibits inaccuracy in range and direction (dysmetria) and moves his shoulder and elbow separately (decomposition of movement). Tremor increases as the finger approaches the nose.

B. Failure of compensation for interaction torques can account for cerebellar ataxia. Subjects flex their elbows while keeping their shoulder stable. In both the control subject and the cerebellar patient, the net elbow torque is large because the elbow is moved. In the control subject, there is relatively little net shoulder torque because the interaction torques are automatically cancelled by muscle torques. In the cerebellar patient, this compensation fails; the muscle torques are present but are inappropriate to cancel the interaction torques. As a result, the patient cannot flex her elbow without causing a large perturbation of her shoulder position. (Adapted, with permission, from Bastian, Zackowski, and Thach 2000.)

C. A subject was asked to alternately pronate and supinate the forearm while flexing and extending at the elbow as rapidly as possible. Position traces of the hand and forearm show the normal pattern of alternating movements and the irregular pattern (dysdiadochokinesia) typical of cerebellar disorder.

cerebellar loss of function. However, cognitive deficits may be more robust and long lasting when cerebellar damage is acquired in childhood.

Thus, cognitive deficits arising from cerebellar damage sometimes can be difficult to characterize. What is clear is that the motor dysfunction after cerebellar loss is more obvious than cognitive dysfunction. It may be that cortical regions of motor control are less able to compensate for losses of cerebellar motor control compared to cortical compensation for impairment of cerebellar computations involved in cognitive processes.

The Cerebellum Indirectly Controls Movement Through Other Brain Structures

Understanding the anatomy of the cerebellum and how it interacts with different brain structures is vital to understanding its function. In this section, we consider the general anatomy of the cerebellum as well as its inputs and outputs.

The Cerebellum Is a Large Subcortical Brain Structure

The cerebellum occupies most of the posterior cranial fossa. It is composed of an outer mantle of gray matter (the cerebellar cortex), internal white matter, and three pairs of deep nuclei: the fastigial nucleus, the interposed nucleus (itself composed of the emboliform and globose nuclei), and the dentate nucleus (Figure 37–2A). The surface of the cerebellum is highly convoluted, with many parallel folds or folia (Latin, leaves).

Two deep transverse fissures divide the cerebellum into three lobes. The primary fissure on the dorsal surface separates the anterior and posterior lobes, which together form the body of the cerebellum (Figure 37–2A). The posterolateral fissure on the ventral surface separates the body of the cerebellum from the smaller flocculonodular lobe (Figure 37–2B). Each lobe extends across the cerebellum from the midline to the most lateral tip. In the orthogonal, anterior-posterior direction, two longitudinal furrows separate three regions: the midline vermis (Latin, worm) and the two cerebellar hemispheres, each split into intermediate and lateral regions (Figure 37–2D).

The cerebellum is connected to the dorsal aspect of the brain stem by three symmetrical pairs of peduncles: the inferior cerebellar peduncle (also called the restiform body), the middle cerebellar peduncle (or brachium pontis), and the superior cerebellar peduncle (or brachium conjunctivum). Most of the output axons of the cerebellum arise from the deep nuclei and project through the superior cerebellar peduncle to other brain areas. The main exception is a group of Purkinje cells in the flocculonodular lobe that project to vestibular nuclei in the brain stem.

The Cerebellum Connects With the Cerebral Cortex Through Recurrent Loops

Many parts of the cerebellum form recurrent loops with the cerebral cortex. The cerebral cortex projects to the lateral cerebellum through relays in the pontine nuclei. In turn, the lateral cerebellum projects back to the cerebral cortex through relays in the thalamus. Peter Strick and his colleagues used viruses for transneuronal tracing in nonhuman primates to show that this recurrent circuit is organized as a series of parallel closed loops, where a given part of the cerebellum connects reciprocally with a specific part of the cerebral cortex (Figure 37–3A). Through these reciprocal connections, the cerebellum interacts with vast regions of the neocortex, including substantial connections to motor, prefrontal, and posterior parietal regions. More recently, Strick's group also demonstrated disynaptic connections between the cerebellum and basal ganglia in nonhuman primates.

The resting state connectivity between the cerebellum and cerebral cortex in humans was studied using fMRI scans of 1,000 subjects. Correlations in activity in different regions of the brain were assessed at low frequencies, measured by blood flow while subjects were at rest. They found that different regions of the cerebellum are functionally connected with cerebral cortical regions across the entire cerebral cortex (Figure 37–3C). Taken together, these studies demonstrate the vast impact the cerebellum could have on many aspects of brain function.

Different Movements Are Controlled by Functional Longitudinal Zones

The cerebellum can be broadly divided into three areas that have distinctive roles in different kinds of movements: the vestibulocerebellum, spinocerebellum, and cerebrocerebellum (Figure 37–4).

The *vestibulocerebellum* consists of the flocculonodular lobe and is the most primitive part of the cerebellum. It receives vestibular and visual inputs, projects to the vestibular nuclei in the brain stem, and participates in balance, other vestibular reflexes, and eye movements. It receives information from the semicircular canals and the otolith organs, which sense the head's motion and its position relative to gravity. Most of this

A. Part of the right hemisphere has been cut away to reveal the underlying cerebellar peduncles.

B. The cerebellum is shown detached from the brain stem.

C. A midsagittal section through the brain stem and cerebellum shows the branching structure of the cerebellum. The cerebellar lobules are labeled with their Latin names and Larsell's Roman numeral designations. (Reproduced, with permission, from Larsell and Jansen 1972.)

D. Functional regions of the cerebellum.

vestibular input arises from the vestibular nuclei in the brain stem. The vestibulocerebellum also receives visual input, from both the pretectal nuclei that lie deep in the midbrain beneath the superior colliculus and the primary and secondary visual cortex through the pontine and pretectal nuclei.

The vestibulocerebellum is unique in that its output bypasses the deep cerebellar nuclei and proceeds directly to the vestibular nuclei in the brain stem. Purkinje cells in the midline parts of the vestibulocerebellum project to the lateral vestibular nucleus to modulate the lateral and medial vestibulospinal tracts, which predominantly control axial muscles and limb extensors to assure balance during stance and gait (Figure 37–5A). Disruption of these projections through lesions or disease impairs equilibrium.

The most striking deficits following lesions of the lateral vestibulocerebellum are in smooth-pursuit eye movement toward the side of the lesion. A patient with a lesion of the left lateral vestibulocerebellum can smoothly track a target that is moving to the right, but only poorly tracks motion to the left, using saccades predominantly (Figure 37–6A). These patients can have normal vestibulo-ocular reflex responses to head rotations but cannot suppress the reflex by fixating an object that rotates with the head (Figure 37–6B). These deficits occur commonly if the lateral

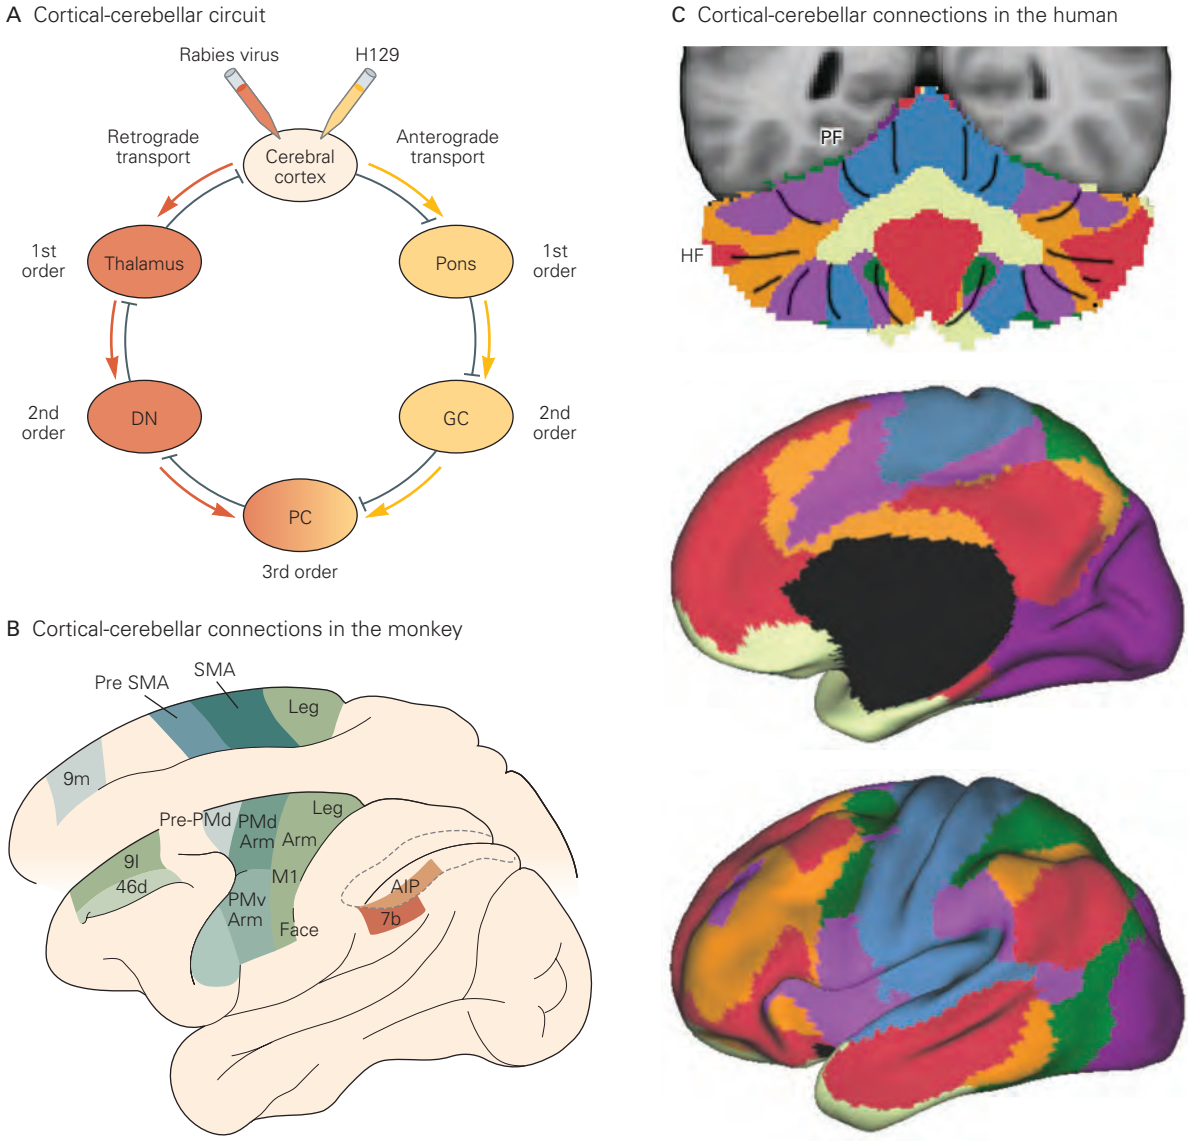

Figure 37–3 **The cerebellum connects to many areas of cerebral cortex.** (Parts A and B adapted, with permission, from Bostan, Dum, and Strick 2013. Copyright © 2013 Elsevier Ltd. part C adapted, with permission, from Buckner et al. 2011. Copyright © 2011 American Physiological Society.)

A. The cortical-cerebellar circuit in monkeys was traced with fluorescence-labeled transsynaptic viruses that can move in an anterograde or retrograde direction. Injection into the cerebral cortex of a retrograde virus, such as rabies virus, will label neurons that project to it and, by crossing synapses, can label second- and possibly higher-order neurons in a pathway. These are shown here in **red** as first-order (thalamus), second-order (deep nucleus), and third-order neurons (Purkinje cells). Injection into the cerebral cortex of an anterograde virus, such as the H129 strain of herpes simplex virus, will label neurons that are targets of the cerebral cortex. These are shown here in **yellow** as first-order (pons), second-order (granule cells), and third-order neurons (Purkinje cells). (Abbreviations: **DN**, dentate nuclei; **GC**, granule cell; **H129**, strain of herpes simplex virus; **PC**, Purkinje cell rabies virus.)

B. Areas of the cerebral cortex connected to the cerebellum. The numbers refer to cytoarchitectonic areas. (Abbreviations: **AIP**, anterior intraparietal area; **M1**, face, arm, and leg areas of the primary motor cortex; **PMd arm**, arm area of the dorsal premotor area; **PMv arm**, arm area of the ventral premotor area; **PrePMd**, predorsal premotor area; **PreSMA**, presupplementary motor area; **SMA arm**, arm area of the supplementary motor area.)

C. Color-coded coronal section of the human cerebellum (**top**) and lateral and medial views of the human cerebral cortex (**bottom**) created from resting state functional connectivity maps (based on functional magnetic resonance imaging scans of 1,000 subjects). Colors correspond to cerebellar and cerebral areas that are connected. Note that the cerebellum is functionally connected with nearly all cerebral areas. (Abbreviations: **HF**, horizontal fissure; **PF**, primary fissure.)

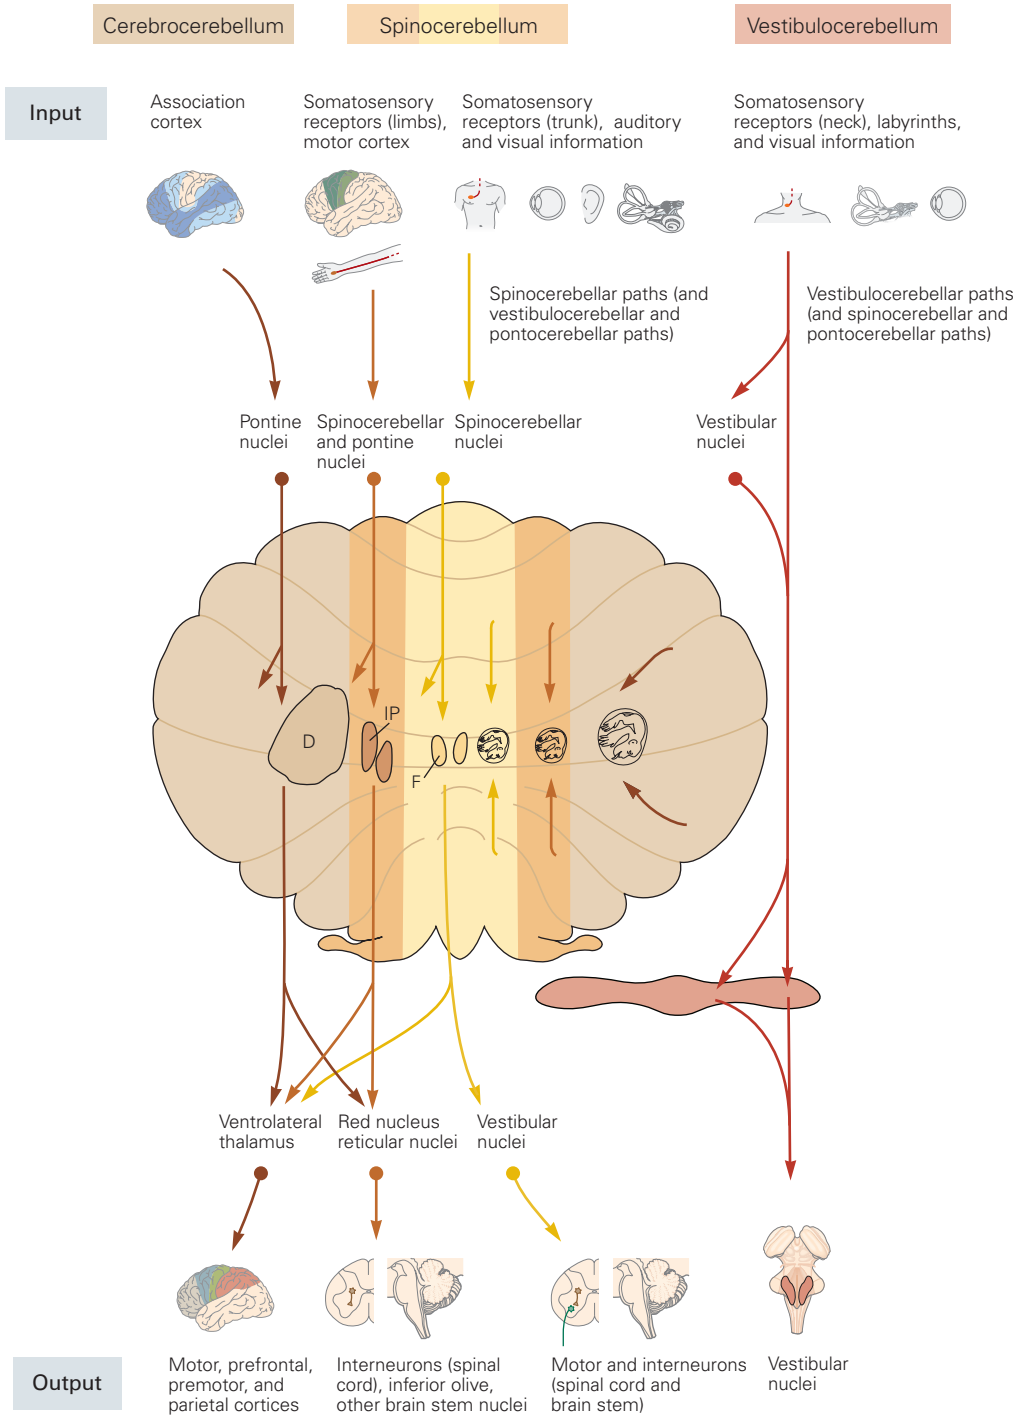

Figure 37–4 **The three functional regions of the cerebellum have different inputs and different output targets.** The cerebellum is shown unfolded, and **arrows** indicate the inputs and outputs of the different functional areas. The body maps in the deep nuclei are based on anatomical tracing and single-cell recordings in nonhuman primates. (Abbreviations: **D**, dentate nucleus; **F**, fastigial nucleus; **IP**, interposed nucleus.) (Adapted, with permission, from Brooks and Thach 1981).

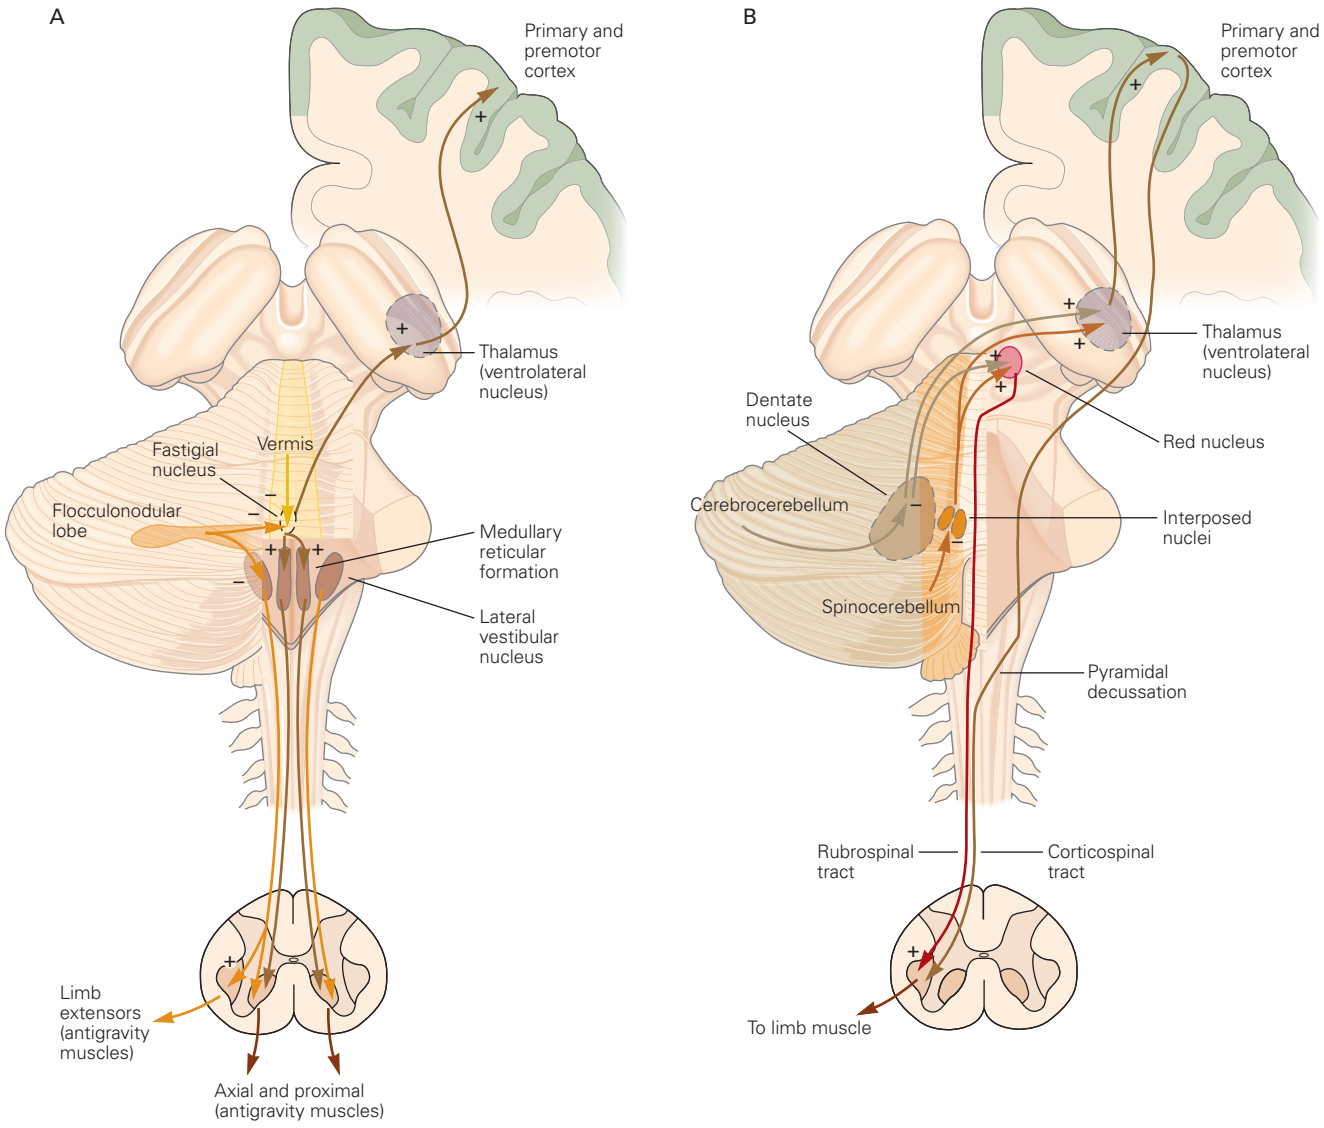

Figure 37–5 Input and output pathways of the cerebellum.

A. Nuclei in the vestibulocerebellum and the vermis control proximal muscles and limb extensors. The vestibulocerebellum (flocculonodular lobe) receives input from the vestibular labyrinth and projects directly to the vestibular nuclei. The vermis receives input from the neck and trunk, the vestibular labyrinth, and retinal and extraocular muscles. Its output is focused on the ventromedial descending systems of the brain stem, mainly the reticulospinal and vestibulospinal tracts and the corticospinal fibers acting on medial motor neurons. The oculomotor connections of the vestibular nuclei have been omitted for clarity.

B. Nuclei in the intermediate and lateral parts of the cerebellar hemispheres control limb and axial muscles. The intermediate part of each hemisphere (spinocerebellum) receives sensory information from the limbs and controls the dorsolateral descending systems (rubrospinal and corticospinal tracts) acting on the ipsilateral limbs. The lateral area of each hemisphere (cerebrocerebellum) receives cortical input via the pontine nuclei and influences the motor and premotor cortices via the ventrolateral nucleus of the thalamus, and directly influences the red nucleus.

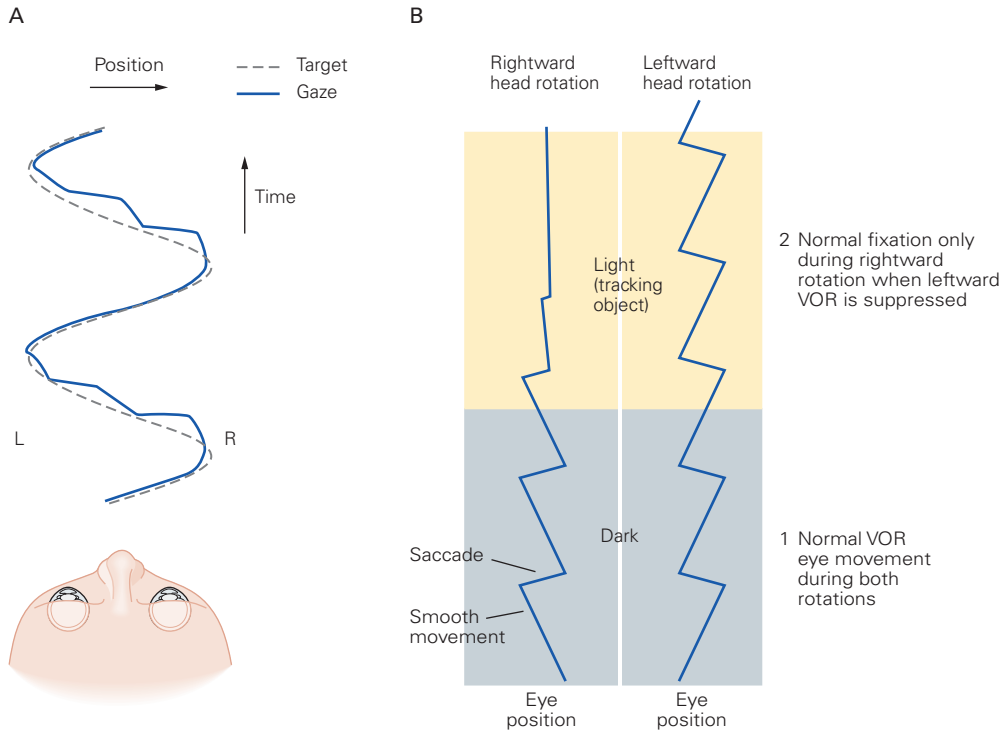

Figure 37–6 Lesions in the vestibulocerebellum have large effects on smooth-pursuit eye movements.

A. Sinusoidal target motion is tracked with smooth-pursuit eye movements as the target moves from left (**L**) to right (**R**). With a lesion of the left vestibulocerebellum, smooth pursuit is punctuated by saccades when the target moves from right to left.

B. In the same patient, responses to vestibular stimulation are normal, whereas object fixation is disrupted during leftward rotation. The traces on the left and right show the eye movements evoked by rightward and leftward head rotation experienced in separate sessions. In each session the patient sat in a chair that rotated continuously in one direction, first in the dark then in the light while fixating on a target that moves along with him. (**1**) In the dark, the eyes show a normal vestibulo-ocular reflex (**VOR**) during rotation in both directions: The eyes move smoothly in the direction opposite to the head's rotation, then reset with saccades in the direction of head rotation. (**2**) In the light, the eye position during rightward head rotation is normal: Fixation on the target is excellent and the vestibulo-ocular reflex is suppressed. During leftward head rotation, however, the subject is unable to fixate on the object and the vestibulo-ocular reflex cannot be suppressed.

vestibulocerebellum is compressed by an acoustic neuroma, a benign tumor that grows on the eighth cranial nerve as it courses directly beneath the lateral vestibulocerebellum.

The *spinocerebellum* is composed of the vermis and intermediate parts of the cerebellar hemispheres (Figure 37–4). It is so named because it receives extensive input from the spinal cord via the dorsal and ventral spinocerebellar tracts. These pathways convey information about touch, pressure, and limb position as well as the spiking activity of spinal interneurons. Thus, these inputs provide the cerebellum with varied information about the changing state of the organism and its environment.

The vermis receives visual, auditory, and vestibular input as well as somatic sensory input from the head and proximal parts of the body. It projects by way of the fastigial nucleus to cortical and brain stem regions that give rise to the medial descending systems controlling proximal muscles of the body and limbs (Figure 37–5A). The vermis governs posture and locomotion as well as eye movements. For example, lesions of the oculomotor region of the vermis cause saccadic eye movements that overshoot their target, much as patients with cerebellar damage make arm movements that overshoot their target.

The adjacent intermediate parts of the hemispheres also receive somatosensory input from the limbs. Neurons here project to the interposed nucleus, which provides inputs to lateral corticospinal and rubrospinal systems on the contralateral side of the brain and controls the more distal muscles of the limbs and digits (Figure 37–5B). Because corticospinal and rubrospinal systems cross the midline as they descend to the spinal cord, cerebellar lesions disrupt ipsilateral limb movements.

The *cerebrocerebellum* comprises the lateral parts of the hemispheres (Figure 37–4). These areas are phylogenetically the most recent and are much larger relative to the rest of the cerebellum in humans and apes than in monkeys and cats. Almost all of the inputs to and outputs from this region involve connections with the cerebral cortex. The output is transmitted through the dentate nucleus, which projects via the thalamus to contralateral motor, premotor, parietal, and prefrontal cortices. The dentate nucleus also projects to the contralateral red nucleus. The lateral hemispheres have many functions but seem to participate most extensively in planning and executing movement. They also have a role in cognitive functions unconnected with motor planning, such as visuospatial and language processes. There is now some correlative evidence implicating the cerebellar hemispheres in aspects of schizophrenia (Chapter 60), dystonia (Chapter 38), and autism (Chapter 62).

Two important principles of cerebellar function have emerged from recordings of the action potentials of single neurons in the cerebellar cortex and deep cerebellar nuclei during arm movements, along with controlled, temporary inactivation of specific cerebellar regions.

First, neurons in these areas discharge vigorously in relation to voluntary movements. Cerebellar output is related to the direction and speed of movement. The deep nuclei are organized into somatotopic maps of different limbs and joints, as in the motor cortex, although the organization of the cerebellar cortex has been characterized as "fractured somatotopy" with multiple disconnected and partial maps. Moreover, the interval between the onset of modulation of the firing of cerebellar neurons and movement is remarkably similar to that for neurons in the motor cortex. This result emphasizes the cerebellum's participation in recurrent circuits that operate synchronously with the cerebral cortex.

Second, the cerebellum provides feedforward control of muscle contractions to regulate the timing of movements. Rather than awaiting sensory feedback, cerebellar output anticipates the muscular contractions that will be needed to bring a movement smoothly, accurately, and quickly to its desired endpoint. Failure of these mechanisms causes the intention tremor of cerebellar disorders. For example, a rapid single-joint movement is initiated by the contraction of an agonist muscle and terminated by an appropriately timed contraction of the antagonist. The contraction of the antagonist starts early in the movement, well before there has been time for sensory feedback to reach the brain, and therefore must be programmed as part of the movement. When the dentate and interposed nuclei are experimentally inactivated, however, contraction of the antagonist muscle is delayed until the limb has overshot its target. The programmed anticipatory contraction of the antagonist in normal movements is replaced by a correction driven by sensory feedback. This correction is itself dysmetric and results in another error, necessitating a new adjustment (Figure 37–7).

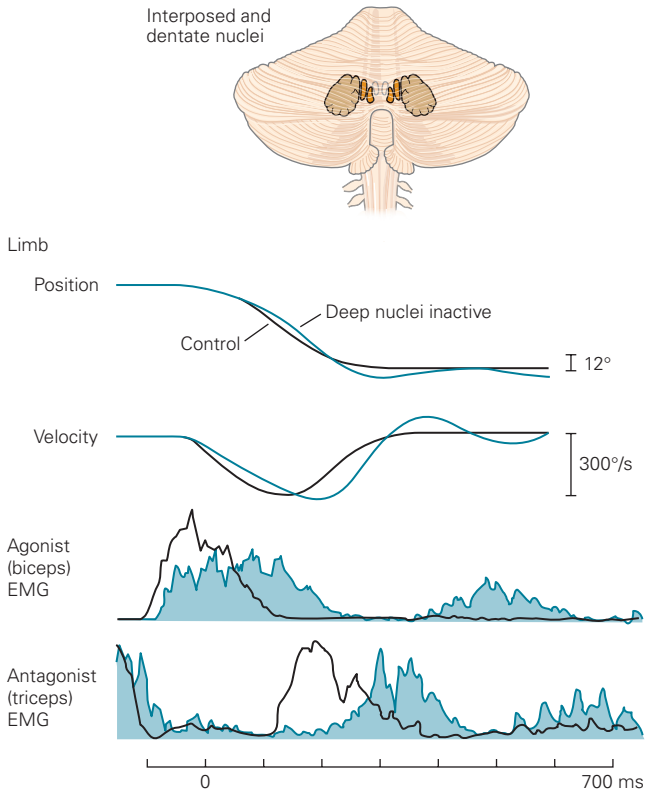

Figure 37–7 **The interposed and dentate nuclei are involved in the precise timing of agonist and antagonist activation during rapid movements.** The interposed (medial) and dentate (lateral) nuclei are highlighted in the drawing of the cerebellum. The records of limb movement show how a monkey normally makes a rapid elbow flexion limb movement and attempts to make the same movement when the interposed and dentate nuclei are inactivated by cooling. The electromyographic (EMG) traces show limb position and velocity and EMG responses of the biceps and triceps muscles. When the deep nuclei are inactivated, activation of the agonist (biceps) becomes slower and more prolonged. Activation of the antagonist (triceps), which is needed to stop the movement at the correct location, is likewise delayed and protracted so that the initial movement overshoots its appropriate extent. Delays in successive phases of the movement produce oscillations similar to the terminal tremor seen in patients with cerebellar damage.

The Cerebellar Cortex Comprises Repeating Functional Units Having the Same Basic Microcircuit

The cellular organization of the microcircuit in the cerebellar cortex is striking, and one of the premises of cerebellar research has been that the details of the microcircuit are an important clue to how the cerebellum works. In this section, we describe three major features of the microcircuit.

The Cerebellar Cortex Is Organized Into Three Functionally Specialized Layers

The three layers of the cerebellar cortex contain distinct kinds of neurons and are functionally specialized (Figure 37–8).

The deepest, or *granular layer*, is the input layer. It contains a vast number of granule cells, estimated at 100 billion, which appear in histological sections as small, densely packed, darkly stained nuclei. The granular layer also contains a few larger Golgi cells and, in some cerebellar regions, a smattering of other neurons such as cells of Lugaro, unipolar brush cells, and chandelier cells. The mossy fibers, one of the two principal afferent inputs to the cerebellum, terminate in this layer. The bulbous terminals of the mossy fibers excite granule cells and Golgi neurons in synaptic complexes called *cerebellar glomeruli* (Figure 37–8). As we will see later when discussing recurrent circuits in the cerebellum, Golgi cells inhibit granule cells.

The middle or *Purkinje cell layer* is the output layer of the cerebellar cortex. This layer consists of a single sheet of Purkinje cell bodies, each 50 to 80 μm in diameter. The fan-like dendritic trees of Purkinje cells extend upward into the molecular layer where they receive inputs from the second major type of afferent to the cerebellum, the climbing fibers, as well as from granule cells and inhibitory interneurons. Purkinje cell axons conduct the entire output of the cerebellar cortex, projecting to the deep nuclei in the underlying white matter or to the vestibular nuclei in the brain stem, where they release the inhibitory transmitter GABA (γ-aminobutyric acid).

The outermost or *molecular layer* contains the spatially polarized dendrites of Purkinje cells, which extend approximately 1 to 3 mm in the anterior-posterior direction but occupy only a very narrow territory in the medial-lateral direction. The molecular layer contains the cell bodies and dendrites of two types of "molecular layer interneurons," the stellate and basket cells, both of which inhibit Purkinje cells. It also contains the axons of the granule cells, called the *parallel fibers* because they run parallel to the long axis of the folia (Figure 37–8). Parallel fibers run perpendicular to the dendritic trees of the Purkinje cells and thus have the potential to form a few synapses with each of a large number of Purkinje cells.

The Climbing-Fiber and Mossy-Fiber Afferent Systems Encode and Process Information Differently

The two main types of afferent fibers in the cerebellum, the mossy fibers and climbing fibers, probably mediate different functions. Both form excitatory synapses with neurons in the deep cerebellar nuclei and in the cerebellar cortex. However, they terminate in different layers of the cerebellar cortex, affect Purkinje cells through very different patterns of synaptic convergence and divergence, and produce different electrical events in the Purkinje cells.

Climbing fibers originate in the inferior olivary nucleus in the brain stem and convey sensory information to the cerebellum from both the periphery and the cerebral cortex. The climbing fiber is so named because each one wraps around the proximal dendrites of a Purkinje neuron like a vine on a tree, making numerous synaptic contacts (Figure 37–9). Each Purkinje neuron receives synaptic input from only a single climbing fiber, but each climbing fiber contacts 1 to 10 Purkinje cells that are arranged topographically along a parasagittal strip in the cerebellar cortex. Indeed, the axons from clusters of related olivary neurons terminate in thin parasagittal strips that extend across several folia, and the Purkinje cells from one strip converge on a common group of neurons in the deep nuclei.

Climbing fibers have an unusually powerful influence on the electrical activity of Purkinje cells. Each action potential in a climbing fiber generates a protracted, voltage-gated Ca^{2+} conductance in the soma and dendrites of the postsynaptic Purkinje cell. This results in prolonged depolarization that produces an electrical event called a "complex spike": an initial large-amplitude action potential followed by a high-frequency burst of smaller-amplitude action potentials (Figure 37–9). Whether these smaller spikes are transmitted down the Purkinje cell's axon is not clear. In awake animals, complex spikes occur spontaneously at low rates, usually around one per second. Specific sensory or motor events cause one or two complex spikes that occur at precise times in relation to those events.

Mossy fibers originate from cell bodies in the spinal cord and brain stem. They carry sensory information from the periphery as well as both sensory information and corollary discharges that report the current movement command (Chapter 30) from the cerebral cortex

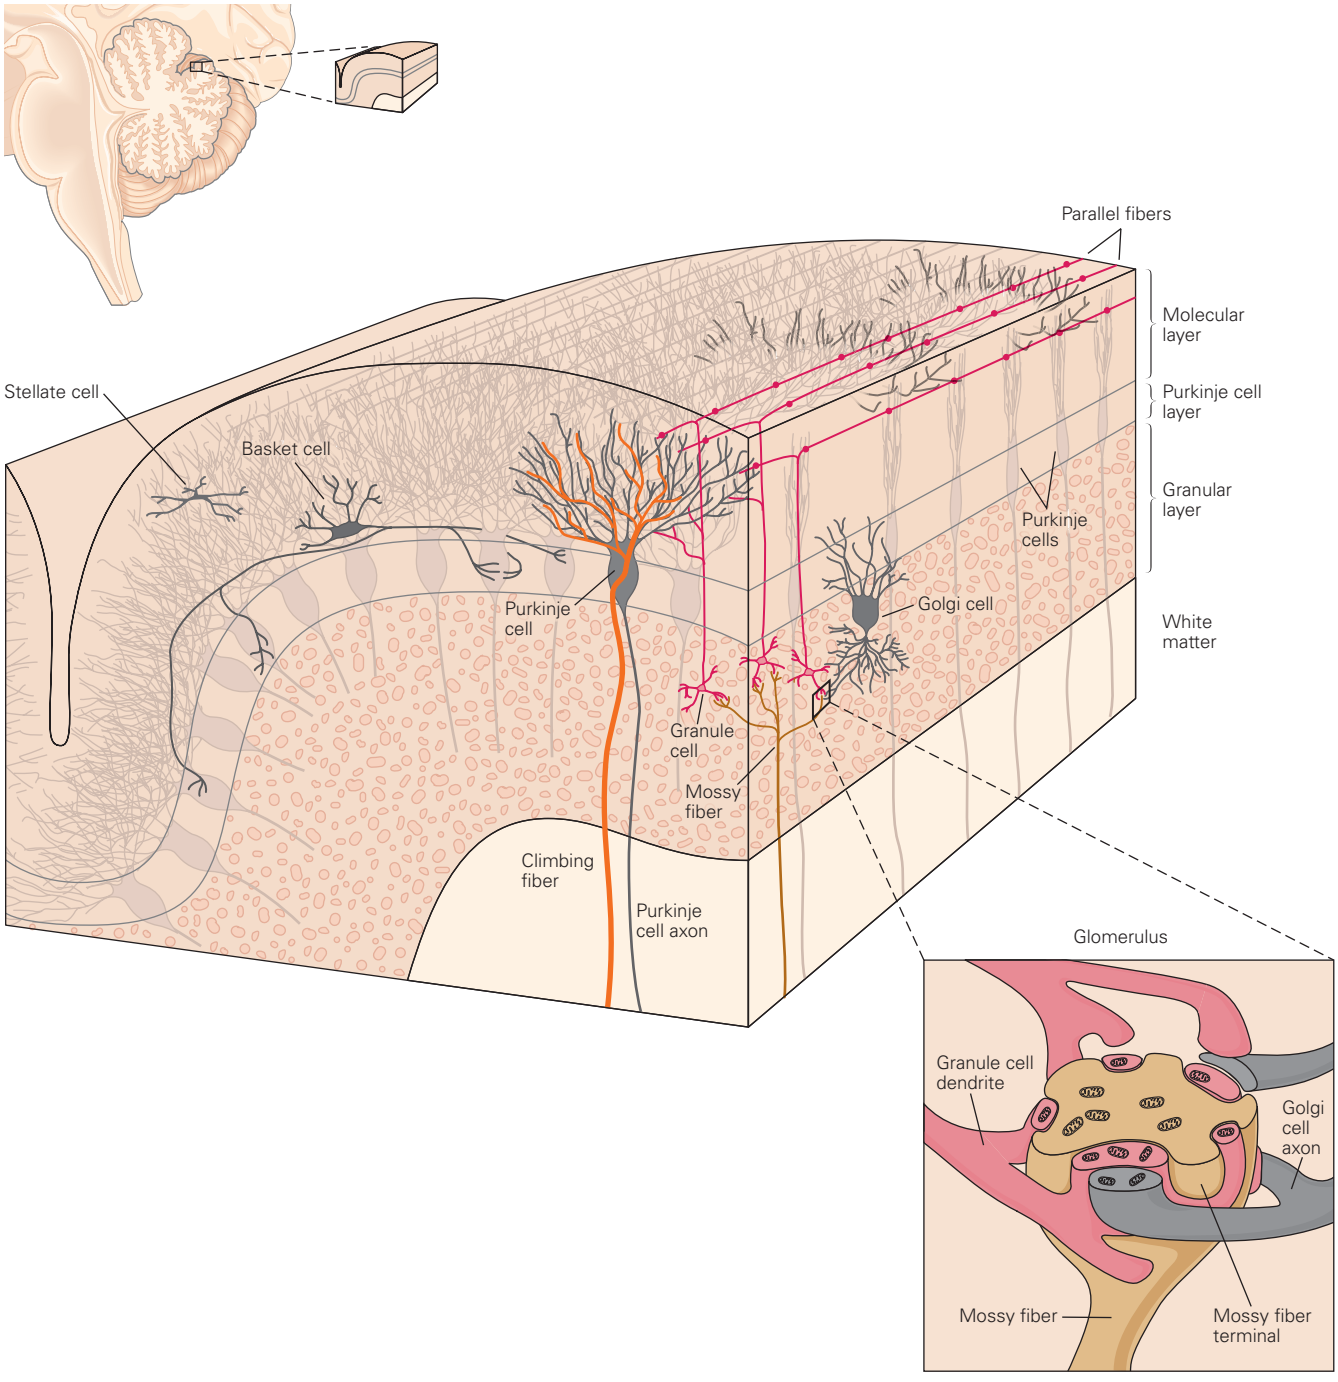

Figure 37–8 The cerebellar cortex contains five main types of neurons organized into three layers. A vertical section of a single cerebellar folium illustrates the general organization of the cerebellar cortex. The detail of a cerebellar glomerulus in the granular layer is also shown. A glomerulus is the synaptic complex formed by the bulbous axon terminal of a mossy fiber and the dendrites of several Golgi and granule cells. Mitochondria are present in all of the structures in the glomerulus, consistent with their high metabolic activity.

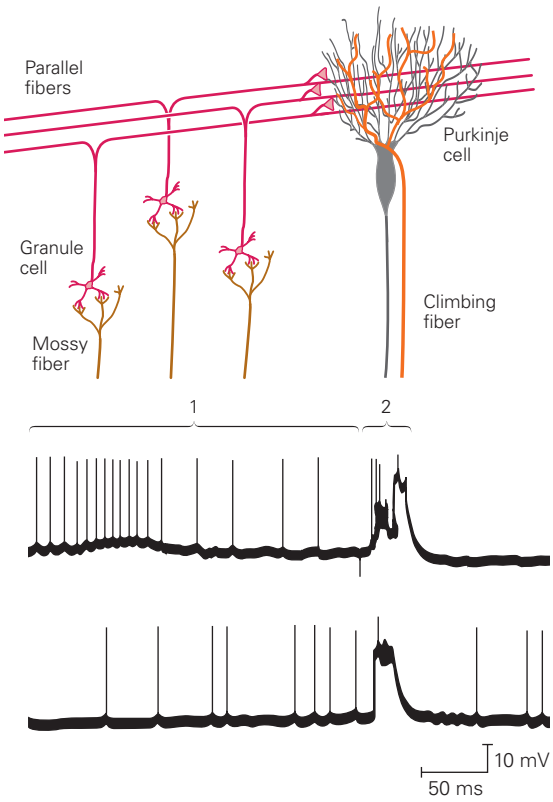

Figure 37–9 Simple and complex spikes recorded intracellularly from a cerebellar Purkinje cell. Simple spikes are produced by mossy-fiber input (**1**), whereas complex spikes are evoked by climbing-fiber synapses (**2**). (Reproduced, with permission, from Martinez, Crill, and Kennedy 1971.)

via the pontine nuclei. Mossy fibers affect Purkinje cells via multisynaptic pathways that have intriguing patterns of convergence and divergence. Individual mossy fibers, acting through granule cells and parallel fibers, have a tiny influence on Purkinje cell output, but collectively, the whole population of mossy fibers has massive effects on cerebellar output.

Mossy fibers form excitatory synapses on the dendrites of granule cells in the granular layer (Figure 37–8). Each granule cell has three to five short dendrites, and each dendrite receives contacts from a single mossy fiber. Due to this paucity of inputs, the spatial integration by a granule cell of its different mossy fiber synapses is not extensive; however, the cell can be the site of convergence of mossy fibers from multiple sensory modalities and motor corollary discharge. The next synaptic relay, between the granule cell axons and Purkinje cells, distributes information with very wide divergence and convergence. The parallel fibers allow each mossy fiber to influence a large number of Purkinje cells, and each Purkinje cell is contacted potentially by axons from somewhere between 200,000 and 1 million granule cells. Importantly, in response to changing conditions there seems to be tremendous potential for adaptation of cerebellar output at the synapses between parallel fibers and Purkinje cells. It appears that only a small fraction of these synapses are active at any given time.

Parallel fibers produce brief, small excitatory potentials in Purkinje cells (Figure 37–9). These potentials converge in the cell body and spread to the initial segment of the axon where they generate conventional action potentials called "simple spikes" that propagate down the axon. In awake animals, Purkinje cells emit a steady stream of simple spikes, with spontaneous firing rates as high as 100 per second even when an animal is sitting quietly. Purkinje cells fire at rates as high as several hundred spikes per second during active eye, arm, and face movements.

The climbing-fiber and mossy-fiber/parallel-fiber systems seem to be specialized for transmission of different kinds of information. Climbing fibers cause complex spikes that seem specialized for event detection. Although complex spikes occur only infrequently, synchronous firing in multiple climbing fibers enables them to signal important events. Synchrony seems to arise partly because signaling between many neurons in the inferior olivary nucleus occurs electrotonically (at gap-junction channels). In contrast, the high firing rates of the simple spikes in Purkinje cells can be modulated up or down in a graded way by mossy-fiber inputs, and thereby encode the magnitude and duration of peripheral stimuli or centrally generated behaviors.

The Cerebellar Microcircuit Architecture Suggests a Canonical Computation

The cerebellar microcircuit is replicated many times across the surface of the cerebellar cortex. This repeating architecture and pattern of convergence and divergence has led to the suggestion that since every such module has the same architecture and pattern of convergence and divergence, the cerebellar cortex performs the same basic "canonical" computation on all of its inputs, and that it potentially transforms cerebellar inputs in a similar way for all cerebellar output systems. Inspection of a diagram of the cerebellar microcircuit (Figure 37–10) reveals a number of different computational components. One general feature is the existence of parallel excitatory and inhibitory pathways to the Purkinje cells or deep cerebellar nuclei. The other general feature is the prevalence of recurrent loops.

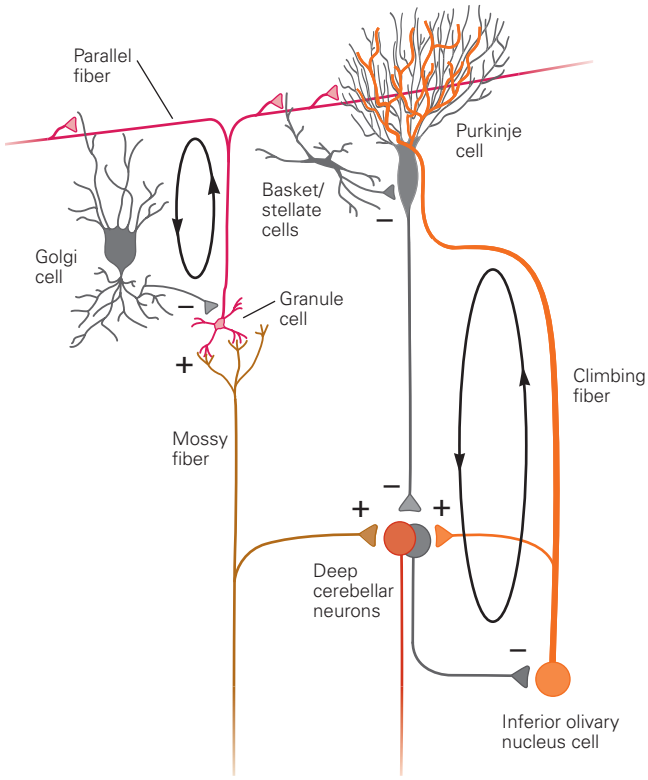

Figure 37–10 Synaptic organization of the cerebellar microcircuit. Excitation and inhibition converge both in the cerebellar cortex and in the deep nuclei. Recurrent loops involve Golgi cells within the cerebellar cortex and the inferior olive outside the cerebellum. (Adapted, with permission, from Raymond, Lisberger, and Mauk 1996. Copyright © 1996 AAAS.)

Parallel Feedforward Excitatory and Inhibitory Pathways

The excitatory inputs relayed from mossy fibers to granule cells to Purkinje cells work in parallel with feedforward inhibitory inputs through the two molecular layer interneurons, the stellate and basket cells. Both of these interneurons receive inputs from parallel fibers and inhibit Purkinje cells, but they have quite different architectures.

The short axons of stellate cells contact the nearby dendrites of Purkinje cells. Thus, a stellate cell acts locally in the sense that it and the Purkinje cell it inhibits are excited by the same parallel fibers. In contrast, a basket cell acts more widely. Its axon runs perpendicular to the parallel fibers (Figure 37–8) and creates flanks of inhibition on Purkinje cells that receive input from parallel fibers other than those that excite the basket cell. Stellate cells affect Purkinje cells via synapses that are on distal dendrites, whereas basket cells make powerful synapses on the cell body of Purkinje cells and seem to be positioned for a powerful influence on Purkinje cell simple spiking. Remarkably, even 60 years after the architecture of the cerebellar microcircuit was described, the functional role of molecular layer interneurons remains a mystery.

Convergence of excitatory and inhibitory pathways is a predominant feature also in the deep cerebellar nuclei. Here, inhibitory inputs from Purkinje cells converge with excitatory inputs from axon collaterals of mossy and climbing fibers (Figure 37–10). Thus, a mossy fiber affects target neurons in the deep nuclei in two ways: directly by excitatory synapses and indirectly by pathways through the cerebellar cortex and the inhibitory Purkinje cells. Neurons of the deep cerebellar nuclei are active spontaneously even in the absence of synaptic inputs, so the inhibitory output of the Purkinje cells both modulates this intrinsic activity and sculpts the excitatory signals transmitted from mossy fibers to the deep nuclei. In almost all parts of the cerebellum, collaterals from climbing fibers to the deep cerebellar nuclei create the opportunity for a similar interaction of excitatory and inhibitory inputs.

Recurrent Loops

An important recurrent loop is contained entirely within the cerebellar cortex and employs Golgi cells to sculpt the activity of the granule cells, the input elements in the cerebellar cortex. Golgi cells receive a few large excitatory inputs from mossy fibers, many smaller excitatory inputs from parallel fibers, and inhibitory inputs from neighboring Golgi cells. The GABAergic terminals from Golgi cells inhibit granule cells (Figure 37–10) and thereby regulate the activity of granule cells and the signals conveyed by the parallel fibers. This loop is evidence that important processing may occur within the granular layer. It may shorten the duration of bursts in granule cells, limiting the magnitude of the excitatory response of granule cells to their mossy fiber inputs, or could ensure that the granule cells respond only when a certain number of their mossy fiber inputs are active.

A second recurrent loop provides Purkinje cells with a way to regulate their own climbing fiber inputs (Figure 37–10). Purkinje cells inhibit GABAergic inhibitory neurons in the deep cerebellar nuclei that project to the inferior olive. When the simple-spike firing of a group of Purkinje cells decreases, the activity of these inhibitory interneurons increases, leading to decreases in the excitability of neurons in the inferior olive. The decreased excitability of the inferior olive reduces both the probability of action potentials in climbing fibers that project to the original group of Purkinje cells and the duration of each burst of climbing fiber action

potentials. In the section on cerebellar learning, we will see how this recurrent loop could allow the cerebellar cortex to control the inputs that cause adaptive changes in the synapses on its Purkinje cells.

The Cerebellum Is Hypothesized to Perform Several General Computational Functions

We know that the cerebellum is important for motor control and some nonmotor functions. Even though we do not yet know how the cerebellar circuit controls these functions, we are able to identity aspects of the control that seem to be particularly "cerebellar." These include reliable feedforward control, internal control of timing, integration of sensory inputs with corollary discharge, and state estimation through internal models.

The Cerebellum Contributes to Feedforward Sensorimotor Control

Sensory feedback is by its nature delayed. Therefore, when a movement is initiated there is a period of time before any useful sensory feedback is received about the movement. We saw earlier that cerebellar damage causes movement disorders that appear to result from out-of-date sensory feedback. If so, it is reasonable to assume that the cerebellum regulates and coordinates movement by preprogramming and coordinating commands for muscular contraction prior to the arrival of useful sensory feedback. The cerebellar output anticipates the muscular contractions that will be needed to bring a movement smoothly, accurately, and quickly to the desired endpoint, and uses sensory feedback mainly to monitor and improve its own performance.

Like neurons in the motor cortex, cerebellar neurons are activated before movement. Still, lesion studies and the symptoms in human motor disorders imply that the cerebellum and motor cortex play very different roles in movement. Lesions of the cerebellum disrupt the accuracy and coordination of voluntary movement, while lesions of the cerebral cortex largely prevent movement.

In addition, the pattern of cerebellar activity, not simply the rate of activity, conveys information for movement control. This is illustrated in mouse models of cerebellar disease. Deletion of certain ion channels produces excessive variability of Purkinje cell simple-spike firing patterns, which seems to lead to ataxia. This suggests that the regularity of cerebellar activity must be closely regulated to achieve normal movement.

The Cerebellum Incorporates an Internal Model of the Motor Apparatus

To program the correct muscle contractions for a smooth, accurate arm movement, the cerebellum needs to have some information about the physical configuration of the arm. Thus, it needs to create and maintain what are called "internal models" of the motor apparatus (Chapter 30). Internal models allow the cerebellum to perform a computation that helps the brain make good estimates of the exact muscle forces needed to move an arm in a desired manner.

An accurate *inverse dynamic* model of the arm, for example, can process sensory data about the current posture of the arm and automatically generate a sequence of properly timed and scaled commands to move the hand to a new desired position. An accurate *forward dynamic* model does the opposite: It processes a copy of a motor command and makes a prediction about the upcoming kinematics (ie, position and speed) of the arm movement. Recordings of the output of the cerebellum have provided evidence compatible with the idea that the cerebellum contains both types of models and that they are used to program both arm and eye movements.

One reason that the cerebellum may need these types of models for motor control is because of the complexities associated with moving linked segments of the body. Consider the mechanics of making a simple arm movement. Because of the mechanics of the arm and the momentum it develops when moving, movement of the forearm alone causes inertial forces that passively move the upper arm. If a subject wants to flex or extend the elbow without simultaneously moving the shoulder, then muscles acting at the shoulder must contract to prevent its movement. These stabilizing contractions of the shoulder joint occur almost perfectly in healthy subjects but not in patients with cerebellar damage, who experience difficulty controlling the inertial interactions among multiple segments of a limb (Figure 37–1B). As a result, patients exhibit greater inaccuracy of multi-joint versus single-joint movements.

In conclusion, the cerebellum uses internal models to allow it to preprogram a sequence of muscle contractions that will generate smooth, accurate movement. It also anticipates the forces that result from the mechanical properties of a moving limb. We do not yet know what these internal models look like in terms of the activity of cerebellar neurons, the circuits that operate as internal models, or how the cerebellar output is transformed into muscle forces. However, given that the properties of the limbs change throughout life, we can be confident that the cerebellum's learning capabilities

are involved in adapting these internal models to help generate the most proficient movements.

The Cerebellum Integrates Sensory Inputs and Corollary Discharge

Sensory signals converge in the cerebellum with motor signals that are called a corollary discharge (or efference copy) because they report commands that are being sent to motor nerves at the same time. For example, some neurons in the dorsal spinocerebellar tract relay inputs from sensory afferents in the spinal cord and transmit sensory signals to the cerebellum. In contrast, the neurons in the spinal cord that give rise to the axons in the ventral spinocerebellar tract receive the same afferent and descending inputs as do spinal motor neurons, and they transmit the final motor command back to the cerebellum. The interaction of sensory signals and corollary discharge allows comparison of the plans for a movement with the sensory consequences. This comparison occurs to some degree at Purkinje cells, but we now know that at least some granule cells receive converging sensory and corollary discharge inputs and could perform the comparison.

Internal models and corollary discharge together provide one possible explanation of the role of the cerebellum in movement. To be able to program accurate movements the cerebellum must be able to estimate the state of the motor system through sensory feedback and knowledge of prior motor activity. Next, it must combine information on the state of the motor system with the goals of the next movement and use internal models of the effector to help create commands for muscle forces that will generate an accurate and efficient movement. During the movement, the cerebellum must monitor movement performance through sensory feedback. Current thinking is that much of this is done by an internal model that converts corollary discharge into predictions of the sensory feedback. The cerebellum then compares real and predicted sensory feedback to determine a sensory prediction error and uses the sensory prediction error to guide corrective movements and learning.

Using a paradigm that required monkeys to ignore the sensory signals caused by their own movement, Kathy Cullen and colleagues have identified a neural correlate of a sensory prediction error in the deep cerebellar nuclei. Specifically, they studied the vestibular sensory signals that result from an animal's active head movements. They showed that the brain attenuates or even eliminates the vestibular sensory signals caused by one's own active head movement in order to better detect unpredictable vestibular signals due to the environment. However, when the head is effectively made heavier by adding resistance via a mechanical device, the vestibular sensory signals no longer match the predicted sensory signals that normally would attenuate the vestibular input. They showed that the cerebellum adjusts its predictions of the vestibular input to account for the changes in head movement caused by resistance due to the mechanical device. After some practice, the predicted and actual self-generated sensory inputs again match, and neurons in the deep cerebellar nucleus return to being unresponsive to vestibular inputs. Cerebellum-dependent learning is described in detail later in this chapter.

The Cerebellum Contributes to Timing Control

The cerebellum seems to have a role in movement timing that goes well beyond its role in regulating the timing of contractions in different muscles (Figure 37–7). When patients with cerebellar lesions attempt to make regular tapping movements with their hands or fingers, the rhythm is irregular and the motions vary in duration and force.

Based on a theoretical model of how tapping movements are generated, Richard Ivry and Steven Keele inferred that medial cerebellar lesions interfere only with accurate execution of the response, whereas lateral cerebellar lesions interfere with the timing of serial events. Such timing defects are not limited to motor events. They also affect the patient's ability to judge elapsed time in purely mental or cognitive tasks, as in the ability to distinguish whether one tone is longer or shorter than another or whether the speed of one moving object is greater or less than that of another. We will see in our discussion of motor learning that the cerebellum is critical for learning the timing of motor acts.

The Cerebellum Participates in Motor Skill Learning

In the early 1970s, on the basis of mathematical modeling of cerebellar function and the cerebellar microcircuit, David Marr and James Albus independently suggested that the cerebellum might be involved in learning motor skills. Along with Masao Ito, they proposed that the climbing-fiber input to Purkinje cells causes changes at the synapses that relay mossy fiber input signals from parallel fibers to Purkinje cells. According to their theory, the synaptic plasticity would lead to changes in simple-spike firing, and these changes would cause behavioral learning. Subsequent experimental evidence has supported and extended this theory of cerebellar motor learning.

Climbing-Fiber Activity Changes the Synaptic Efficacy of Parallel Fibers

Climbing fibers can selectively induce *long-term depression* in the synapses between parallel fibers and Purkinje cells that are activated concurrently with the climbing fibers. Many studies in brain slices and cultured Purkinje cells have found that concurrent stimulation of climbing fibers and parallel fibers depresses the Purkinje cell responses to subsequent stimulation of the same parallel fibers. The depression is selective for the parallel fibers that were activated in conjunction with the climbing-fiber input and does not appear in synapses from parallel fibers that had not been stimulated along with climbing fibers (Figure 37–11A). The resulting depression can last for minutes to hours.

Many studies in a variety of motor learning systems have recorded activity in Purkinje cells that is consistent with the predictions of the cerebellar learning theory. For example, if an unexpected resistance is applied to a well-practiced arm movement, extra muscle tension will be required to move. Climbing fiber activity can signal error until the unexpected resistance is learned. They presumably depress the synaptic

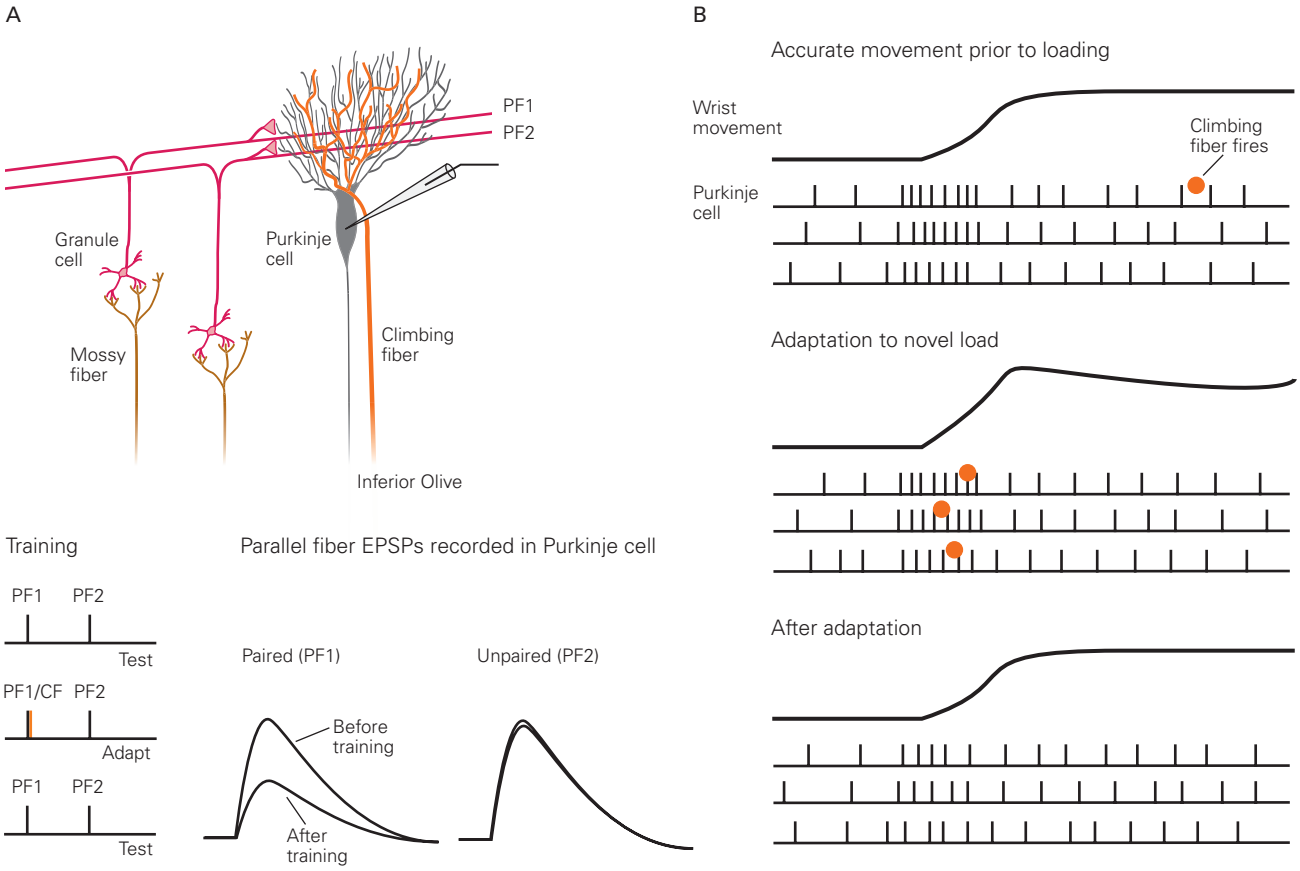

Figure 37–11 Long-term depression of the synaptic input from parallel fibers to Purkinje cells is one plausible mechanism for cerebellar learning.

A. Two different groups of parallel fibers and the presynaptic climbing fibers are electrically stimulated in vitro. Repeated stimulation of one set of parallel fibers (**PF1**) at the same time as the climbing fibers produces a long-term reduction in the responses of those parallel fibers to later stimulation. The responses of a second set of parallel fibers (**PF2**) are not depressed because they are not stimulated simultaneously with the presynaptic climbing fibers. (Abbreviations: **CF**, climbing fiber; **EPSP**, excitatory postsynaptic potential.) (Adapted from Ito et al. 1982.)

B. Top: An accurate wrist movement by a monkey is accompanied by a burst of simple spikes in a Purkinje cell, followed later by discharge of a single climbing fiber in one trial. **Middle:** When the monkey must make the same movement against a novel resistance (adaptation), climbing-fiber activity occurs during movement in every trial and the movement itself overshoots the target. **Bottom:** After adaptation, the frequency of simple spikes during movement is quite attenuated, and the climbing fiber is not active during movement or later. This is the sequence of events expected if long-term depression in the cerebellar cortex plays a role in learning. Climbing fiber activity is usually low (1/s) but increases during adaptation to a novel load. (Adapted, with permission, from Gilbert and Thach 1977.)

strength of parallel fibers involved in generating those errors, namely those that drove Purkinje simple-spike firing at the time of the climbing-fiber activity (Figure 37–11B). With successive movements, the parallel-fiber inputs conveying the flawed central command are increasingly suppressed, a more appropriate pattern of simple-spike activity emerges, and eventually movement errors disappear, along with the climbing-fiber error signal. Although this kind of result is consistent with the theory of cerebellar learning, it stops short of proving that the neural and behavioral learning was caused by long-term depression of the synapses from parallel fibers onto Purkinje cells.

The Cerebellum Is Necessary for Motor Learning in Several Different Movement Systems

The cerebellum is involved in learning a wide variety of movements, ranging from limb and eye movements to walking. In each movement system, motor learning operates to improve the feedforward control of movement. Errors render motor control transiently dependent on sensory feedback, and motor learning restores the ideal situation where performance is accurate without relying on sensory feedback.

Adaptation of limb movements that rely on eye–hand coordination can be demonstrated by having people wear prisms that deflect the light path sideways. When a person plays darts while wearing prism goggles that displace the entire visual field to the left, the initial dart throw lands to the left side of the target by an amount proportional to the strength of the prisms. The subject gradually adapts to the distortion through practice; within 10 to 30 throws, the darts land on target (Figure 37–12). When the prisms are removed, the adaptation persists, and the darts hit to the right of the target by roughly the same distance as the initial prism-induced error. Patients with a damaged cerebellar cortex or inferior olive are severely impaired or unable to adapt at all in this test.

Classical conditioning of the eye-blink response also depends on an intact cerebellum. In this form of associative learning, a puff of air is directed at the cornea, causing the eye to blink at the end of a neutral stimulus such as a tone. If the tone and the puff are paired repeatedly with a fixed duration of the tone, then the brain learns the tone's predictive power and the tone alone is sufficient to cause a blink. Michael Mauk and his colleagues have shown that the brain also can learn about the timing of the stimulus so that the eye blink occurs at the right time. It is even possible to learn to blink at different times in response to tones of different frequencies.

All forms of conjugate eye movement require the cerebellum for correct performance, and each form is subject to motor learning that involves the cerebellum. For example, the vestibulo-ocular reflex normally keeps the eyes fixed on a target when the head is rotated (Chapter 27). Motion of the head in one direction is sensed by the vestibular labyrinth, which initiates eye movements in the opposite direction to prevent visual images from slipping across the retina. When humans and experimental animals wear glasses that change the size of a visual scene, the vestibulo-ocular reflex initially fails to keep images stable on the retina because the amplitude of the reflex is inappropriate to the new conditions. After the glasses have been worn continuously for several days, however, the size of the reflex becomes progressively reduced (for miniaturizing glasses) or increased (for magnifying glasses) (Figure 37–13A). These changes are required to prevent images from slipping across the retina because magnified (or miniaturized) images also move faster (or slower). The performance of the baseline vestibulo-ocular reflex does not depend heavily on the cerebellum, but its adaptation does and can be blocked in experimental animals by lesions of the lateral part of the vestibulocerebellum called the floccular complex.

Saccadic eye movements also depend on the integrity of Purkinje cells in the oculomotor vermis in lobules V, VI, and VII of the vermis (Figure 37–2C). These cells discharge prior to and during saccades, and lesions of the vermis cause saccades to become hypermetric, much as we see in the arm movements of cerebellar patients. The outputs from neurons of the vermis concerned with saccades are transmitted through a very small region of the caudal fastigial nucleus to the saccade generator in the reticular formation.

The same Purkinje cells participate in a form of motor learning called saccadic adaptation. This adaptation is demonstrated by having a monkey fixate on a target straight ahead and then displaying a new target at an eccentric location. During the saccade to the new target, the experimenter moves the new target to a more eccentric location. Initially, the subject needs to make a second saccade to fixate on the target. Gradually, over several hundred trials, the first saccade grows in amplitude so that it brings the eye directly to the final location of the target (Figure 37–13B). Recordings during saccadic adaptation have revealed that climbing fiber inputs to the Purkinje cells in the oculomotor vermis signal saccadic errors during learning, and the simple-spike firing rate of the same cells adapts gradually along with the monkey's eye movements. Thus, the oculomotor vermis is a likely site for motor learning of the amplitude of saccadic eye movements. The story

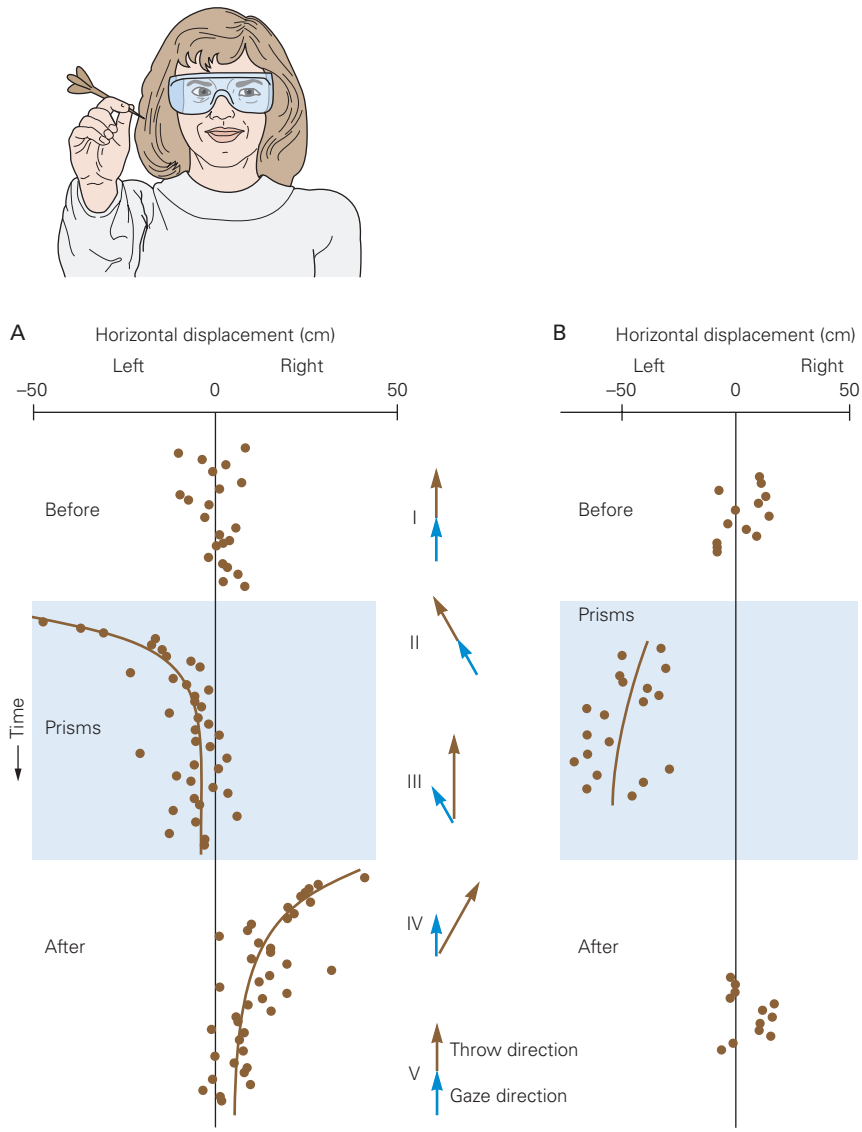

Figure 37–12 Adjustment of eye–hand coordination to a change in optical conditions. The subject wears prism goggles that bend the optic path to her right. She must look to her left along the bent light path to see the target directly ahead. (Adapted, with permission, from Martin et al. 1996).

A. Without prisms, the subject throws with good accuracy (**I**). The first hit after the prisms have been put in place is displaced left of center because the hand throws where the eyes are directed. Thereafter, hits trend rightward toward the target, away from where the eyes are looking (**II**). After removal of the prisms, the subject fixes her gaze in the center of the target; the first throw hits to the right of center, away from where the eyes are directed. Thereafter, hits trend toward the target (**III**). Immediately after removing the prisms, the subject directs her gaze toward the target; her adapted throw is to the right of the direction of gaze and to the right of the target (**IV**). After recovery from adaptation, she again looks at and throws toward the target (**V**). Data during and after prism use have been fit with exponential curves. Gaze and throw directions are indicated by the **blue** and **brown arrows**, respectively, on the *right*. The inferred gaze direction assumes that the subject is fixating the target.

B. Adaptation fails in a patient with unilateral infarctions in the territory of the posterior inferior cerebellar artery that affect the inferior cerebellar peduncle and inferior lateral posterior cerebellar cortex.

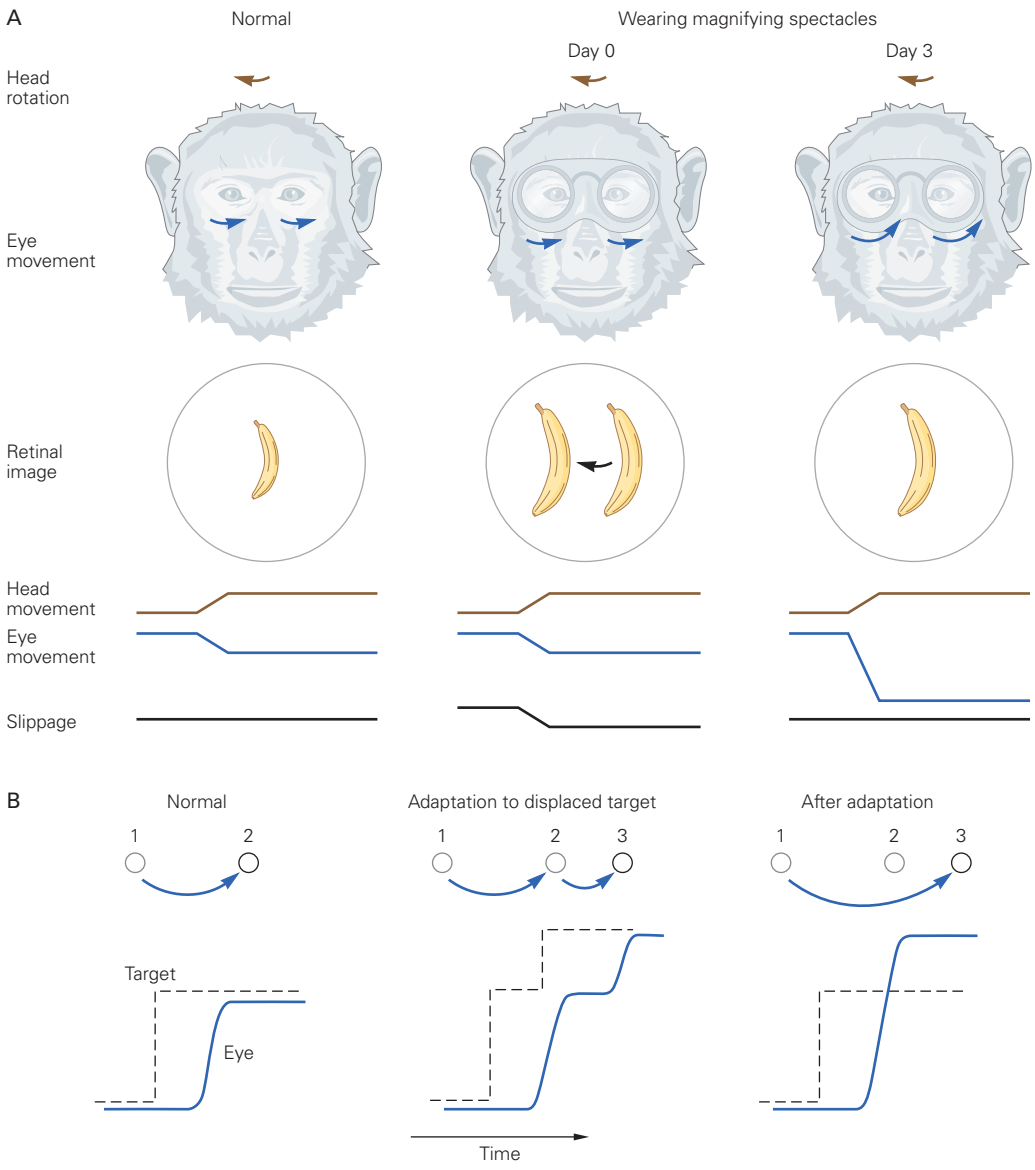

Figure 37–13 Cerebellar learning in the vestibulo-ocular reflex and in saccadic eye movements.

A. Motor learning in the vestibulo-ocular reflex of a monkey wearing magnifying spectacles. The columns show normal conditions before learning, the situation when the monkey first dons the spectacles (day 0), and after complete adaptation (day 3). Eye movements are normally equal and opposite to head turns, and the banana stays stable in the retina during head turns. With the spectacles on, the banana appears larger; when the head turns, the vestibulo-ocular reflex is too small and the banana's image slips across the retina. After adaptation, the eye movements are large enough that the image of the banana again remains stable on the retina during head turns. (Adapted, with permission, from Lisberger 1988.)

B. Motor learning in saccadic eye movements. The columns show saccades under normal conditions, on the first adaptation trial, and after full adaptation. Normally, the saccade responds to a change in target position by bringing the eye almost perfectly to the new target position. During adaptation, the target moves to a new position during the initial saccade, requiring a second saccade to bring the eye to the new, final target position. After adaptation, the original target position evokes a larger saccade that is appropriate to bring the eye to the new target position, even though the target does not move.

is very similar for smooth-pursuit eye movements, except that the relevant part of the cerebellum is the floccular complex, using the same Purkinje cells that participate in adaptation of the vestibulo-ocular reflex.

Finally, learning of new walking patterns has been studied in cerebellar patients using a split-belt treadmill that requires one leg to move faster than the other. Cerebellar damage does not impair the ability to use feedback to immediately change the walking pattern when the two belt speeds differ: Patients can lengthen the time that they stand on the slower treadmill belt and shorten the time that they stand on the faster treadmill belt. However, cerebellar patients cannot learn over hundreds of steps to make their walking pattern symmetric, whereas healthy individuals can (see Figure 30–14).

Learning Occurs at Several Sites in the Cerebellum

We know now that there are many sites of synaptic and cellular plasticity in the cerebellar microcircuit. Almost every synapse that has been studied undergoes either potentiation or depression, and the theory of cerebellar learning has been broadened accordingly. Detailed analyses of the role of cerebellar circuits in motor learning have been conducted in several motor systems: adaptation of multiple kinds of eye movements, classical conditioning of the eye blink, and motor learning in arm movements.

In today's broadened theory of cerebellar learning, learning occurs not only in the cerebellar cortex, as postulated by Marr, Albus, and Ito, but also in the deep cerebellar nuclei (Figure 37–14). Our understanding of learning in the cerebellar cortex is based partly on long-term depression of the synapses from parallel fibers to Purkinje cells, but many other synapses are characterized by plasticity, and they also probably participate. Available evidence is still compatible with the long-standing idea that inputs from climbing fibers provide the primary instructive signals that lead to changes in synaptic strength within the cerebellar cortex, but now there is room for the possibility of other instructive signals as well. Learning probably results from coordinated synaptic plasticity at multiple sites rather than from changes at a single site.

Studies of classical conditioning of the eye blink and adaptation of the vestibulo-ocular reflex provide strong evidence that learning occurs in both the cerebellar cortex and the deep cerebellar nuclei. Further, considerable evidence suggests that learning may occur first in the cerebellar cortex and then be transferred to the deep cerebellar nuclei. At least for eye blink conditioning, the cerebellar cortex may play a special role in learning timing.

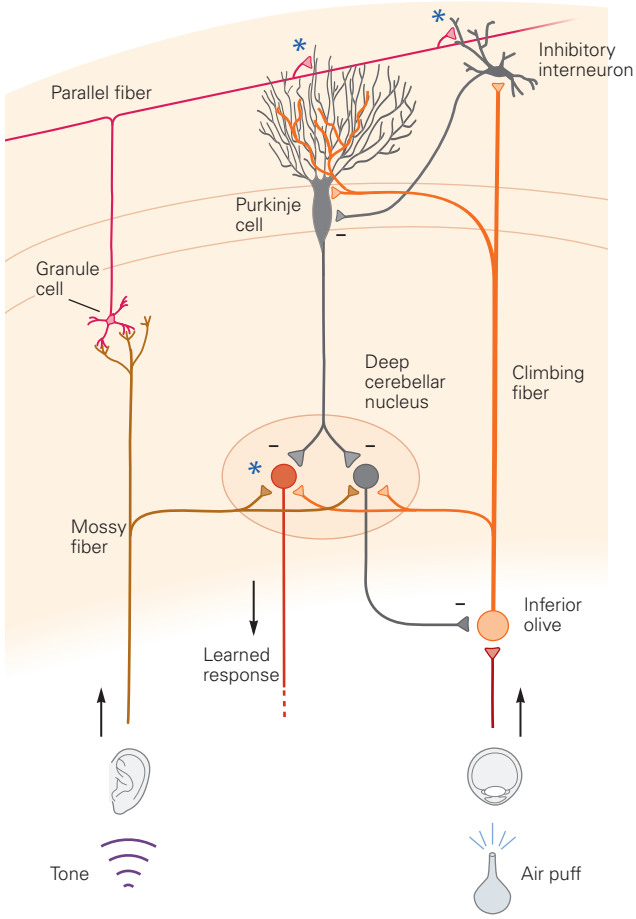

Figure 37–14 Learning in the cerebellar microcircuit can occur in the cerebellar cortex and the deep cerebellar nuclei. The diagram is based on classical conditioning of blinking, which is driven by pairing a tone (so-called conditioned stimulus carried by mossy fibers) and an air puff (the unconditioned stimulus carried by climbing fibers). Learning occurs at the parallel fiber–Purkinje cell synapses when the climbing fiber and parallel fibers are active together. Learning also occurs at the mossy-fiber synapse onto the deep cerebellar nuclei. (Sites of learning are denoted by **asterisks**.) While this example diagrams a classical conditioning paradigm, plasticity occurs at the same sites during adaptation of the vestibulo-ocular reflex when head turns are associated with image motion on the retina (Chapter 27). (Adapted, with permission, from Carey and Lisberger 2002.)

As discussed earlier, the cerebellum makes use of internal models to ensure smooth and accurate movement in advance of any guidance by sensory feedback. Synaptic changes that lead to circuit learning could be the mechanisms that create and maintain accurate internal models. One important function of learning in the cerebellum may be the continuous tuning of

internal models. Cerebellar internal models may use sensory feedback to adjust synaptic and cellular function so that motor commands produce movements that are rapid, accurate, and smooth. Thus, the cerebellum appears to be the learning machine envisioned by the earliest investigators, but its learning capabilities may be greater and more widely dispersed than originally imagined and may affect all cerebellar contributions to behavior.

Highlights

1. The cerebellum plays a critical role in movement. Damage to the cerebellum leads to profound movement incoordination called ataxia, which affects all movements ranging from eye and limb movements to balance and walking. Cerebellar damage also leads to some sensory deficits but only during active movement.
2. The cerebellum also plays a role in cognitive and emotional behavior. Deficits in these domains are less immediately obvious after cerebellar damage but appear with formalized testing. There is probably a common mechanism for deficits across both motor and nonmotor domains, but the mechanism is not yet understood.
3. The cerebellum acts through its connections to other brain structures. Its inputs come indirectly from wide regions of the cerebral cortex, as well as from the brainstem and spinal cord. Cerebellar outputs project to the vestibular nuclei, the brainstem reticular formation, and the red nucleus and via the thalamus to wide regions of the cerebral cortex.
4. Reciprocal connections between the cerebellum and the cerebral cortex include sensory and motor cortices as well as wide regions of the parietal and prefrontal cortices. Cerebrocerebellar connections are organized as a series of parallel, closed, recurrent loops, where a given region of the cerebral cortex makes both efferent and afferent connections with a given part of the cerebellum.
5. The circuit of the cerebellar cortex is highly stereotyped, suggesting a common computational mechanism for its interactions with other brain regions. It includes an input granular layer where mossy fibers synapse on granule cells and Golgi cells provide inhibitory feedback; an inhibitory Purkinje cell layer, with the sole output neurons of the cerebellar cortex; and a molecular layer where Purkinje cell dendrites and inhibitory interneurons receive inputs from the parallel fibers that emerge from the axons of granule cells.
6. The climbing-fiber and mossy-fiber inputs to the cerebellum are very different anatomically. Each Purkinje cell receives many synaptic contacts from a single climbing fiber but can be influenced via granule cells by a huge number of mossy fibers. Climbing fibers fire at very low frequencies and cause unitary "complex spikes" in Purkinje cells. Mossy fibers cause "simple spikes" that can discharge at very high rates. It is thought that the interplay between these inputs is essential for learning.
7. Theories of cerebellar motor control emphasize several general principles. The cerebellum is important for generating reliable feedforward action before there has been time for useful sensory feedback to occur. It plays a key role in the internal control of timing. The cerebellum relies on computations that combine sensory inputs with corollary discharge reporting the movement that was commanded. Internal models of the motor effector organs and the world allow the cerebellum to estimate the state of the motor system and guide accurate feedforward actions.
8. Learning and adaptation of movement are fundamental functions of the cerebellum. Cerebellar learning requires feedback about movement errors and updates movement on a trial-by-trial basis. There are many sites of synaptic plasticity in the cerebellum, and current evidence for motor learning systems supports at least two sites of learning in the cerebellum. One site involves long-term depression of the synapses from parallel fibers to Purkinje cells, guided by errors signaled by climbing-fiber inputs. The other site is in the deep cerebellar nuclei. It is likely that the same learning mechanism is used for cognitive and emotional processing.

The Basal Ganglia

Highlights

The traditional view that the basal ganglia play a role in movement arises primarily because diseases of the basal ganglia, such as Parkinson and Huntington disease, are associated with prominent disturbances of movement, and from the belief that basal ganglia neurons send their output exclusively to the motor cortex by way of the thalamus. However, we now know that the basal ganglia also project to wide areas of the brain stem and via the thalamus to nonmotor areas of the cerebral cortex and limbic system, thereby providing a mechanism whereby they contribute to a wide variety of cognitive, motivational, and affective operations. This understanding also explains why diseases of the basal ganglia are frequently associated with complex cognitive, motivational, and affective dysfunction in addition to the better-known motor disturbances.

This chapter provides a perspective on the fundamental contributions of the basal ganglia (Figure 38–1) to overall brain function. Recent advances in the fields of artificial neural networks and robotics emphasize that behavioral function is an emergent property of signal processing in physically connected networks (Chapter 5). Thus, how components of networks are connected and how their input signals are transformed into output signals impose important constraints on final behavioral outputs. We first describe the principal anatomical and physiological features of the basal ganglia network and consider the constraints these might impose on their function. We consider the extent to which the basal ganglia have been conserved during vertebrate brain evolution and, based on these insights, review evidence suggesting that the basal ganglia's normal functions are to select between incompatible behaviors and to mediate reinforcement learning. We conclude by examining important insights into how the system can malfunction in some of the major diseases involving the basal ganglia.

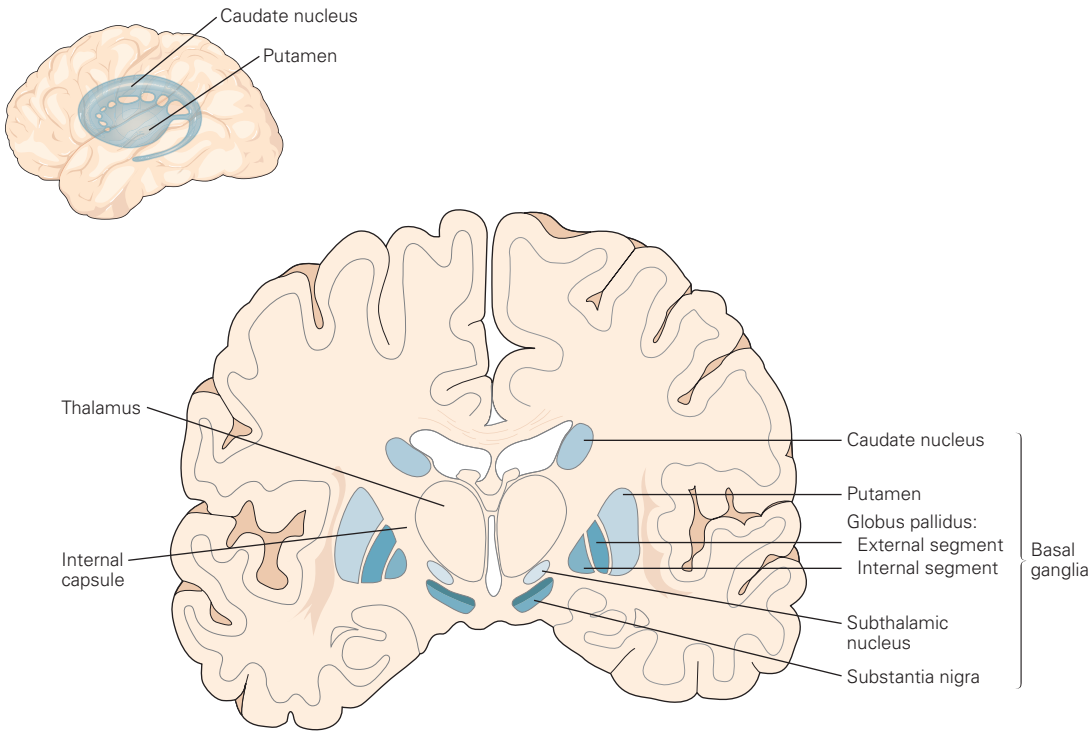

Figure 38–1 The basal ganglia and surrounding structures. The nuclei of the basal ganglia are identified on the right in this coronal section of a human brain. (Adapted from Nieuwenhuys, Voogd, and van Huijzen 1981.)

The Basal Ganglia Network Consists of Three Principal Input Nuclei, Two Main Output Nuclei, and One Intrinsic Nucleus

The striatum (a collective term for the caudate nucleus and putamen; see Figure 38–1), subthalamic nucleus, and substantia nigra pars compacta/ventral tegmental area are the three major input nuclei of the basal ganglia, receiving signals directly and indirectly from structures distributed throughout the neuraxis (Figure 38–2).

The Striatum, Subthalamic Nucleus, and Substantia Nigra Pars Compacta/Ventral Tegmental Area Are the Three Principal Input Nuclei of the Basal Ganglia

The striatum is the largest nucleus of the basal ganglia. It receives direct input from most regions of the cerebral cortex and limbic structures, including the amygdala and hippocampus. Important input from sensorimotor and motivational regions of the brain stem is relayed indirectly via the thalamus. In rodents, the number of contacts received in the striatum from the cerebral cortex and thalamus are approximately equivalent. Finally, important modulatory input to the striatum comes from the substantia nigra pars compacta (dopamine), midbrain raphe (serotonin), and pedunculopontine nucleus (acetylcholine).

The striatum is subdivided functionally on the basis of the organization of input connections, principally the topographically organized afferents from the cerebral cortex. Limbic, associative, and sensorimotor territories are generally recognized along a ventromedial-dorsolateral continuum. This diversity of input shows that the basal ganglia receive signals from brain regions involved in different motivational, emotional, cognitive, and sensorimotor processes, implying that whatever the basal ganglia are doing, they are doing it for a wide range of brain processes.

An additional architectural feature of the striatum suggests that the basal ganglia are performing more or less the same operations on their inputs from functionally diverse afferent structures. Specifically, within each of the striatum's functional territories, the cellular architecture is remarkably similar. In all regions, inhibitory γ-aminobutyric acid (GABA)-ergic medium spiny neurons are the principal cell type (>90% of all neurons). In addition, in all functionally defined regions, the medium spiny neurons are separated into two populations according to the relative expression of neuroactive peptides (substance P and dynorphin versus enkephalin) or the expression of D_1 and D_2 dopamine receptors, which are thought to positively and negatively modulate cyclic adenosine monophosphate signaling in these neurons. These populations contribute differentially to different efferent projections of the striatum. In addition to these long-range inhibitory connections to other basal ganglia nuclei, medium spiny neurons also send local collaterals to adjacent cells. Colocalized GABAergic and peptidergic neurotransmission provides local mutually inhibitory and excitatory influences. The remaining 5% to 10% of neurons in the striatum are purely GABAergic and cholinergic interneurons, which can be distinguished according to neurochemical, electrophysiological, and in some cases morphological characteristics. The fact that this local cellular architecture is present in all functional regions suggests that neurons in the striatum are applying the same or similar computations on functionally diverse afferent pathways.

The subthalamic nucleus has traditionally been considered an important internal relay in the "indirect output pathway" from the striatum to the basal ganglia output nuclei (see below). It is now also recognized as a second important input nucleus of the basal

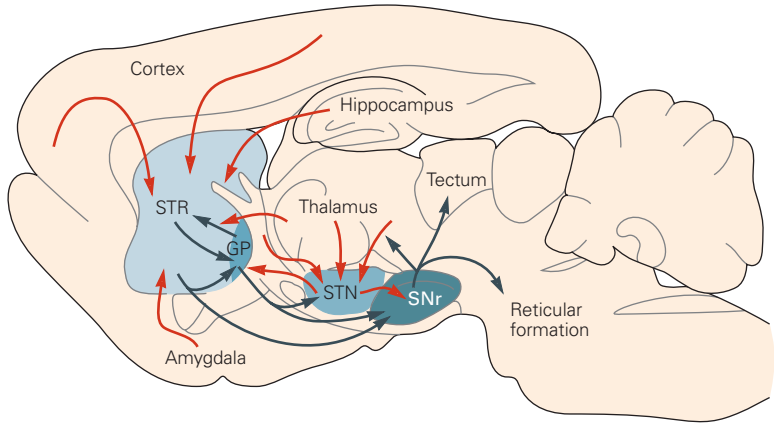

Figure 38–2 The principal input, intrinsic, and output connections of the mammalian basal ganglia. The main input nuclei are the striatum (**STR**), subthalamic nucleus (**STN**), and substantia nigra pars compacta (not shown). They receive input directly from the thalamus, cerebral cortex, and limbic structures (amygdala and hippocampus). The main output nuclei are the substantia nigra pars reticulata (**SNr**) and internal globus pallidus/entopeduncular nucleus (not shown). The external globus pallidus (**GP**) is classified as an intrinsic nucleus as most of its connections are with other basal ganglia nuclei. Structures are shown on a sagittal schematic of the rodent brain. **Red** and **dark gray arrows** denote excitatory and inhibitory connections, respectively.

ganglia. Topographically organized inputs derive not only from large parts of frontal cortex, but also from various thalamic and brain stem structures. The subthalamic nucleus is the only component of the basal ganglia that has excitatory (glutamatergic) output connections. These project to both output nuclei and to the intrinsic external globus pallidus.

The substantia nigra pars compacta/ventral tegmental area contain an important population of dopaminergic neurons. These neurons represent the third major input station of the basal ganglia and give rise to the nigrostriatal and mesolimbic/mesocortical dopamine projections. They receive significant afferent connections from other basal ganglia nuclei (the striatum, globus pallidus, and subthalamus), but also from many structures in the brain stem (eg, superior colliculus, rostromedial tegmental region, raphe nuclei, pedunculopontine nucleus, and parabrachial area). Other afferent connections are from the frontal cortex and the amygdala. This pattern of connectivity is important because it suggests the most important direct influence over the dopaminergic neurons arises from evolutionarily ancient parts of the brain (see below).

Individual dopaminergic neurons have highly branching axons that project into extensive regions of not only the other basal ganglia nuclei but also external structures (eg, frontal cortex, septal area, amygdala, habenula). This suggests that their important modulatory signals are widely broadcast throughout targeted structures. The highest concentration of dopaminergic terminals is found in the striatum, where synaptic and nonsynaptic contacts are formed with both medium spiny cells and interneurons. The existence of nonsynaptic contacts gives rise to what has been called *volume transmission*. This occurs when neurotransmitters diffuse through the brain's extracellular fluid from release points that may be remote from targeted cells. Consequently, volume transmission typically has a longer time course than synaptic neurotransmission. Deployment of volume transmission in targeted structures is further evidence for the idea that the effects of dopamine in targeted structures are widely broadcast and spatially imprecise. Variable proportions of GABAergic neurons (substantia nigra and the ventral tegmental area) and glutamatergic neurons (ventral tegmental area) contribute to local processing in these structures.

The Substantia Nigra Pars Reticulata and the Internal Globus Pallidus Are the Two Principal Output Nuclei of the Basal Ganglia

The internal globus pallidus/entopeduncular nucleus is one of the two principal output nuclei. It receives inputs from other basal ganglia nuclei and projects to external targets in the thalamus and brain stem. GABAergic input from the striatum and external globus pallidus are inhibitory, while input from the subthalamic nucleus is glutamatergic and excitatory. Neurons of the internal globus pallidus are themselves GABAergic and have high levels of tonic activity. Under normal circumstances, this imposes powerful inhibitory effects on targets in the thalamus, lateral habenula, and brain stem.

The substantia nigra pars reticulata is the second principal output nucleus. It also receives afferents from other basal ganglia nuclei and provides efferent connections to the thalamus and brain stem. Inhibitory (GABAergic) inputs come from the striatum and globus pallidus (external) and excitatory input from the subthalamus. Pars reticulata neurons are also GABAergic and impose strong inhibitory control over parts of the thalamus and brain stem, including the superior colliculus, pedunculopontine nucleus, and parts of the midbrain and medullary reticular formation.

The External Globus Pallidus Is Mostly an Intrinsic Structure of the Basal Ganglia

Most connections of the globus pallidus are with other basal ganglia nuclei, including inhibitory (GABAergic) input from the striatum and excitatory (glutamatergic) input from the subthalamus, and the globus pallidus provides inhibitory efferent connections to all the basal ganglia's input and output nuclei. This pattern of connections suggests that that the external globus pallidus is an essential regulator of internal basal ganglia activity.

Having described the core components of the basal ganglia, we will now consider in more detail how they are connected, first with each other and then with external structures in the brain.

The Internal Circuitry of the Basal Ganglia Regulates How the Components Interact

The Traditional Model of the Basal Ganglia Emphasizes Direct and Indirect Pathways

An influential interpretation of the intrinsic circuitry of the basal ganglia was proposed in the late 1980s by Roger Albin and colleagues (Figure 38–3A). In their scheme, signals originating in the cerebral cortex are distributed to two populations of medium spiny output neurons in the striatum.

Neurons containing substance P and a preponderance of D_1 dopamine receptors make direct inhibitory

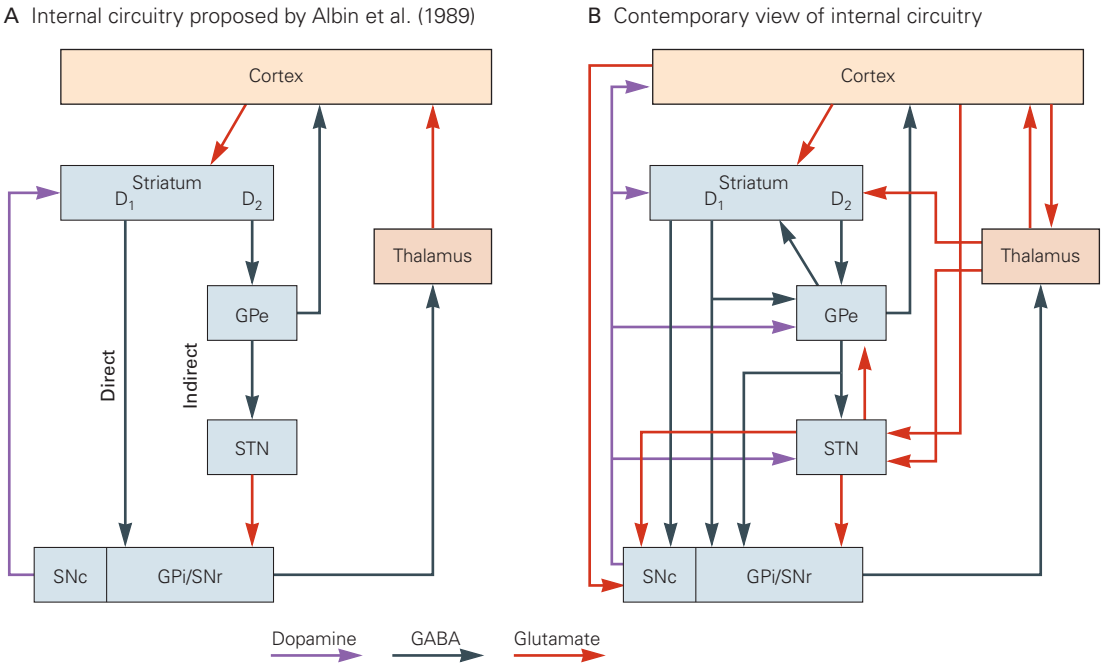

Figure 38–3 Intrinsic connections within the basal ganglia.

A. The influential proposal by Roger Albin and colleagues (1989) is presented, where output of the basal ganglia is determined by the balance between a *direct pathway* from the striatum to the output nuclei (internal globus pallidus [**Gpi**] and substantial nigra pars reticulata [**SNr**]), which promotes behavior, and an *indirect pathway* from the striatum to the output nuclei via relays in the external globus pallidus (**GPe**) and subthalamic nucleus (**STN**), which suppresses behavior. The balance between the direct and indirect projections was thought to be regulated by afferent dopaminergic signals from substantia nigra pars compacta (**SNc**) acting on differentially distributed D_1 and D_2 dopamine receptors.

B. More recent anatomical investigations have revealed a rather more complex organization where the transformations of basal ganglia inputs that generate outputs are less easy to predict.

contact with the basal ganglia output nuclei—the direct pathway. In contrast, striatal neurons containing enkephalin and expressing mainly D_2 dopamine receptors make excitatory contact with the output nuclei via relays in the globus pallidus and subthalamus—the indirect pathway. Basal ganglia output was thought to reflect a cortically determined balance between these inhibitory and excitatory projections terminating on the two output structures (the internal globus pallidus and substantia nigra pars reticulata). In this model, a behavior would be promoted when the direct pathway was dominant and inhibited when the indirect pathway was dominant.

Detailed Anatomical Analyses Reveal a More Complex Organization

Recent anatomical observations show that the internal circuitry of the basal ganglia is more complex than originally envisaged (Figure 38–3B). The main findings have been that: (1) medium spiny neurons of the direct pathway also provide collateral input to the globus pallidus; (2) globus pallidus neurons also make direct contact with the output nuclei in addition to the traditional indirect connections to the subthalamus—often with branching collaterals to all three structures; (3) the globus pallidus also projects back to the striatum and to structures outside the basal ganglia; (4) the subthalamic nucleus also projects back to the external globus pallidus, in addition to the feedforward connections to the two basal ganglia output nuclei; and (5) major inputs to the subthalamic nucleus originate from both cortical and subcortical structures external to the basal ganglia. Consequently, the subthalamus is now considered a major input structure of the basal ganglia (see above), rather than a simple relay in the intrinsic indirect projection. A modern appreciation of this complex organization within the basal ganglia suggests it is no longer possible to intuit how a particular input might be transformed by the basal ganglia to generate a specific output. For this reason, computational modeling of the internal circuitry of the basal ganglia has become increasingly important.

Although the overall pattern of intrinsic circuitry is complex (Figure 38–3B), connections between components of the basal ganglia are topographically ordered

throughout. Some of these projections are comparatively focused (eg, the striatonigral projection), while others are more diffuse (eg, the subthalamonigral projection). Significant reductions in the comparative numbers of neurons in afferent structures, the striatum, and the output nuclei suggest a dramatic compression of information as it is processed within the basal ganglia.

Basal Ganglia Connections With External Structures Are Characterized by Reentrant Loops

Inputs Define Functional Territories in the Basal Ganglia

The functional status of inputs to the striatum from the cerebral cortex, limbic structures, and thalamus provides the rationale for classifying functional territories within the basal ganglia nuclei (limbic, associative, and sensorimotor). However, the manner in which the afferent projections make contact with neurons of the basal ganglia nuclei suggests important functional differences. For example, axons arriving in the striatum from the cerebral cortex and central lateral thalamic nucleus appear to make few contacts with many striatal neurons. In contrast, inputs from other regions, principally the parafascicular thalamic nucleus, have axons that make many contacts with fewer individual striatal neurons. Afferent connections to the subthalamic nucleus, at least from cerebral cortex, are also topographically organized according to the limbic, associative, and sensorimotor classification. However, there is no evidence of the same kind of precise topographical input from external structures to SNc and VTA dopamine neurons in the ventral midbrain.

Output Neurons Project to the External Structures That Provide Input

Basal ganglia output neurons project to regions of the thalamus (the intralaminar and ventromedial nuclei) that project back to basal ganglia input nuclei as well as to those regions of cortex that provided the original inputs to the striatum. Similarly, outputs from the basal ganglia to the brain stem tend to target those regions that provide input to the striatum via the thalamic midline and intralaminar nuclei. Importantly, projections from the basal ganglia output nuclei to the thalamus and brain stem are also topographically ordered.

Finally, many output projections of the basal ganglia are extensively collateralized, thereby simultaneously contacting targets in the thalamus, midbrain, and hindbrain. An example of the functional consequences of this organization is that a subset of neurons in the substantia nigra pars reticulata associated with oral behavior can simultaneously influence the activity in the specific regions of the thalamus/cortex, midbrain, and hindbrain that interact during the production of oral behavior.

Reentrant Loops Are a Cardinal Principle of Basal Ganglia Circuitry

Spatial topographies associated with input projections, intrinsic connections, and outputs of the basal ganglia provided the basis for the influential organizational principle suggested by Garrett Alexander and colleagues in 1989. Connections between the cerebral cortex and basal ganglia can be viewed as a series of reentrant parallel projecting, partly segregated, cortico-striato-nigro-thalamo-cortical loops or channels (Figure 38–4). Thus, an important component of the projections from different functional areas of cerebral cortex (eg, limbic, associative, sensorimotor) makes exclusive contact with specific regions of the basal ganglia input nuclei. This regional separation is maintained in forward projections throughout the internal circuitry. Focused output signals from functional territories represented in the basal ganglia output nuclei are returned, via appropriate thalamic relays, to the cortical regions providing the original input signals.

The concept of parallel projecting reentrant loops through the basal ganglia has been extended to their connections with sensorimotor and motivational structures in the brain stem, including the superior colliculus, periaqueductal gray, pedunculopontine, and parabrachial nuclei. This implies that the reentrant loop architecture through the basal ganglia must have predated the evolutionary expansion of the cerebral cortex. An important difference is that for the cortical loops the thalamic relay is on the output side of the loop, whereas for the subcortical loops, the thalamic relay is on the input side (Figure 38–5). Further work will be required to test whether projections from different brain stem structures, as they pass through the thalamic and basal ganglia relays, are functionally distinct channels.

In summary, the partially segregated reentrant loop organization is one of the dominant features characterizing the connections between the basal ganglia and external structures. This pattern of connections provides important clues as to the role played by the basal ganglia nuclei in overall brain function. However, at

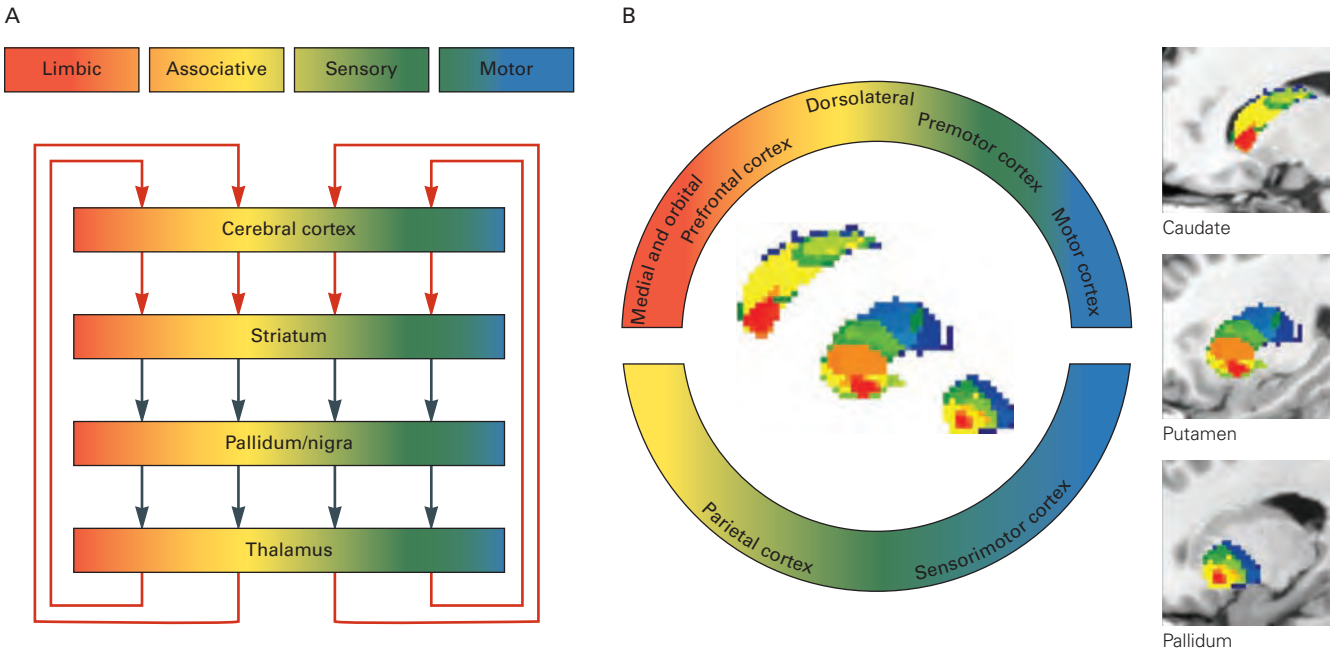

Figure 38–4 Connections between the basal ganglia and cerebral cortex.

A. The connections between the cerebral cortex and basal ganglia can be viewed as a series of parallel projecting, largely segregated loops or channels. Functional territories represented at the level of cerebral cortex are maintained throughout the basal ganglia nuclei and thalamic relays. However, for each loop, the relay points in the cortex, basal ganglia, and thalamus offer opportunities for activity inside the loop to be modified by signals from outside the loop. **Red** and **dark gray arrows** represent excitatory and inhibitory connections, respectively.

B. Spatially segregated rostral-caudal gradient of human frontal cortical connectivity in caudate, putamen, and pallidum. The color-coded ring denotes regions of cerebral cortex in the sagittal plane. (Reproduced, with permission, from Draganski et al. 2008. Copyright © 2008 Society for Neuroscience.)

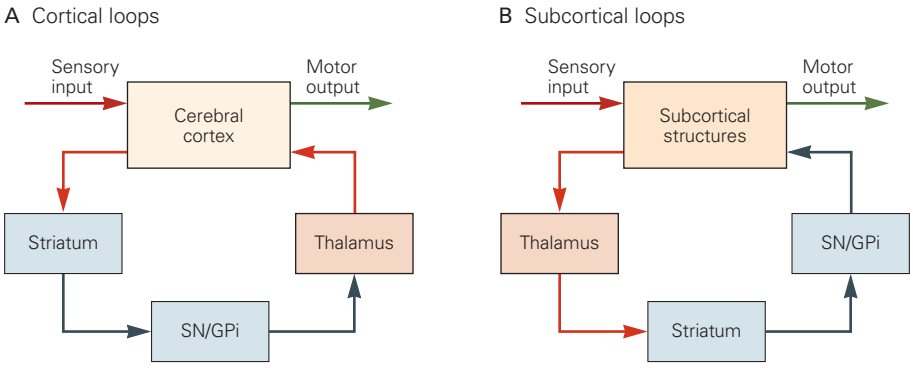

Figure 38–5 Cortical and subcortical sensorimotor loops through the basal ganglia.

A. For cortical loops, the position of the thalamic relay is on the return arm of the loop.

B. In the case of all subcortical loops, the position of the thalamic relay is on the input side of the loop. **Red** indicates predominantly excitatory regions and connections, while **dark gray** indicates inhibitory regions and connections. (Abbreviations: **SN/GPi**, substantia nigra/globus pallidus; **Thal**, thalamus.)

this point, it is important not to think of the reentrant loop architecture as comprising a series of independent and isolated functional channels. At each node or relay point in the loop (eg, in the cortex, the input nuclei, the output nuclei, and the thalamus), there is the opportunity for information flow within the loop to be modified by information from outside the loop (see the section on reinforcement learning below).

At the beginning of this chapter, we stated that behavior is an emergent property of signal processing within a neural network. Having specified the systems-level network of the basal ganglia, we now consider the signals that are being processed within this system.

Physiological Signals Provide Further Clues to Function in the Basal Ganglia

The Striatum and Subthalamic Nucleus Receive Signals Mainly from the Cerebral Cortex, Thalamus, and Ventral Midbrain

Signals received by the striatum from the cerebral cortex and thalamus are conveyed by excitatory glutamatergic neurotransmission. These fast, phasically active excitatory inputs are mediated predominantly by α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) and kainate receptors when the medium spiny neurons are near resting potential; *N*-methyl-D-aspartate (NMDA) receptors play a greater role when the neurons are depolarized. Glutamatergic inputs from both cerebral cortex and thalamus also impinge on striatal interneurons.

It is important to appreciate that these signals come from external structures that are simultaneously generating a wide range of behavioral options. Since these options could not all be expressed at the same time, these inputs to the basal ganglia are thought to be in competition with each other. Another important signal to the striatum is an efference copy of the output activity from the external structures that generate behavioral responses. For example, the sensorimotor territories of the dorsolateral striatum receive collateral fibers from motor cortex axons that send signals to the spinal cord.

The effects of dopaminergic inputs from the ventral midbrain on striatal neuronal activity are complicated, with many conflicting results. In part, this is due to the problem of evoking normal patterns of input activity in slice and anaesthetized preparations. However, recent developments in optogenetic technology in alert, active animals have enabled investigators both to record and manipulate dopamine signals to the striatum in a temporally controlled manner. Consequently, current evidence suggests dopamine can increase signal-to-noise ratios in the striatum, enhancing the effects of strong external inputs while suppressing weak ones. There is further evidence that dopamine can increase the excitability of medium spiny neurons in the direct pathways while at the same time decreasing the excitability of those in the indirect pathway.

Finally, dopamine input is necessary for both long-term potentiation and long-term depression of glutamatergic inputs to striatal medium spiny neurons from both cortex and thalamus. This latter point is of great significance for the role played by the basal ganglia in reinforcement learning (see below). Dopamine can also influence the activity of GABAergic and cholinergic interneurons. Although anatomically significant, much less is known about the role(s) of serotoninergic inputs to the basal ganglia.

The main external sources of input to the striatum also provide parallel inputs to the subthalamic nucleus. The subthalamus therefore receives phasic excitatory (glutamatergic) signals from the cerebral cortex, thalamus, and brain stem. Following cortical activation, short-latency excitatory effects in the subthalamus are thought to be mediated via these "hyperdirect" connections, whereas longer-latency suppressive effects are more likely to come from indirect inhibitory inputs from other basal ganglia nuclei, principally the external globus pallidus. The subthalamus receives short-latency excitatory sensory input from the brain stem (eg, the superior colliculus); it is also influenced by dopaminergic, serotonergic, and cholinergic modulatory inputs.

Ventral Midbrain Dopamine Neurons Receive Input From External Structures and Other Basal Ganglia Nuclei

Afferent signals to the dopaminergic neurons in the ventral midbrain come from a wide variety of autonomic, sensory, and motor areas and operate over a range of time scales. For example, laterally located neurons in the substantia nigra receive short-latency excitatory inputs from cortical and subcortical sensorimotor regions, while more medially positioned neurons receive both short-latency sensory signals and autonomic-related inputs from the hypothalamus over longer time scales.

Important inhibitory control over dopaminergic neurons is exercised by GABAergic neurons, both local and distant from areas like the rostromedial tegmentum. However, the densest inputs to the dopaminergic neurons are inhibitory inputs from the striatum and

globus pallidus and excitatory signals from the subthalamic nucleus. The midbrain raphe nuclei provide important modulatory serotonergic input, while both the pedunculopontine nucleus and lateral dorsal tegmental nucleus provide cholinergic and glutamatergic inputs. An important functional question concerning the wide range of afferent signals to dopaminergic neurons is whether dopamine performs a highly integrative role or performs an essential function that is accessed by numerous different systems at different times.

Disinhibition Is the Final Expression of Basal Ganglia Output

The basal ganglia exercise influence over external structures by the fundamental processes of inhibition and disinhibition (Figure 38–6). GABAergic neurons in the basal ganglia output nuclei typically have high tonic firing rates (40–80 Hz). This activity ensures that target regions of the thalamus and brain stem are maintained under a tight and constant inhibitory control.

Focused excitatory inputs from external structures to the striatum can impose focused suppression (mediated via direct pathway GABAergic inhibitory connections) on subpopulations of output nuclei neurons. This focused reduction of inhibitory output effectively releases or disinhibits targeted regions in the thalamus (eg, ventromedial nucleus) and brain stem (eg, superior colliculus) from normal inhibitory control. This sudden release from tonic inhibition allows activity in the targeted region to influence behavioral output, which in the case of the midbrain superior colliculus is to elicit saccadic eye movements.

The patterns of signaling within the basal ganglia architecture provide important insights into what the overall functional properties of these networks might be (see below). Further constraints on the likely core functions of the basal ganglia also become apparent when considering the evolutionary history of the vertebrate brain.

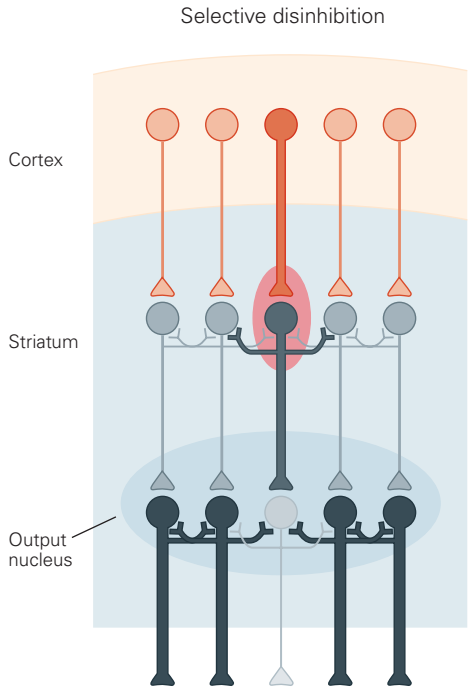

Figure 38–6 The diagram illustrates the principle of selection operating at the level of the basal ganglia output nuclei. Throughout the figure, the relative levels of activity within the competing channels are represented by the thickness of projections, and for clarity, the indirect pathway and the return connections of the loops via the thalamus have been omitted. One of the competing inputs to the striatum (the middle one) is more active than its competitors. Relative activities in the direct inhibitory pathways (shown here) differentially suppress activity in the different channels within the output nuclei. Because output nuclei neurons are also inhibitory and tonically active, the selected channel will be the one with the strongest inhibitory input from the striatum. Tonic inhibitory output is maintained on the nonselected channels. This selective disinhibitory mechanism operating at the level of the output nuclei means that selection will be an emergent property of the entire reentrant network. Disinhibition of selected external targets will allow them to direct movement, while nonselected targets remain inhibited and unable to influence behavior. **Red**, excitatory; **gray**, inhibitory.

Throughout Vertebrate Evolution, the Basal Ganglia Have Been Highly Conserved

Detailed comparisons between the mammalian basal ganglia and those found in phylogenetically ancient vertebrates (eg, the lamprey) have found striking similarities in their individual components, internal organization, inputs from external structures (the cortex/pallium and thalamus), and the efferent projections of their output nuclei. For example, both direct and indirect pathways from striatal medium spiny neurons have been observed in the lamprey. Similarly, tonically active GABAergic output neurons are present in the lamprey internal globus pallidus and substantia nigra pars reticulata. The neurotransmitters and membrane properties of basal ganglia neurons are also remarkably similar in evolutionarily ancient and modern species.

This high degree of morphological and neurochemical conservation implies that the architecture and operation of basal ganglia circuits have been retained for more than 500 million years. The basal ganglia are therefore an essential component of brain architecture

that is shared by all vertebrate species. Bearing in mind that a function emerges from specific patterns of signals being processed in specific neural networks, the conservation of basal ganglia architecture across vertebrate species places an additional important constraint on their overall function. Whatever computational problems the basal ganglia evolved to solve in evolutionarily ancient species, the same problems are likely to have remained unchanged and to confront all vertebrate species, including humans.

Thus far, we have identified features of basal ganglia morphology, connectional architecture, signal processing, and evolution that provide potential insights as to the role of the basal ganglia in overall brain function. Thus, proposed functions must be consistent with the predominant looped architecture that connects external structures with the basal ganglia and with an internal circuitry that is shared across the limbic, associative, and sensorimotor territories of the basal ganglia nuclei, and they must be shared by all vertebrate species. With these constraints in mind, we now consider functional properties that could be supported by the basal ganglia.

Action Selection Is a Recurring Theme in Basal Ganglia Research

Despite numerous suggestions that the basal ganglia are involved in a wide range of functions, including perception, learning, memory, attention, many aspects of motor function, and even analgesia and seizure suppression, evidence is accumulating that these nuclei have an underlying role in a variety of selection processes. Thus, throughout the prodigious literature on the basal ganglia there are recurring references to the involvement of these nuclei in the essential brain functions of action selection and reinforcement learning. In this and the next section we will evaluate the extent to which these core processes are consistent with the functional constraints identified above.

All Vertebrates Face the Challenge of Choosing One Behavior From Several Competing Options

Vertebrates are multifunctional organisms: They have to maintain energy and fluid balances, defend against harm, and engage in reproductive activities. Different areas of the brain operate in parallel to deliver these essential functions but must share limited motor resources. Sherrington's "final common motor path" means it is impossible to talk and drink at the same time. Thus, a fundamental selection problem, continually faced by all vertebrates, is determining which functional system should be allowed to direct behavioral output at any point in time. This is a problem that has not changed materially over the course of 500 million years of evolutionary history. What has changed over this time are the behavioral options that have evolved in different species to implement the core functions of survival and reproduction. Consequently, there has to be a system in the vertebrate brain that can adjudicate between the motivational systems that simultaneously compete for behavioral expression.

A similar selection problem also arises within vertebrate multimodal sensory systems. The visual, auditory, olfactory, and tactile systems are continually faced with multiple external stimuli, each one of which could drive a movement incompatible with one specified by others (eg, orienting/approach, avoidance/escape). It is therefore imperative to select a stimulus that will become the focus of attention and direct movement. The problem is which stimulus should be given access to the motor systems at any one time. Selective attention provides an effective solution to this problem, making it an essential feature of vertebrate brain function.

In summary, despite great evolutionary changes in the range, power, and sophistication of the sensory, motivational, cognitive, and motor systems that compete for behavioral expression in different species, the fundamental computational problems of selection have remained unaltered. And, if the basal ganglia provide a generic solution to the problems of selection, a high degree of structural and functional conservation within vertebrate brain evolution would be expected.

Selection Is Required for Motivational, Affective, Cognitive, and Sensorimotor Processing

In his *Principles of Psychology* (1890), William James observed, "Selection is the very keel on which our mental ship is built." In this statement, he is telling us that the neural systems of motivation, emotion, cognition, perception, and motor performance, at some stage, need to consult a mechanism that can select between parallel processed but incompatible options (Figure 38–7). It is therefore significant that intrinsic circuits in the basal ganglia nuclei are similar across the limbic, associative, and sensorimotor territories.

Such repetition within the basal ganglia circuitry suggests that the same or similar computational processes are applied to inputs from very different functional origins. This duplicated circuitry would therefore be in a position to resolve competitions between high-level motivational goals in the limbic territories;

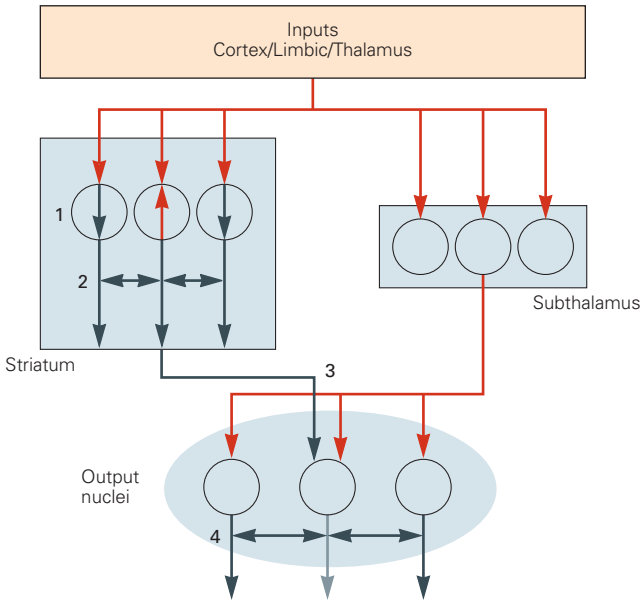

Figure 38–7 Cooperative mechanisms in the basal ganglia that would promote selection.

1. Because cortical and some thalamic inputs make comparatively few contacts with individual striatal neurons, a large population of sufficiently synchronized excitatory inputs is required to depolarize the membrane of a medium spiny neuron to an "up" state sufficient for it to fire action potentials. This mechanism can be seen as an input filter to exclude weak or less biologically significant competitors. The **internal arrows** in striatal neurons denote "up" (**red**) and "down" (**gray**) states.

2. Local GABAergic and peptidergic inhibitory collaterals between striatal spiny neurons and longer-range inhibitory effects of interneurons should cause highly activated striatal elements to suppress activity in adjacent more weakly activated channels.

3. The combination of focused inhibition from the striatum with the more diffuse excitation from the subthalamus would both decrease the activity in selected channels and increase activity in nonselected channels in the basal ganglia output nuclei. The output from just one of the striatal and subthalamic neurons has been illustrated to make this point.

4. Local inhibitory collaterals between output nuclei neurons should further sharpen the difference between inhibited and noninhibited channels.

competitions between incompatible cognitive representations in the central associative territories; and competitions between incompatible sensory and motor options resolved in the lateral sensorimotor regions.

The Neural Architecture of the Basal Ganglia Is Configured to Make Selections

At various times during the past 40 years, and more so recently, it has been argued that the principle function of the basal ganglia is to select between competing and incompatible behavioral options. It has now been recognized that many aspects of the basal ganglia architecture are consistent with this view (Figure 38–6). The parallel loops originating from and returning to diverse cortical and subcortical functional systems can be viewed as the basic substrate for selection.

The phasic excitatory input signals from the cerebral cortex and thalamus to the different functional territories of the striatum can be seen to carry signals representing the behavioral options competing for expression. To ensure that all options could in principle be assessed against all others, there needs to be a "common currency." This term refers to the parameter according to which qualitatively different functional options can be compared for the purpose of selection. This parameter would be represented by the relative magnitudes of input signals to the striatum, thereby providing each competitor with a measure of relative biological importance or salience. In principle, it should be necessary only for the basal ganglia to appreciate which option is most salient in terms of the common currency.

Processing within the parallel projecting internal architecture (Figure 38–6) would ensure that channels associated with the most salient input activity would cause focused inhibition at the level of the output nuclei (the winning options), while at the same time maintaining or increasing the tonic inhibitory activity in output channels returning to regions specifying weaker (losing) options. Experiments that have recorded neural activity in basal ganglia output nuclei in active animals describe populations of task-sensitive neurons whose activity is reduced or paused prior to movement (the winning option). Conversely, there is a separate, often larger population whose high level of tonic activity is further increased or at least maintained (the losing options). The returning signals within the disinhibited channel(s) are necessary to permit the structures providing the strongest motivational, cognitive, or sensorimotor inputs to access the shared motor resources. Importantly, the maintained or increased levels of inhibitory efferent signals within nonselected channels would prevent the output of nonselected target structures from distorting the selected option's input to the motor system. Thus, this model of the basal ganglia works by keeping all potential behavioral options under tight inhibitory control and selectively removing the inhibition from the option proving the most salient input.

A central-selection control architecture, similar to the systems-level architecture of the basal ganglia just described, was used successfully to select actions for

an autonomous mobile robot. Subsequently, it was confirmed that a biologically constrained computer simulation of basal ganglia architecture could do likewise. This work with artificial agents is important because it confirms that selection is indeed an emergent property of systems-level basal ganglia circuitry. The next question is: If the overall architecture can select, are there mechanisms within the basal ganglia that would support or facilitate this function?

Intrinsic Mechanisms in the Basal Ganglia Promote Selection

At each of the major relay points within each of the reentrant loops passing though the basal ganglia (external structures, input nuclei, intrinsic nuclei, output nuclei, and the thalamus), signals flowing within the parallel channels can be subjected to influences originating outside the loop. The selection model outlined above requires features within the internal circuitry of the basal ganglia that permit different channels to interact competitively with each other. Several of these can be identified (Figure 38–7). Together, these mechanisms can be viewed as a cooperative sequence of processes, each of which would facilitate the overall goal of selection. In addition, there is substantial evidence that the relative activity of direct and indirect striatal projection pathways is critical for action selection. The traditional and widely accepted view is that the relative activity in the direct and indirect pathways determines whether or not an animal will perform a particular movement. For example, recent optogenetic stimulation of direct pathway neurons leads to more movement, while optogenetic stimulation of indirect pathway neurons leads to less movement. However, an alternative view for which there is increasing evidence is that simultaneous activity in both pathways is critical for the process of selecting what to do. Here, the idea is that the direct pathway conveys signals representing the most salient options, while the indirect pathway is important for inhibiting the competing weaker options. The latter idea is consistent with the now repeated observations that both projection pathways are concurrently active during movement initiation and that specific patterns of activity in each pathway are associated with different movements.

Selection Function of the Basal Ganglia Questioned

Despite the wide appeal of the selection hypothesis of basal ganglia function, it is by no means universally accepted. Indeed, arguments against it have been voiced based on different studies, the results of which are considered incompatible with the selection model. For example, it has been reported that lesions or suppression of neural activity in motor territories of the internal globus pallidus failed to alter the reaction time between a sensory cue and the triggered movement.

These results could indicate that the basal ganglia are mainly involved in selecting and executing actions that are self-paced, or memory-driven, rather than cue-driven. However, a possibility not considered by these studies is that for well-practiced tasks it is likely that the sensory regions of the basal ganglia will be the most important. This is because such tasks can be performed under stimulus–response habitual control, where selection of the stimulus that triggers the response would be the critical selection. Thus, a failure to disrupt sensory cue selection in such tasks following experimental disruption of the relevant sensory region of basal ganglia would be far stronger evidence against the selection model.

Another recent study claims that in some tasks action choice is already clear in cortical activity even before it reaches the basal ganglia and that the basal ganglia activity is mainly related to reinforcing the commitment to perform the action. This study, and many others like it, base their claims on recordings from afferent structures showing that the neurons are coding the selected stimulus/action/motor program prior to relevant neural responses recorded from within the basal ganglia. An alternative interpretation of these data would be that recordings from all afferent structures that provide competing inputs to the basal ganglia will have shorter latencies than related signals recorded from within the basal ganglia. If in these experiments afferent recordings were from the structure proving the most salient of the competing inputs, then it will be coding for the ultimately selected option *before* it has been selected by basal ganglia.

Other findings are that recordings in the basal ganglia correlate with metrics of movement (eg, speed) and that dopamine signals in the striatum can affect the probability and also the vigor of movement. It is sometimes argued that these results are more indicative of the basal ganglia helping to commit to movement and determining the parameters of movement rather than simply selecting what to do. At least two alternative views could explain why recorded activity in the basal ganglia correlates with movement metrics. First, as mentioned above, one of the significant inputs to the striatum is an efference copy of signals relayed to the motor plant. It would be strange if these signals did not contain information about movement metrics. Second, at this point, it is probably wise to recognize

that actions are multidimensional and, as they are learned, require selections about not only *what* to do but also *where* to do it, *when* to do it, and *how* to do it.

The fact that correlates of these various properties of action can be recorded within the basal ganglia nuclei should not necessarily be surprising. Recent studies suggest that *what* and *where* options may arrive to the basal ganglia via glutamatergic input, for example, from the cortex, while *when* options may be modulated by dopaminergic inputs. One of the reasons we know that actions comprise these different dimensions is that each of them can be independently manipulated by reinforcement learning. It is to that topic, which is likely to be an inherent property of a selection architecture, that we now turn.

Reinforcement Learning Is an Inherent Property of a Selection Architecture

The basal ganglia have long been associated with fundamental processes of reinforcement learning. In his famous Law of Effect, first published in his book *Animal Intelligence* (1911), Edward Lee Thorndike proposed that "any act which in a given situation produces satisfaction becomes associated with that situation so that when the situation recurs the act is more likely than before to recur also." Using contemporary language, Thorndike is stating that in a given context an action that has been associated with reward is more likely to be selected in the future when the same or similar contexts are encountered.

Stated in this way, reinforcement learning can be seen as a process for biasing action selection; consequently, it would be expected to operate by modulating activity in the mechanism(s) responsible for selection. How would a reinforcer (reward or punishment) bias selection in the basal ganglia architecture described above? Theoretically, competition between the options represented in the reentrant loops could be biased by sensitizing a reward-related loop at any of its relay points (cortex, input nuclei, globus pallidus, output nuclei, and thalamus). Here, we present just two examples where there is good evidence that reward operating at different nodes within the basal ganglia's reentrant loop circuitry can bias selection (Figure 38–8).

Intrinsic Reinforcement Is Mediated by Phasic Dopamine Signaling Within the Basal Ganglia Nuclei

The popular view of reinforcement in the basal ganglia is that action selection is biased by a dopamine teaching signal that adjusts the sensitivity of intrinsic circuitry so that responses to inputs associated with unpredicted rewards are enhanced (Figure 38–8A). In this model, therefore, the process of reinforcement learning is intrinsic to the basal ganglia nuclei. However, as we have seen above, dopaminergic neurons have highly divergent axons that terminate in wide areas of targeted nuclei. Add to this the problem of volume transmission and the fact that dopaminergic neurons often respond together as a population to relevant events and the problem of how to reinforce only those elements associated with reward or punishment immediately becomes apparent.

It is thought that this issue is addressed by invoking the concept of a decaying eligibility trace. That is, spiking activity in the population of neurons associated with an action that leads to reward is thought to alter the state specifically of those neurons, making them receptive to later widely broadcast reward-related reinforcement signals. There is evidence that this process operates within the basal ganglia. Thus, in most contemporary models, competing behavioral options are represented by specific neurons, the activity of which can be reinforced by phasic increases or decreases in afferent dopamine signals.

Because behavioral experiments have established that unpredicted reward rather than reward per se is critical for learning, the phasic response properties of dopaminergic neurons have captured the imagination of both the biological and computational neuroscience communities. The powerful combination of biological experimentation and computational analyses now indicates clearly that the phasic activity of midbrain dopaminergic neurons provides a teaching signal for reinforcement learning.

While recording from dopaminergic neurons in the ventral midbrain, most studies presented subjects (usually monkeys) either with rewards or neutral stimuli that predicted rewards. The results of these experiments showed that the phasic dopamine responses evoked by unexpected rewards, or the onset of stimuli that predict them, had short response latencies (~100 ms from stimulus onset) and short durations (again ~100 ms). The magnitude of these responses was shown to be influenced by a range of factors including the size, reliability, and extent the reward would be delayed. Importantly, when a neutral stimulus predicted reward (as in traditional Pavlovian conditioning), the phasic dopamine response transferred from the reward to the predicting stimulus. Alternatively, if a reward was predicted but not delivered, the dopaminergic neurons paused briefly at the time the reward would have been delivered. A particularly exciting

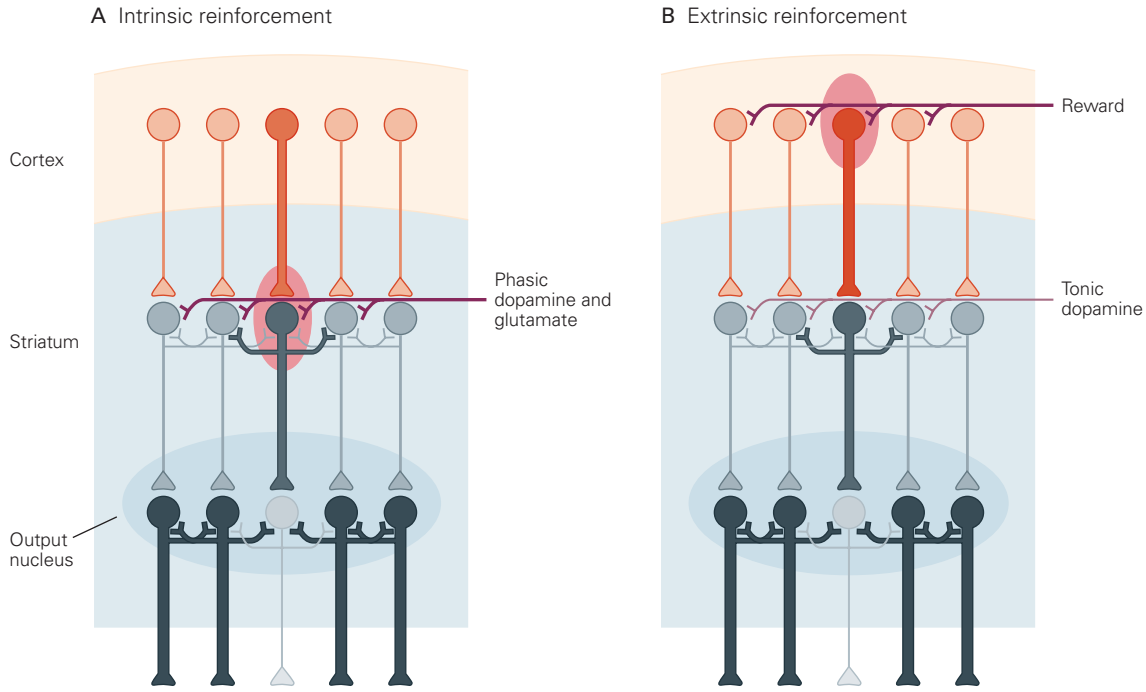

Figure 38–8 **Two separate reinforcement mechanisms can bias selection within the reentrant parallel-loop architecture of the basal ganglia.** (Return connections of the loops via the thalamus have been omitted for clarity.)

A. Intrinsic reinforcement (**red oval**) involves the selective sensitization of corticostriatal neurotransmission (indicated by the relative thickness of striatal projection neurons in different channels). Transmission in recently active (selected) channel(s) is reinforced by the combined phasic release of dopamine and glutamate evoked by an unpredicted biologically salient sensory event (eg, reward). Nonactive channels lack the eligibility trace required for dopamine reinforcement at the synapse. The resulting selective plasticity would cause reinforced versions of recent behavioral output to be preferentially reselected, thereby establishing an association between action and outcome.

B. Recent investigations demonstrate that an association with reward (**red oval**) can potentiate processing in structures providing afferent signals to the striatum. Insofar as selection by the basal ganglia is determined in part by the relative strength of inputs to the striatum (the common currency), reward-related modulation of afferent signals would effectively bias selection to favor reward-related inputs. Again, the thickness of projections in the figure denotes relative levels of activation.

finding was that these responses resembled the reward prediction error term in a machine learning reinforcement algorithm. It was therefore widely concluded that phasic dopamine responses could be operating as the brain's teaching signal in reinforcement learning.

With the advent of optogenetic methodology, it has now been established beyond reasonable doubt that phasic dopamine responses can signal both positive and negative reward prediction errors and that these responses correspondingly increase and decrease the probability that prior behavior will be selected. It is thought that phasic dopamine acts by strengthening inputs onto direct pathway neurons in the striatum and weakening inputs onto indirect pathway neurons. Consequently, there is evidence that direct pathway activity can lead animals to do more of a certain action, while indirect pathway activity would lead animals not to do an action.

However, the roles of these pathways may be more complex than this simple dichotomy. In accordance with the different action dimensions outlined above (*what*, *where*, *when*, and *how*), activity in both the direct and indirect pathways can reinforce or discourage faster or slower movements, depending on which movements lead to reward in that context. Furthermore, the effects of optogenetic self-stimulation of these pathways on action reinforcement seem to be different between the associative (dorsomedial) and sensorimotor (dorsolateral) domains of the striatum. This could be consistent with different dopamine signals observed in the ventral tegmental area, which projects more medially in the striatum, compared to those in the substantia nigra pars compacta, which projects more laterally. The latter has a higher proportion of dopaminergic neurons that respond to stimulus salience and preferentially respond when the animal

initiates self-paced movements (eg, pressing a lever for food whenever it wants, rather than when a sensory cue is presented).

Nonetheless, a wealth of experimental data indicates that phasic dopamine-evoked neural plasticity in the basal ganglia can bias future behavioral selections according to the value of the predicted outcome. This conclusion is consistent with the view that the basal ganglia operate as a generic selection mechanism that can support reinforcement learning.

Extrinsic Reinforcement Could Bias Selection by Operating in Afferent Structures

A second, less widely acknowledged mechanism for biasing selection within the reentrant loop architecture is by modulation of the input salience of competing behavioral options that previously have been associated with a reinforcer—reward or punishment (Figure 38–8B). Since the relative magnitudes of input saliences in competing channels are the common currency by which competing options are judged, reinforcement-induced boosting of a particular channel's input to a selection mechanism would increase the probability of that option being selected in the future.

Evidence in the literature indicates that when a particular stimulus is associated with reward, its representation is enhanced in many of the afferent structures projecting to the basal ganglia. The origin of the reinforcement signals that modulate processing in the input structures is currently unknown. However, the pretuning of basal ganglia inputs by association with reward implies that options associated with high-value outcomes would have a correspondingly higher probability of being selected. Continual updating of input saliences by reward and punishment would bias selections in such a way that the acquisition of reward (or avoidance of punishment) would be maximized in the long term. Finally, it is probably the reward-related tuning of afferent input to the ventral midbrain that enables dopaminergic neurons to accurately report reward prediction errors.

In summary, it is likely that reinforcement learning will be an additional inherent property of a selection architecture. The synaptic relay points at various locations around the parallel reentrant loop architecture provide ample opportunity for the activity in specific loops to be modulated by reward and punishment. There is now good evidence that selection bias can be achieved by reward via a mechanism involving the widespread release of dopamine within the basal ganglia. Reinforcement selectivity is likely to be achieved via some form of eligibility mechanism. A second possibility is that the relative salience of behavioral options can be modulated by reward and punishment acting directly within the structures that provide input to the basal ganglia.

Behavioral Selection in the Basal Ganglia Is Under Goal-Directed and Habitual Control

Over the past decades, it has become apparent that actions can be learned and then selected based on goal-directed or habitual control. Initially, as we learn to perform particular actions to obtain specific outcomes, these actions are goal-directed, and their performance is highly sensitive to changes in the expected value of the outcome or to changes in the contingency between the action and the outcome. With repetition and consolidation, actions can become not only more efficient but also more automatic, controlled by a stimulus–response type circuit.

In the case of habits, performance becomes less sensitive to changes in the outcome value or changes in contingency between action and the outcome, but rather is controlled by the salience of antecedent stimuli or contexts. Interestingly, shifts from goal-directed to habitual behaviors can be produced not only by extended training, but also by different schedules of reinforcement. Thus, the formation of habits is favored when rewards are delivered according to random time intervals, while goal-directed control is favored when rewards are delivered after a random number of actions.

Different cortical-basal ganglia loops seem to support the learning and performance of goal-directed actions versus habits. The acquisition of goal-directed actions appears to rely on the associative cortical-basal ganglia circuit involving the dorsomedial or associative striatum, the prelimbic cortex, the mediodorsal thalamus, the orbitofrontal cortex, and the amygdala. On the other hand, the formation of habits depends upon circuits coursing through the dorsolateral or sensorimotor striatum, infralimbic cortex, and the central amygdala.

It has been shown that since these two fundamental modes of behavioral control operate through different reentrant loops it has been possible to cause shifts between them through specific manipulations within the basal ganglia. Thus, damage to or inactivation of the associative territories effectively blocks goal-directed control while leaving automatic habitual control relatively unimpaired. Conversely, disruption of the sensorimotor basal ganglia causes habitual performance to switch back to goal-directed control.

Finally, efficient habits, where known stimuli or circumstances trigger a particular response, are very helpful in everyday life such as tying one's shoelaces or locking the front door. However, we also encounter circumstances that cause us to reevaluate our actions. Shifting between goal-directed actions and habits allows us to act flexibly in the environment, and inability to do so may underlie distorted behaviors observed in addiction and other behavioral and neurological disorders of the basal ganglia. It is to this topic that we now turn.

Diseases of the Basal Ganglia May Involve Disorders of Selection

The focus of this chapter has been how the functional architecture of the basal ganglia and their evolutionary history have determined their role in overall brain function. One of the motivations for this exercise that we all have is an intrinsic scientific interest in trying to understand something we currently do not. However, there is another important reason to better understand how the basal ganglia operate. In humans, basal ganglia dysfunction is associated with numerous debilitating conditions including Parkinson disease, Huntington disease, Tourette syndrome, schizophrenia, attention deficit disorder, obsessive-compulsive disorder, and many addictions. Numerous studies have attempted to shed light on how basal ganglia dysfunction leads to the symptoms that characterize these disorders. This effort can only be helped if we have a better understanding of what a complicated system like the basal ganglia is trying to do when it is operating normally.

A Selection Mechanism Is Likely to Be Vulnerable to Several Potential Malfunctions

Thus far, we have considered the theoretical and empirical evidence supporting the idea that the looped circuitry of the basal ganglia acts as a generic selection mechanism within which reinforcement learning operates to maximize reward and minimize punishment. If action selection and reinforcement learning are the normal functions of the basal ganglia, it should be possible to interpret many of the human basal ganglia–related disorders in terms of selection or reinforcement malfunctions.

Normal selection requires that the selected option is disinhibited at the level of basal ganglia output, while inhibition of nonselected or losing options is maintained or increased (Figure 38–9A). An obvious failure in such a system would be if none of the options were able to achieve sufficient disinhibition to reach a

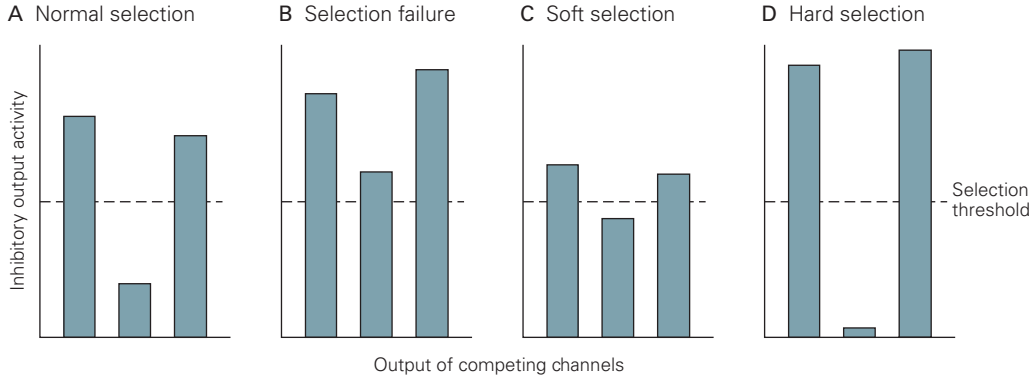

Figure 38–9 Potential disorders of behavior selection.

A. Normal selection within the basal ganglia is characterized by a reduction in inhibition of selected channels below a proposed selection threshold (central channel) while maintaining or increasing inhibition of nonselected channels (left and right channels). Consequently, the disinhibited target structure is able to initiate the action it controls, while the nonselected targets are maintained under inhibitory control.

B. Insufficient reduction in tonic inhibition of all channels means no target structure would be sufficiently disinhibited. This circumstance could explain the akinesia in Parkinson disease.

C. A failure to adequately disinhibit the selected channel or suppress disinhibitory activity in competing channels would cause current selections to be vulnerable to interruption. This disorder could account for the inability to maintain a train of thought and easy distraction by nonattended events in schizophrenia and attention deficit hyperactivity disorder.

D. One channel may become pathologically dominant either through abnormal disinhibition of the selected channel or excessive tonic inhibition of competing channels. This would make the relevant option easy to select and highly resistant to interruption. Hard selections may explain obsessive-compulsive disorder and addictive behaviors.

critical selection threshold (Figure 38–9B). However, a further important point when thinking about selection malfunctions is to appreciate that output inhibition and disinhibition are likely to be continuously variable rather than discrete on/off states. In that case, the difference between the disinhibited and inhibited channels would determine how "hard" or "soft" the selection is. When the difference is large (Figure 38–9D), competing options are likely to find the current selection is resistant to interruption—a larger than normal input salience would be required to cause the system to switch selections. Conversely, when the difference is small (Figure 38–9C), it would be comparatively easy for a competing option to initiate a selection switch.

Support for these ideas comes from behavioral observations showing that at the beginning of task learning there is frequently easy switching between strategies. However, as the task becomes well learned, the system becomes increasingly resistant to alternative strategies. Appreciation of the concepts of hard and soft selection could therefore play an important role when thinking about how a selection mechanism might become dysfunctional in the context of basal ganglia diseases.

Parkinson Disease Can Be Viewed in Part as a Failure to Select Sensorimotor Options

The cardinal symptoms of Parkinson disease are akinesia (difficulties in initiating movement), bradykinesia (initiated movements are slow), and rigidity (stiffness and resistance to passive movement). Tremor is often but not always present. The principal neurological deficit responsible for the motor symptoms of Parkinson disease is thought to be the progressive degeneration of dopaminergic neurotransmission in the basal ganglia.

A consequence of this loss of dopamine is increased tonic and oscillatory activity in the recordings from basal ganglia output nuclei. Since the output of the basal ganglia is GABAergic and inhibitory, in Parkinson disease, targeted structures are receiving high and uneven levels of inhibitory input. This condition impairs the normal selective (disinhibitory) function of the basal ganglia; movements are difficult to select and, when possible, are slow to execute.

Parkinson disease is, however, more nuanced than this. Over much of this progressive condition, the loss of dopaminergic transmission differentially affects the sensorimotor territories of the basal ganglia, leaving the limbic and associative territories comparatively unaffected. As discussed in the section on goal-directed and habitual control, the sensorimotor territories of the basal ganglia play an essential role in selecting habitual actions. Perhaps, therefore, it is not surprising that many of the motor features of Parkinson disease can be interpreted in terms of a loss of automatic habits. While patients can do things, they are trapped in the slower, serial, and voluntary mode of goal-directed control. In the future, it will be interesting to see if subtle losses of habitual control can be detected before clinical symptoms appear, thereby acting as an early marker for the condition.

Huntington Disease May Reflect a Functional Imbalance Between the Direct and Indirect Pathways

Huntington disease is a genetically transmitted disorder, the initial symptoms of which are subtle changes in mood, personality, cognition, and physical skills. The abnormal movements are characterized by jerky, random, and uncontrollable movements called chorea. The disease is associated with neuronal degeneration. Damage in the early stage is most evident in the striatal medium spiny neurons, but later spreads to other regions of the nervous system.

Observations that neuronal degeneration is evident in limbic, associative, and sensorimotor territories of the striatum would explain why the disease is characterized by disturbances of affect, cognition, and sensorimotor function. Also noteworthy is that the most vulnerable neurons are those in the striatum that project to the external globus pallidus (the indirect pathway) rather than the neurons that project directly to the basal ganglia output nuclei. At the level of the output nuclei, this disturbance would tip the balance in favor of the striatal projection responsible for disinhibition. Consequently, the symptoms of Huntington disease could reflect interference with expression of the selected affective, cognitive, and sensorimotor behaviors by competitors not being sufficiently suppressed.

Schizophrenia May Be Associated With a General Failure to Suppress Nonselected Options

Schizophrenic psychosis is a condition in which there are also disturbances of affect, cognition, and sensorimotor function. Typical symptoms include delusions (false beliefs not based in reality), hallucinations (hearing or seeing things that do not exist), disorganized thinking (inferred from disorganized speech), and abnormal motor behavior (unpredictable agitation, stereotypy, and failure to concentrate on the matter in hand). The disease is progressive, and in later stages, negative symptoms characterized by flattened affect, social withdrawal, absence of thought, and reduced motor behavior become evident (Chapter 60).

Understanding the neurobiological basis of schizophrenia has been complicated by many inconsistent experimental procedures, high variability in symptoms, the side effects of medications, substance abuse, and variability in response to treatments. There is, however, a consistent link between schizophrenia and the basal ganglia insofar as a major class of antipsychotic drugs acts to suppress dopaminergic neurotransmission. In terms of simple regional density of axon terminals and postsynaptic dopamine receptors, dopaminergic transmission within the basal ganglia is likely to be influenced most profoundly by dopamine-related pharmacological therapies. Moreover, there is evidence that dopamine dysregulation in the basal ganglia is intrinsic to the pathology of schizophrenia rather than a medication side effect; predates the psychosis; and is a risk factor for the illness. The implication here is that schizophrenia is associated with a net excess of dopaminergic transmission in the basal ganglia.

So how might dysregulation of this form distort the normal functions of selection and reinforcement? First, the observation that schizophrenia is characterized by disturbances of affect, cognition, and sensorimotor behavior again suggests that the neurobiological substrate will be present in each of the basal ganglia's functional territories. Second, a recurrent theme is that with the positive symptoms there seems to be too much of everything—intense emotional intrusions, too many ideas out of control, spontaneous sensory experiences, too many distracting stimuli, and unpredictable motor agitation. One way of unifying this confusing array of symptoms is to assume that they represent a similar basic fault playing out in different functional territories of the basal ganglia. Here, the basic fault could be a failure on the part of the mechanism responsible for suppressing the impact of competing but nonselected options. Consequently, in all functional territories, the currently selected option would be pathologically vulnerable to interruption (Figure 38–9C).

Attention Deficit Hyperactivity Disorder and Tourette Syndrome May Also Be Characterized by Intrusions of Nonselected Options

Further examples of hyperactive conditions that have been linked to basal ganglia dysfunction may also be due to a faulty selection mechanism where the system in each case is vulnerable to intrusions. Attention deficit hyperactivity disorder (ADHD), like schizophrenia, could in part be the result of a failure in the mechanism responsible for suppressing nonselected sensory options, thereby making it difficult to maintain a focus of attention. Alternatively, the impulsive aspects of the condition could reflect a malfunction in the neural systems that generate behavioral options based on the value of likely consequences. In this situation, options driven by immediately desired sensory events would take precedence over competing representations of disadvantageous longer-term consequences.

In the case of Tourette syndrome, converging evidence indicates that the involuntary behavioral intrusions (verbal and motor tics) are associated with aberrant activity in the cortical–basal ganglia–thalamic loops. In animal models, similar motor tics can be evoked by blocking inhibitory neurotransmission in local areas of the sensorimotor striatum. Were the disease state also to cause a similar failure of inhibition or inappropriate excitation in parts of the striatum not engaged by the current selection, disruptive motor intrusions might be expected. Furthermore, were the locus of the excessive excitation to remain constant and the motor characteristics of the intrusion to be repeated, it is likely that the mechanism for establishing automatic habits would be engaged, thereby further enhancing the automatic involuntary nature of the intrusion.

Obsessive-Compulsive Disorder Reflects the Presence of Pathologically Dominant Options

Persons with obsessive-compulsive disorder compulsively repeat specific actions (hand washing, counting things, checking things) or have particular thoughts repeatedly come to mind uninvited (obsessions). Studies using functional neuroimaging when the symptoms are present consistently report abnormal activation at various locations within the cortical-striatum-thalamus-cortical loops.

In terms of a selection mechanism dysfunction, the symptoms of obsessive-compulsive disorder would be expected when, for whatever reason, the input salience of relevant functional channels would be abnormally dominant, thereby making it difficult for competing options to interrupt or cause behavioral or attentional switching (hard selection). The fact that the obsessional and compulsive options are dominant behaviors that have been learned suggests that the fault responsible for obsessive-compulsive disorder may lie with the reinforcement mechanism capable of adjusting input salience. Of course, such a fault could be of genetic and/or environmental origin.

Addictions Are Associated With Disorders of Reinforcement Mechanisms and Habitual Goals

Addiction to drugs and other behaviors (eg, gambling, sex, eating) represents a dramatic dysregulation of

motivational selections. This is caused by an exaggerated salience of addiction-related stimuli, binge indulgence, and withdrawal anxiety. When addictions are being acquired, changes in dopaminergic and opioid peptide transmission in the basal ganglia have been reported.

Insofar as these transmission systems have been linked with fundamental mechanisms of reinforcement, it might be expected that the selective reinforcement of addiction-related stimuli would lead to observed increases in the ability of these stimuli to capture behavior. Alternatively, the increases in negative emotional states and stress-like responses experienced during withdrawal have been associated with reductions in dopamine function. In the limbic territories of the basal ganglia, such reductions are typically associated with negative reinforcement.

A final point to note is that if addiction-associated stimuli can automatically trigger the motivation/goal to indulge (ie, an automatic stimulus–goal association), a similar kind of mechanism may be operating in the limbic territories as is currently assigned to stimulus–response habits in the sensorimotor territories. Thus, if in the case of drug addiction the goal of drug acquisition may be correctly described as a stimulus-driven habit, the practicalities of obtaining the drug can be highly goal directed (eg, robbing a convenience store, phoning the dealer) and not at all habitual.

From the above sections, it can be seen that interpreting disorders of the basal ganglia in terms of dysregulations of selection and reinforcement does not require implausible intellectual contortions. Indeed, this could be regarded as further support for the view that the systems-level function of the basal ganglia is to operate as a generic selection mechanism. Moreover, having an overriding conceptual framework based on potential disorders of normal function has an important advantage for guiding future research. Instead of fishing in the brains of patients and animal models for clues of what might have gone wrong, one is hunting within a specified network for a malfunction that would be expected to produce the observed disorder.

Highlights

1. The basal ganglia are an interconnected group of nuclei located at the base of the forebrain and midbrain. There are three major input structures (the striatum, the subthalamic nucleus, and the dopamine cells of substantia nigra) and two major output structures (the internal globus pallidus and substantia nigra pars reticulata).
2. Input structures receive projections from most regions of the cerebral cortex, limbic system, and brain stem, many via relays in the thalamus. Inputs to the striatum and subthalamus are topographically organized.
3. The spatial topography is maintained throughout the intrinsic basal ganglia connections, as well as in projections back to the cortex, limbic system, and brain stem structures. Thus, an essential feature of systems-level basal ganglia architecture can be viewed as a series of reentrant loops.
4. The striatum was thought to be connected to the output nuclei via direct and indirect pathways. However, recent anatomical evidence suggests a more complex internal architecture.
5. Phasic excitatory input to the basal ganglia is mediated by the neurotransmitter glutamate. Tonic inhibitory output from the basal ganglia is mediated by the neurotransmitter GABA. The reentrant loops keep afferent structures under strong inhibitory control. For any task, the tonic inhibitory firing of some output neurons pauses, while for others, it is maintained or increased.
6. Basal ganglia architecture appeared at the outset of vertebrate evolution and has been highly conserved throughout. This suggests that the computational problems they solve are likely to be problems faced by all vertebrate species.
7. The internal microarchitecture of the intrinsic basal ganglia nuclei is largely the same throughout their motivational, affective, cognitive, and sensorimotor territories. This suggests that the same basal ganglia algorithm is applied to all general classes of brain function.
8. A recurring theme within the basal ganglia literature is their involvement in action selection and reinforcement learning.
9. The selection hypothesis is supported by the following: (1) Selection is a generic problem faced by all vertebrates. (2) A selection algorithm common to all basal ganglia territories could resolve competitions between incompatible motivational, affective, cognitive, and sensorimotor options. (3) Many intrinsic processes could support a selection function. (4) Selective removal of output inhibition within a multiple reentrant looped architecture is necessarily a selection process. (5) Computational models of basal ganglia architecture effectively select the actions of multifunctional robots.
10. Abundant evidence indicates that the basal ganglia are an essential substrate for reinforcement

learning where selections are biased by the valence/value of past outcomes.

11. The multidimensional aspects of action (what, where, when, and how to do something) can be independently modified by reinforcement learning. It will be important to determine whether these different aspects of action are learned within the same or different functional territories of the basal ganglia.
12. Recent optogenetic investigations have confirmed that phasic dopamine signaling can act as a training signal for reinforcement learning.
13. Within the reentrant looped architecture, future selections can be biased not only within the basal ganglia by dopamine but also at synapses in external afferent structures and the thalamic relays.
14. Reinforcement learning can bias selections on the basis of outcome value (goal-directed), or by operating on an acquired automatic stimulus–response association (habit). Goal-directed and habitual selections are made in different functional territories of the basal ganglia.
15. Insofar as diseases of the basal ganglia in humans can be interpreted as selection malfunctions, additional support is provided for the idea that the basal ganglia operate as a generic selection module.

Brain–Machine Interfaces

Understanding the normal function of the nervous system is central to understanding dysfunction caused by disease or injury and designing therapies. Such treatments include pharmacological agents, surgical interventions, and, increasingly, electronic medical devices. These medical devices fill an important gap between largely molecularly targeted and systemic medications and largely anatomically targeted and focal surgical lesions.

In this chapter, we focus on medical devices that measure or alter electrophysiological activity at the level of populations of neurons. These devices are referred to as brain–machine interfaces (BMIs), brain–computer interfaces, or neural prostheses. We use the term BMI to refer to all such devices because there is no standard distinction among them. BMIs can be organized into four broad categories: those that restore lost sensory capabilities, those that restore lost motor capabilities, those that regulate pathological neural activity, and those that restore lost brain processing capabilities.

BMIs can help people perform "activities of daily living," such as feeding oneself, physically dressing and grooming oneself, maintaining continence, and walking. A type of BMI that we will discuss extensively in this chapter converts electrical activity from neurons in the brain into signals that control prosthetic devices to help people with paralysis. By understanding how neuroscience and neuroengineering work together to create current BMIs, we can more clearly envision how many neurological diseases and injuries can be treated with medical devices.

BMIs Measure and Modulate Neural Activity to Help Restore Lost Capabilities

Cochlear Implants and Retinal Prostheses Can Restore Lost Sensory Capabilities

One of the earliest and most widely used BMIs is the cochlear implant. People with profound deafness can benefit from restoration of even some audition. Since the 1970s, several hundred thousand people who have a peripheral cause of deafness that leaves the cochlear nerve and central auditory pathways intact have received cochlear implants. These systems have restored considerable hearing and spoken language, even to children with congenital deafness who have learned to perceive speech using cochlear implants.

Cochlear implants operate by capturing sounds with a microphone that resides outside the skin and sending these signals to a receiver surgically implanted under the skin near the ear. After conversion (encoding) to appropriate spatial-temporal signal patterns, these signals electrically stimulate spiral ganglion cells in the cochlear modiolus (Chapter 26). In turn, signals from the activated cochlear cells are transmitted through the auditory nerve to the brain stem and higher auditory areas where, ideally, the neural signals are interpreted as the sounds captured by the microphone.

Another example of a BMI is a retinal prosthesis. Blindness can be caused by diseases such as retinitis pigmentosa, an inherited retinal degenerative disease. At present, there is no cure and no approved medical therapy to slow or reverse the disease. Retinal prostheses currently enable patients to recognize large letters and locate the position of objects. They operate by capturing images with a camera and sending these signals to a receiver positioned within the eye. After conversion to appropriate spatial-temporal patterns, these electrical signals stimulate retinal ganglion cells in the retina through dozens of electrodes. In turn, these cells send their signals through the optic nerve to the thalamus and higher visual areas where, ideally, the afferent signals are interpreted as the image captured by the camera.

Motor and Communication BMIs Can Restore Lost Motor Capabilities

BMIs are also being developed to assist paralyzed people and amputees by restoring lost motor and communication function. This is the central topic of this chapter. First, electrical neural activity in one or more brain areas is measured using penetrating multielectrode arrays placed, for example, in the arm and hand region of the primary motor cortex, dorsal and ventral premotor cortex, and/or intraparietal cortex (particularly the parietal reach region and medial intraparietal area) (Figure 39–1).

Second, an arm movement is attempted but cannot be made in the case of people with paralysis. Action potentials and *local field potentials* are measured during these attempts. With 100 electrodes placed in the primary motor cortex and another 100 in the dorsal premotor cortex, for example, action potentials from approximately 200 neurons and local field potentials from 200 electrodes are measured. Local field potentials are lower-frequency signals recorded on the same electrodes as the action potentials and believed to arise from local synaptic currents of many neurons near the electrode tips. Together, these neural signals contain considerable information about how the person wishes to move her arm.

Third, the relationship between neural activity and attempted movements is characterized. This relationship makes it possible to predict the desired movement from new neural activity, a statistical procedure we refer to as *neural decoding*. Fourth, the BMI is then operated in its normal mode where neural activity is measured in real time and desired movements are decoded from the neural activity by a computer. The decoded movements can be used to guide prosthetic devices, such as a cursor on a computer screen or a robotic arm. It is also possible to electrically stimulate muscles in a paralyzed limb to enact the decoded movements, a procedure known as *functional electrical stimulation*. Many other prosthetic devices can be envisioned as we increasingly interact with the world around us electronically (eg, smart phones, automobiles, and everyday objects that are embedded with electronics so that they can send and receive data—known as the "internet of things").

Finally, because the person can see the prosthetic device, she can alter her neural activity by thinking different thoughts on a moment-by-moment basis so as to guide the prosthetic device more accurately. This closed-loop feedback control system can make use of nonvisual sensory modalities as well, including delivering pressure and position information from electronic sensors wrapped on or embedded in a prosthetic arm. Such surrogate sensory information can be transformed into electrical stimulation patterns that are delivered to proprioceptive and somatosensory cortex.

The BMIs described above include motor and communication BMIs. Motor BMIs aim to provide natural control of a robotic limb or a paralyzed limb. In the case of upper-limb prostheses, this involves the

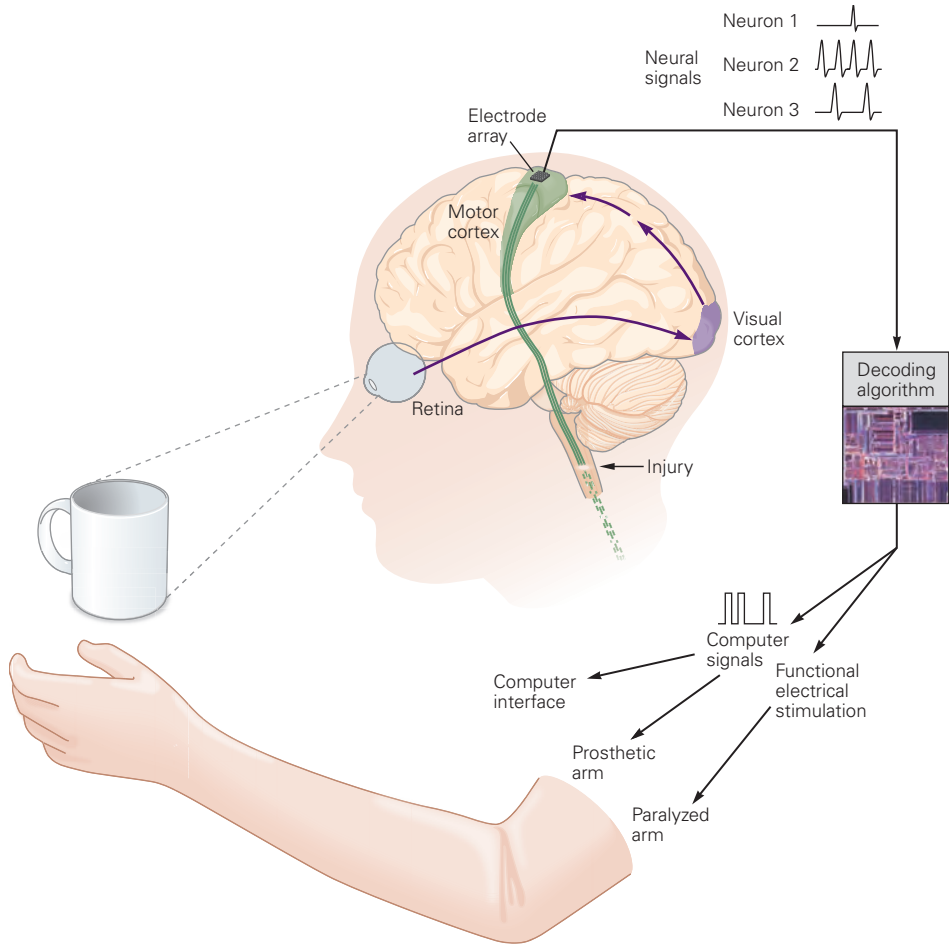

Figure 39–1 Concept of motor and communication brain–machine interfaces. One or more electrode arrays are implanted in brain regions such as the primary motor cortex, dorsal and ventral premotor cortex, or intraparietal cortex. They record action potentials from tens to hundreds of neurons and local field potentials. The recorded neural activity is then converted by a decoding algorithm into (1) computer commands for controlling a computer interface or a prosthetic (robotic) arm, or (2) stimulation patterns for functional electrical stimulation of muscles in a paralyzed arm.

precise movement of the arm along a desired path and with a desired speed profile. Such control is indeed an ambitious ultimate goal, but even intermediate steps toward this goal could improve quality of life by restoring some lost motor function and improving the patient's ability to carry out "activities of daily living." For example, numerous people with tetraplegia could benefit from being able to feed themselves.

Communication BMIs are designed to provide a fast and accurate interface with a plethora of electronic devices. The ability to move a computer cursor around an on-screen keyboard allows a patient to type commands for computers, smart phones, voice synthesizers, smart homes, and the "internet of things." Ideally, communication BMIs would allow for a communication rate at which most people speak or type. Such BMIs would benefit people with amyotrophic lateral sclerosis (ALS), who often become "locked in" and unable to communicate with the outside world through any movements. Communication BMIs would also benefit people with other neurodegenerative diseases that severely compromise the quality of movement and speech, as well as those with upper spinal cord injury. The ability to reliably type several words per minute is a meaningful improvement in quality of life for many patients.

Motor and communication BMIs build on basic neuroscientific research in voluntary movement (Chapter 34). The design and development of BMIs have so far depended on laboratory animal research, largely with nonhuman primates; recently, however, pilot clinical trials with humans with paralysis have begun.

Pathological Neural Activity Can Be Regulated by Deep Brain Stimulation and Antiseizure BMIs

BMIs have been developed to help people with disorders involving pathological neural activity in the brain, such as Parkinson disease and epilepsy. People with Parkinson disease benefit by having hand and arm tremor reduced. At present, there is no cure for Parkinson disease, and many people become resistant to pharmacological treatments. A deep brain stimulator (DBS) can help these people by delivering electrical pulses to targeted areas in the brain to disrupt the aberrant neural activity.

DBS is controlled by a neurostimulator implanted in the chest, with wires to stimulating electrodes in deep brain nuclei (eg, the subthalamic nucleus). The nuclei are continuously stimulated with these electrodes in order to alter the aberrant neural activity. This method can often greatly reduce Parkinson disease–related tremor for years. A DBS applied to different brain areas can also help people with essential tremor, dystonia, chronic pain, major depression, and obsessive-compulsive disorder.

Millions of people experiencing epileptic seizures are currently treated with antiseizure medications or neurosurgery, both of which often result in incomplete or impermanent seizure reduction. Antiseizure BMIs have shown considerable promise for further improving quality of life. These fully implanted BMIs operate by continuously monitoring neural activity in a brain region determined to be involved with seizures. They identify unusual activity that is predictive of seizure onset and then respond within milliseconds to disrupt this activity by electrically stimulating the same or a different brain region. This closed-loop response can be fast enough that seizure symptoms are not felt and seizures do not occur.

Replacement Part BMIs Can Restore Lost Brain Processing Capabilities

BMIs are capable of restoring more than lost sensory or motor capabilities. They are, in principle, capable of restoring internal brain processing. Of the four categories of BMIs, this is the most futuristic. An example is a "replacement part" BMI. The central idea is that if enough is known about the function of a brain region, and if this region is damaged by disease or injury, then it may be possible to replace this brain region.

Once the normal input activity to a brain region is measured (see next section), the function of the lost brain region could then be modeled in electronic hardware and software, and the output from this substitute processing center would then be delivered to the next brain region as though no injury had occurred. This would involve, for example, reading out neural activity with electrodes, mimicking the brain region's computational functions with low-power microelectronic circuits, and then writing in electrical neural activity with stimulating electrodes.

This procedure might also be used to initiate and guide neural plasticity. A replacement part BMI that is currently being investigated focuses on restoring memory by replacing parts of the hippocampus that are damaged due to injury or disease. Another potential application would be to restore the lost functionality of a brain region damaged by stroke.

These systems represent the natural evolution of the BMI concept, a so-called "platform technology" because a large number of systems can be envisioned by mixing and matching various write-in, computational, and read-out components. The number of neurological diseases and injuries that BMIs should be able to help address ought to increase as our understanding of the functions of the nervous system and the sophistication of the technology continue to grow.

Measuring and Modulating Neural Activity Rely on Advanced Neurotechnology

Measuring and modulating neural activity involves four broad areas of electronic technologies applied to the nervous system (so-called neurotechnology). The first area is the type of neural sensor; artificial neural sensors are designed with different levels of invasiveness and spatial resolution (Figure 39–2). Sensors that are external to the body, such as an *electroencephalogram* (EEG) cap, have been used extensively in recent decades. The EEG measures signals from many small metal disks (electrodes) applied to the surface of the scalp across the head. Each electrode detects average activity from a large number of neurons beneath it.

More recently, implantable electrode-array techniques, such as subdural *electrocorticography* (ECoG) and finely spaced micro-ECoG electrodes, have been used. Since ECoG electrodes are on the surface of the brain and are thus much closer to neurons than EEG electrodes, ECoG has higher spatial and temporal resolution and thus provides more information with which to control BMIs.

Most recently, arrays of *penetrating intracortical electrodes*, which we focus on in this chapter, have been used. The intracortical electrode arrays are made of silicon or other materials and coated with biocompatible materials. The arrays are implanted on the surface of the brain, with the electrode tips penetrating 1 to 2 mm

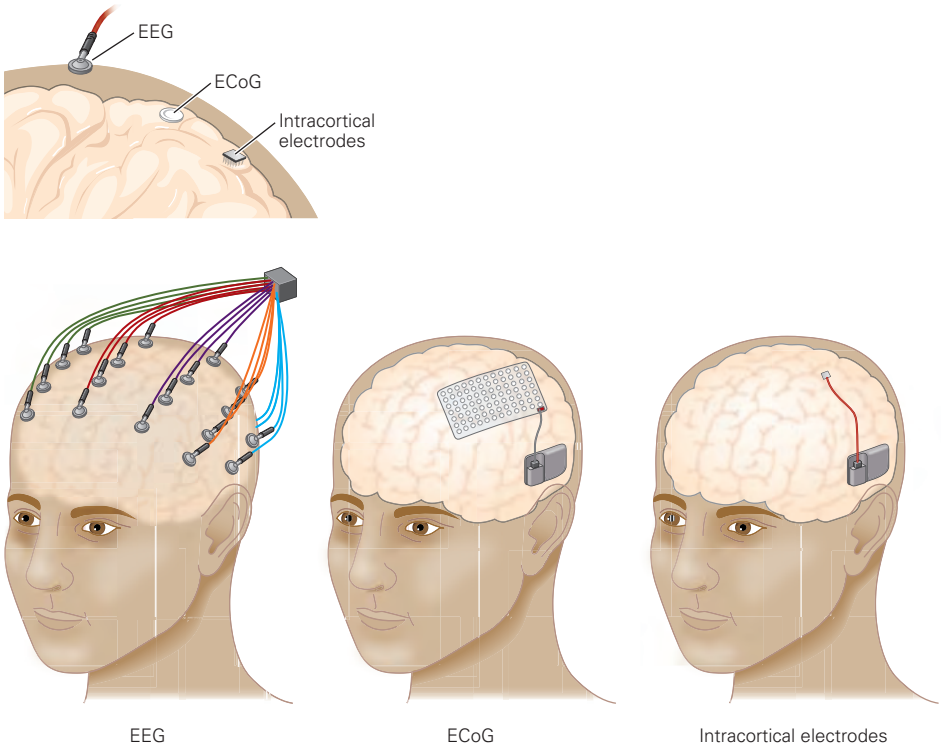

Figure 39–2 Brain–machine interfaces use different types of neural sensors. Electrical neural signals can be measured with various techniques ranging from electroencephalography (**EEG**) electrodes on the surface of the skin, to electrocorticography (**ECoG**) electrodes on the surface of the brain, to intracortical electrodes implanted in the outer 1 to 2 mm of cortex. The signals that can be measured range from the average of many neurons, to averages across fewer neurons, and finally to action potentials from individual neurons. (Adapted, with permission, from Blabe et al. 2015.)

into the cortex. They have the ability to record action potentials from individual neurons, as well as local field potentials from small clusters of neurons near each electrode tip. The electrodes are able to record high-fidelity signals because they are inserted into the brain, bringing the electrode tips within micrometers of neurons. This is beneficial for BMI performance because individual neurons are the fundamental information-encoding units in the nervous system, and action potentials are the fundamental units of the digital code that carries information from the input to the output region of a neuron. Moreover, intracortical electrodes can deliver electrical microstimulation to either disrupt neural activity (eg, DBS) or write in surrogate information (eg, proprioceptive or somatosensory information).

The second area of neurotechnology is scaling up the number of neurons measured at the same time. While one neuron contains some information about a person's intended movement, tens to hundreds of neurons are needed to move a BMI more naturally, and even more neurons are needed to approach naturalistic levels of motor function. Although it is possible to place electrode arrays in many areas across the brain, thereby gaining more information from multiple areas, a key challenge is to measure activity from thousands of neurons within each individual brain area. Many efforts are underway to achieve this goal, including use of electrode arrays with many tiny shafts, each with hundreds of electrode contacts along its length; many tiny electrodes that are not physically wired together, but are instead inserted into the brain as stand-alone islands that transmit data outside of the head and receive power wirelessly; and optical imaging technologies that can capture the activity of hundreds or more neurons by detecting how each neuron's fluorescence changes over time.

The third area is low-power electronics for signal acquisition, wireless data communications, and wireless powering. In contrast to the BMI systems described above, which implant a passive electrode array in which each electrode is wired to the outside world by a connector passing through the skin, future BMIs will be fully implanted like DBS systems. Electronic circuits are needed to amplify neural signals, digitize them, process them (eg, to detect when

an action potential occurred or to estimate local field potential power), and transmit this information to a nearby receiver incorporated into a prosthetic arm, for example. Power consumption must be minimized for two reasons. First, the more power is consumed, the more power a battery or a wireless charging system would need to provide. Batteries would therefore need to be larger and replaced more often, and delivering power wirelessly is challenging. Second, using power generates heat, and the brain can only tolerate a small temperature increase before there are deleterious effects. These trade-offs are similar to those of smart phones, which represent the current best technology available for low-power electronics.

The final area is so-called supervisory systems. Software running on electronic hardware is at the heart of BMIs. Some software implements the mathematical operations of the neural decoding, while other software must tend to aspects of the BMI's overall operation. For example, the supervisory software should monitor whether or not a person wishes to use the prosthesis (eg, if the person is sleeping); if neural signals have changed, thereby requiring recalibration of the decoder; and overall BMI performance and safety.

Having discussed the range of different BMIs and neurotechnologies being developed, in the rest of this chapter we focus on motor and communication BMIs. We first describe different types of decoding algorithms and how they work. We then describe recent progress in BMI development toward assisting paralyzed people and amputees. Next, we consider how sensory feedback can improve BMI performance and how BMIs can be used as an experimental paradigm to address basic scientific questions about brain function. Finally, we conclude with a cautionary note about ethical issues that can arise with BMIs.

BMIs Leverage the Activity of Many Neurons to Decode Movements

Various aspects of movement—including position, velocity, acceleration, and force—are encoded in the activity of neurons throughout the motor system (Chapter 34). Even though our understanding of movement encoding in the motor system is incomplete, there is usually a reliable relationship between aspects of movement and neural activity. This reliable relationship allows us to estimate the desired movement from neural activity, a key component of a BMI.

To study movement encoding, one typically considers the activity of an individual neuron across repeated movements (referred to as "trials") to the same target. The activity of the neuron can be averaged across many trials to create a spike histogram for each target (Figure 39–3A). By comparing the spike histograms for different targets, one can characterize how the neuron's activity varies with the movement produced. One can also assess using the spike histograms whether the neuron is more involved in movement preparation or movement execution.

In contrast, estimating a subject's desired movement from neural activity (referred to as movement *decoding*) needs to be performed on an individual trial while the neural activity is being recorded. The activity of a single neuron cannot unambiguously provide such information. Thus, the BMI must monitor the activity of many neurons on a single trial (Figure 39–3B) rather than one neuron on many trials. A desired movement can be decoded from the neural activity associated with either preparation or execution of the movement. Whereas preparation activity is related to the movement goal execution activity is related to the moment-by-moment details of movement (Chapter 34).

Millions of neurons across multiple brain areas work together to produce a movement as simple as reaching for a cup. Yet in many BMIs, desired movements can be decoded reasonably accurately from the activity of dozens of neurons recorded from a single brain area. Although this may seem surprising, the fact is that the motor system has a great deal of redundancy—many neurons carry similar information about a desired movement (Chapter 34). This is reasonable because millions of neurons are involved in controlling the contractions of dozens of muscles. Thus, most of the neurons in regions of dorsal premotor cortex and primary motor cortex controlling arm movement are informative about most arm movements.

When decoding a movement, the activity of one neuron provides only incomplete information about the movement, whereas the activity of many neurons can provide substantially more accurate information about the movement. This is true for activity associated with both movement preparation and execution. There are two reasons why using multiple neurons is helpful for decoding. First, a typical neuron alone cannot unambiguously determine the intended movement direction. Consider a neuron whose activity (during either preparation or execution) is related to movement direction via a cosine function, known as a *tuning curve* (Figure 39–4A). If this neuron fires at 30 spikes per second, the intended movement direction could be either 120° or 240°. However, by recording from a second neuron whose tuning curve is different from that of the first neuron, the movement direction can be

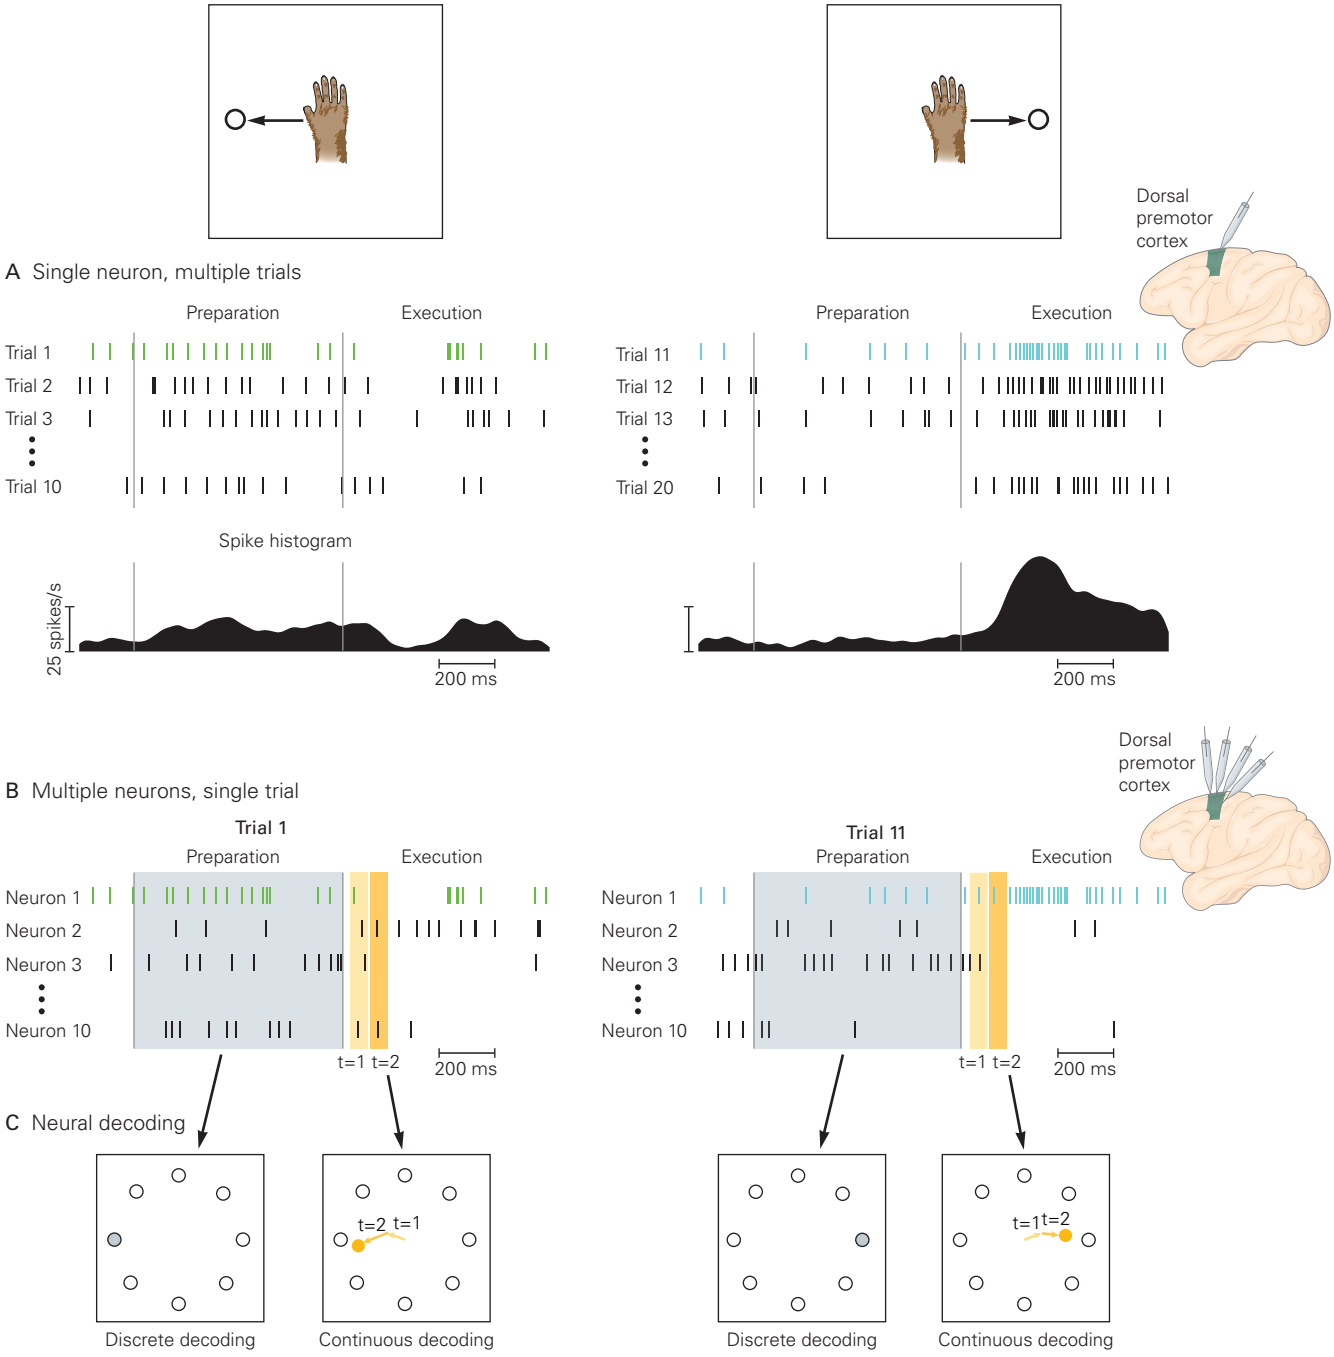

Figure 39–3 **Movement encoding uses the activity of individual neurons averaged across experimental trials, whereas movement decoding uses the activity of many neurons on individual experimental trials.**

A. Activity of one neuron recorded in the dorsal premotor cortex of a monkey preparing and executing leftward arm movements (*left*) and rightward arm movements (*right*). Characterizing the movement encoding of a neuron involves determining how the activity of the neuron on repeated leftward or rightward movements (each row of spike trains) relates to aspects of arm movement. **Below** is the spike histogram for this neuron for leftward and rightward movements, obtained by averaging neural activity across trials. This neuron shows a greater level of preparation activity for leftward movements and a greater level of execution activity for rightward movements. Many neurons in the dorsal premotor cortex and primary motor cortex show movement-related activity in both the preparation and execution epochs like the neuron shown.

B. Neural activity for many neurons recorded in the dorsal premotor cortex for one leftward movement (*left*) and one rightward movement (*right*). The spike trains for neuron 1 correspond to those shown in part **A**. Spike counts are taken during the preparation epoch, typically in a large time bin of 100 ms or longer to estimate movement goal. In contrast, spike counts are taken during the execution epoch typically in many smaller time bins, each lasting tens of milliseconds. Using such short time bins provides the temporal resolution needed to estimate the moment-by-moment details of the movement.

C. Neural decoding involves extracting movement information from many neurons on a single experimental trial. In the subject's workspace, there are eight possible targets (**circles**). Discrete decoding (see Figure 39–5) extracts the target location; the estimated target is filled in with **gray**. In contrast, continuous decoding (see Figure 39–6) extracts the moment-by-moment details of the movement; the **orange dot** represents the estimated position at one moment in time.

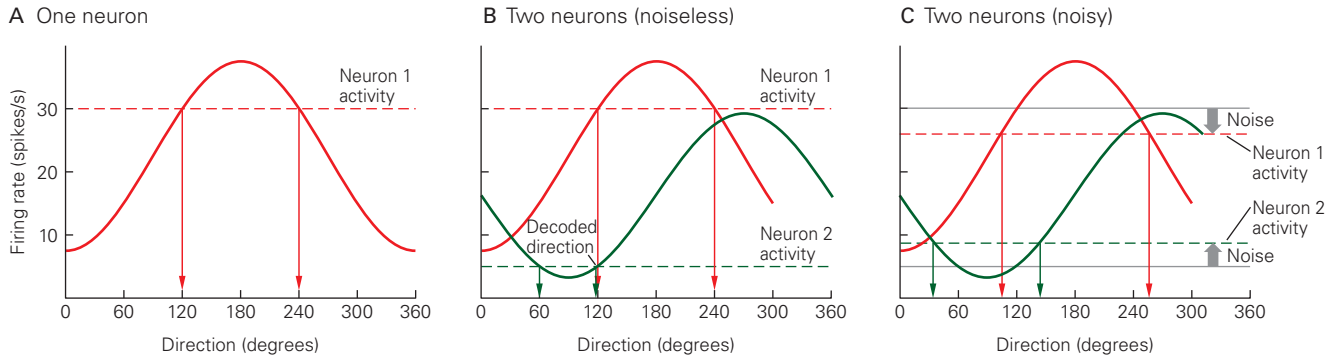

Figure 39–4 More than one neuron is needed for accurate movement decoding.

A. The tuning curve of one neuron defines how the neuron's activity varies with movement direction. If this neuron shows activity of 30 spikes/s, it could correspond to movement in the 120° or 240° direction.

B. A second neuron (**green**) with a different tuning curve shows activity of 5 spikes/s, which could correspond to movement in the 60° or 120° direction. The only movement direction consistent with the activity of both neurons is 120°, which is determined to be the decoded direction.

C. Because neural activity is "noisy" (represented as a vertical displacement of the dashed lines), it is usually not possible to conclusively determine the movement direction from the activity of two neurons. Here, no one movement direction is consistent with the activity of both neurons.

more accurately determined. If the second neuron fires at 5 spikes per second, corresponding to a movement in either the 60° or 120° direction, the only movement direction that is consistent between the two neurons is 120° (Figure 39–4B). Thus, by recording from these two neurons simultaneously, the intended reach direction can be determined more accurately than by recording from one neuron. (However, two neurons do not necessarily provide a perfect estimate of the intended reach direction due to noise, as described next.)

The second reason why decoding a movement from the activity of several neurons gives greater accuracy is because a neuron's activity level usually varies across repeated movements in the same direction. This variability is typically referred to as spiking "noise." Let us say that due to spiking noise the first neuron fires at slightly less than 30 spikes per second and the second neuron fires at slightly more than 5 spikes per second (Figure 39–4C). Under these conditions, no single movement direction is consistent with the activity level of both neurons. Instead, a compromise must be made between the two neurons to determine a movement direction that is as consistent as possible with their activities. By extending this concept to more than two neurons, the movement direction can be decoded even more accurately as the number of neurons increases.

Decoding Algorithms Estimate Intended Movements From Neural Activity

Movement decoders are a central component of BMIs. There are two types of BMI decoders: discrete and continuous (Figure 39–3C). A *discrete decoder* estimates one of several possible movement goals. Each of these movement goals could correspond to a letter on a keyboard. A discrete decoder solves a classification problem in statistics and can be applied to either preparation activity or execution activity. A *continuous decoder* estimates the moment-by-moment details of a movement trajectory. This is important, for example, for reaching around obstacles or turning a steering wheel. A continuous decoder solves a regression problem in statistics and is usually applied to execution activity rather than preparation activity because the moment-by-moment details of a movement can be more accurately estimated from execution activity (Chapter 34).

Motor BMIs must produce movement trajectories as accurately as possible to achieve the desired movement and typically use a continuous decoder to do this. In contrast, communication BMIs are concerned with enabling the individual to transmit information as rapidly as possible. Thus, the speed and accuracy with which movement goals (or keys on a keyboard) can be selected are of primary importance. Communication BMIs can use a discrete decoder to directly select a desired key on a keyboard or a continuous decoder to continuously guide the cursor to the desired key, where only the key eventually struck actually contributes to information conveyance. This seemingly subtle distinction has implications that influence the type of neural activity required and therefore the brain area that is targeted, as well as the type of decoder that is used.

Neural decoding involves two phases: calibration and ongoing use. In the calibration phase, the relationship between neural activity and movement is characterized by a statistical model. This can be achieved by recording neural activity while a paralyzed person attempts to move, imagines moving, or passively observes movements of a computer cursor or robotic limb. Once the relationship has been defined, the statistical model can then be used to decode new observed neural activity (ongoing use phase). The goal during the ongoing use phase is to find the movement that is most consistent with the observed neural activity (Figure 39–4B,C).

Discrete Decoders Estimate Movement Goals

We first define a population activity space, where each axis represents the firing rate of one neuron. On each trial (ie, movement repetition), we can measure the firing rate of each neuron during a specified period, and together they yield one point in the population activity space. Across many trials, involving multiple movement goals, there will be a scatter of points in the population activity space. If the neural activity is related to the movement goal, then the points will be separated in the population activity space according to the movement goal (Figure 39–5A). During the calibration phase, *decision boundaries* that partition the population activity space into different regions are determined by a statistical model. Each region corresponds to one movement goal.

During the ongoing use phase, we measure new neural activity for which the movement goal is unknown (Figure 39–5B). The decoded movement goal is determined by the region in which the neural activity lies. For example, if the neural activity lies within the region corresponding to the leftward target, then the discrete decoder would guess that the subject intended to move to the leftward target on that trial. It is possible that the subject intended to move to the rightward target, even though the recorded activity lies within the region corresponding to the leftward target. In this case, the discrete decoder would incorrectly estimate the subject's intended movement goal. Decoding accuracy typically increases with an increasing number of simultaneously recorded neurons.

Continuous Decoders Estimate Moment-by-Moment Details of Movements

Arm position, velocity, acceleration, force, and other aspects of arm movement can be decoded using the methods described here with varying levels of accuracy. For concreteness, we will discuss decoding movement velocity because it is one of the quantities most strongly reflected in the activity of motor cortical

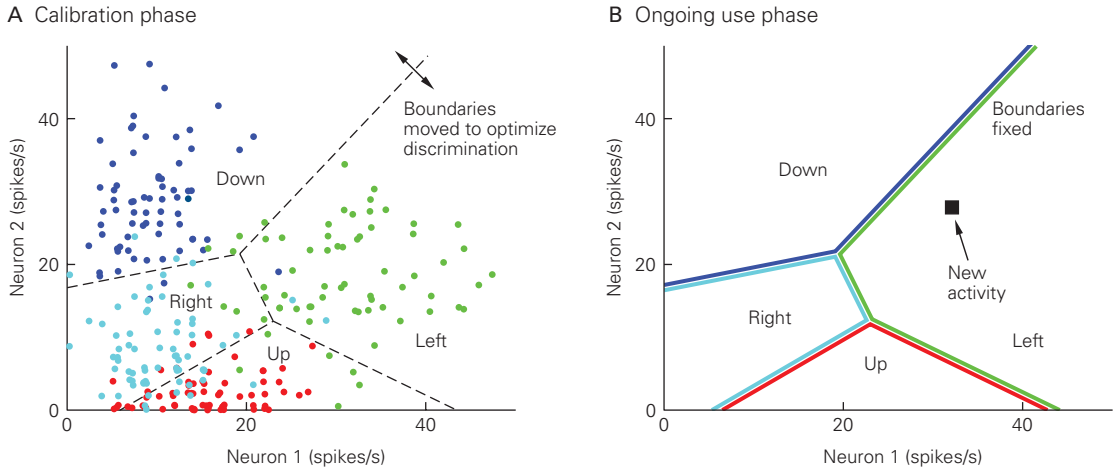

Figure 39–5 Discrete decoding.

A. Calibration phase. A population activity space is shown for two neurons, where each axis represents the firing rate of one neuron. On each trial (ie, movement repetition), the activity of the two neurons together defines one point in the population activity space. Each point is colored by the movement goal, which is known during the calibration phase. Decision boundaries (**dashed lines**) are determined by a statistical model to optimize discrimination among the movement goals. The decision boundaries define a region in the population activity space for each movement goal.

B. Ongoing use phase. During this phase, the decision boundaries are fixed. If we record new neural activity (**square**) for which the movement goal is unknown, the movement goal is determined by the region in which the neural activity lies. In this case, the neural activity lies in the region corresponding to the leftward target, so the decoder would guess that the subject intended to move to the leftward target.

neurons and is the starting point for the design of most BMI systems.

Consider a population of neurons whose level of activity indicates the movement velocity (ie, speed and direction). During the calibration phase, a "pushing vector" is determined for each neuron (Figure 39–6A). A pushing vector indicates how a neuron's activity influences movement velocity. Various continuous decoding algorithms differ in how they determine the pushing vectors. One of the earliest decoding algorithms, the population vector algorithm (PVA), assigns each neuron's pushing vector to point along the neuron's preferred direction (see Figure 34–22A). A neuron's preferred direction is defined as the direction of movement for which the neuron shows the highest level of activity (ie, peak of curves in Figure 39–4). Much of the pioneering work on BMIs used the PVA. However, the PVA does not take into account the properties of the spiking noise (ie, its variance and covariance across neurons), which influences the accuracy of the decoded movements. A more accurate decoder, the optimal linear estimator (OLE), incorporates the properties of the spiking noise to determine the pushing vectors.

During the ongoing use phase, the pushing vectors are each scaled by the number of spikes emitted by the corresponding neuron at each time step (Figure 39–6B). At each time step, the decoded movement is the vector sum of the scaled pushing vectors across all neurons. The decoded movement represents a change in position during one time step (ie, velocity). The BMI cursor (or limb) position (Figure 39–6C) is then updated according to the decoded movement.

To further improve decoding accuracy, the estimation of velocity at each time step should take into account not only current neural activity (as illustrated in Figure 39–6), but also neural activity in the recent past. The rationale is that movement velocity (and other kinematic variables) changes gradually over time, and so neural activity in the recent past should be informative about the movement velocity. This can be achieved by temporally smoothing the neural activity before applying a PVA or OLE or by using a Kalman filter to define a statistical model describing how movement velocity (or other kinematic variables) changes smoothly over time. With a Kalman filter, the estimated velocity is a combination of the scaled pushing vectors at the current time step (as in Figure 39–6B) and the estimated velocity at the previous time step. Indeed, continuous decoding algorithms that take into account neural activity in the recent past have been shown to provide higher decoding accuracy than those that do not. The Kalman filter and its extensions are widely used in BMIs and among the most accurate continuous decoding algorithms available.

Increases in Performance and Capabilities of Motor and Communication BMIs Enable Clinical Translation

Patients with paralysis wish to perform activities of daily living. For people with ALS or upper spinal cord injury who are unable to speak or to move their arms, the most desired tasks are often the ability to communicate, to move a prosthetic (robotic) arm, or to move the paralyzed arm by stimulating the musculature. Having described how neural signals can be read out from motor areas of the brain and how these electrical signals can be decoded to arrive at BMI control signals, we now describe recent progress toward restoring these abilities.

The majority of laboratory studies are carried out in able-bodied nonhuman primates, although paralysis is sometimes transiently induced in important control experiments. Three types of experimental paradigms are in broad use, differing in the exact way in which arm behavior is instructed and visual feedback is provided during BMI calibration and ongoing use. Setting

Figure 39–6 (Opposite) Continuous decoding.

A. During the calibration phase, a pushing vector is determined for each of 97 neurons. Each vector represents one neuron and indicates how one spike from that neuron drives a change in position per time step (ie, velocity). Thus, the units of the plot are millimeters per spike during one time step. Different neurons can have pushing vectors of different magnitudes and directions.

B. During ongoing use, spikes are recorded from the same neurons as in panel A during movement execution. At each time step, the new length of an arrow is obtained by starting with its previous length in panel A and scaling it by the number of spikes produced by the neuron of the same color during that time step. If a neuron does not fire, there is no arrow for that neuron during that time step. The decoded movement (**black arrow**) is the vector sum of the scaled pushing vectors, representing a change in position during one time step (ie, velocity). For a given neuron, the direction of its scaled pushing vectors is the same across all time steps. However, the magnitudes of the scaled pushing vectors can change from one time step to the next depending on the level of activity of that neuron.

C. The decoded movements from panel B are used to update the position of a computer cursor (**orange dot**), robotic limb, or paralyzed limb at each time step.

these differences aside, we focus below on how BMIs function and perform. We also highlight recent pilot clinical trials with people with paralysis.

Subjects Can Type Messages Using Communication BMIs

To investigate how quickly and accurately a communication BMI employing a discrete decoder and preparation activity can operate, monkeys were trained to fixate and touch central targets and prepare to reach to a peripheral target that could appear at one of several different locations on a computer screen. Spikes were recorded using electrodes implanted in the premotor cortex. The number of spikes occurring during a particular time window during the preparation epoch was used to predict where the monkey was preparing to reach (Figure 39–7A). If the decoded target matched the peripheral target, a liquid reward was provided to indicate a successful trial.

By varying the duration of the period in which spike counts are taken and the number of possible targets, it was possible to assess the speed and accuracy of target selections (Figure 39–7B). Decoding accuracy tended to increase with the period in which spike counts are taken because spiking noise is more easily averaged out in longer periods.

An important metric for efficient communication is information transfer rate (ITR), which measures how much information can be conveyed per unit time. A basic unit of information is a bit, which is specified by a binary value (0 or 1). For example, with three bits of information, one can specify which of $2^3 = 8$ possible targets or keys to press. Thus, the metric for ITR is bits per second (bps). ITR increases with the period in which spike counts are taken, then declines. The reason is that ITR takes into account both how accurately and how quickly each target is selected. Beyond some point of diminishing returns of a longer period, accuracy fails to increase rapidly enough to overcome the slowdown in target-selection rate accompanying a longer period.

Overall performance (ITR) increases with the number of possible targets, despite a decrease in decoding accuracy, because each correct target selection conveys more information. Fast and accurate communication

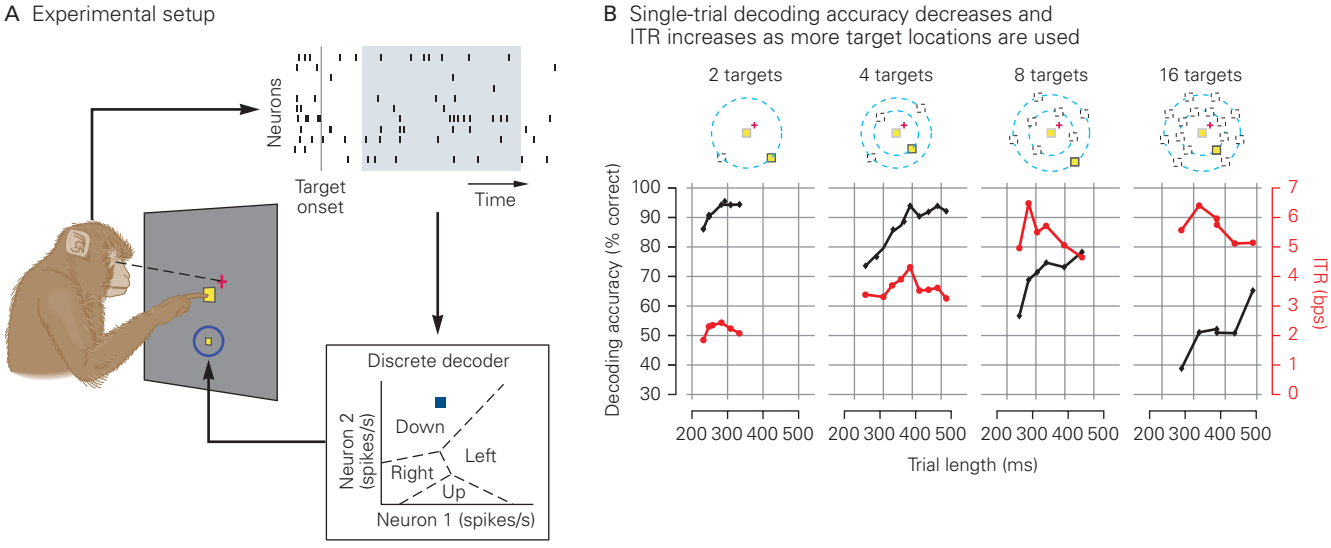

Figure 39–7 A communication brain–machine interface can control a computer cursor using a discrete decoder based on neural activity during the preparation epoch.

A. After a monkey touched a central target (**large yellow square**) and fixated a central point (**red +**), a peripheral target (**small yellow square**) appeared and the monkey prepared to reach to it. Spike counts were taken during the preparation epoch and fed into a discrete decoder. The duration of the period in which spike counts are taken (ie, width of **light blue** shading) affects decoding performance and information transfer rate (**ITR**) (see panel **B**). Based on the spike counts (**blue square**), the discrete decoder guessed the target the monkey was preparing to reach to.

B. Decoding accuracy (**black**) and information transfer rate (**ITR, bits/s; red**) are shown for different trial lengths and numbers of targets. Trial length was equal to the duration of the period in which spike counts were taken (varied during the experiment) plus 190 ms (fixed during the experiment). The latter provided time for visual information of the peripheral target to reach the premotor cortex (150 ms), plus the time to decode the target location from neural activity and render the decoded target location on the screen (40 ms). (Adapted, with permission, from Santhanam et al. 2006.)

has been demonstrated in BMIs with this design based on a discrete decoder applied to preparatory activity. The ITR of this BMI is approximately 6.5 bps, which corresponds to approximately two to three targets per second with greater than 90% accuracy.

Recent studies have also investigated how quickly and accurately a communication BMI employing a continuous decoder and execution activity can operate. Two different types of continuous decoders were evaluated: a standard Kalman filter decoding movement velocity (V-KF) and a recalibrated feedback intention-trained Kalman filter (ReFIT-KF). The V-KF was calibrated using the neural activity recorded during actual arm movements (ie, open-loop control). The ReFIT-KF incorporated the closed-loop nature of BMIs into decoder calibration by assuming that the user desired to move the cursor straight to the target at each time step.

To assess performance, both types of decoders were used in closed-loop BMI control (Figure 39–8A). Monkeys were required to move a computer cursor from a central location to eight peripheral locations and back. A gold standard for performance evaluation was established by having the monkeys also perform the same task using arm movements. The ReFIT-KF outperformed the V-KF in several ways: Cursor movements using ReFIT-KF were straighter, producing less movement away from a straight line to the target; cursor movements were faster, approaching the speed of arm movements (Figure 39–8B); and there were fewer (potentially frustrating) long trials.

Given its performance benefits, the ReFIT-KF is being used in clinical trials by people with paralysis (Figure 39–8C). Spiking activity was recorded using a 96-channel electrode array implanted in the hand control area of the left motor cortex. Signals were filtered to extract action potentials and high-frequency local field potentials, which were decoded to provide "point-and-click" control of the BMI-controlled cursor. The subject was seated in front of a computer monitor and was asked, "How did you encourage your sons to practice music?" By attempting to move her right hand, the computer cursor moved across the screen and stopped over the desired letter. By attempting to squeeze her left hand, the letter beneath the cursor was selected, much like clicking a mouse button.

BMI performance in the clinical trials was assessed by measuring the number of intended characters subjects were able to type (Figure 39–8D). Subjects were able to demonstrate that the letters they typed were intended by using the delete key to erase occasional mistakes. These clinical tests showed that it is possible to type at a rate of many words per minute using a BMI.

Subjects Can Reach and Grasp Objects Using BMI-Directed Prosthetic Arms

Patients with paralysis would like to pick up objects, feed themselves, and generally interact physically with the world. Motor BMIs with prosthetic limbs aim to restore this lost motor functionality. As before, neural activity is decoded from the brain but is now routed to a robotic arm where the wrist is moved in three dimensions (x, y, and z) and the hand is moved in an additional dimension (grip angle, ranging from an open hand to a closed hand).

In one test of a robotic arm, a patient with paralysis was able to use her neural activity to direct the robotic arm to reach out, grab a bottle of liquid, and bring it to her mouth (Figure 39–9). The three-dimensional reaches and gripping were slower and less accurate than natural arm and hand movements. Importantly, this demonstrated that the same BMI paradigm originally developed with animals, including measuring and decoding signals from motor cortex, works in people even years after the onset of neural degeneration or the time of neural injury.

BMI devices directing prosthetic arms and hands are now able to do more than just control three-dimensional movement or open and close the hand. They can also orient the hand and grasp, manipulate, and carry objects. A person with paralysis was able to move a prosthetic limb with 10 degrees of freedom to grasp objects of different shapes and sizes and move them from one place to another (Figure 39–10). Completion times for grasping and moving objects were considerably slower than natural arm movements, but the results are encouraging. These studies illustrate the existing capabilities of prosthetic arms and also the potential for even greater capabilities in the future.

Subjects Can Reach and Grasp Objects Using BMI-Directed Stimulation of Paralyzed Arms

An alternative to using a robotic arm is to restore lost motor function to the biological arm. Arm paralysis results from the loss of neural signaling from the spinal cord and brain, but the muscles themselves are often still intact and can be made to contract by electrical stimulation. This capacity underlies functional electrical stimulation (FES), which sends electrical signals via internal or external electrodes to a set of muscle groups. By shaping and timing the electrical signals sent to the different muscle groups, FES is able to move the arm and hand in a coordinated fashion to pick up objects.

Laboratory studies in monkeys have demonstrated that this basic approach is viable in principle.

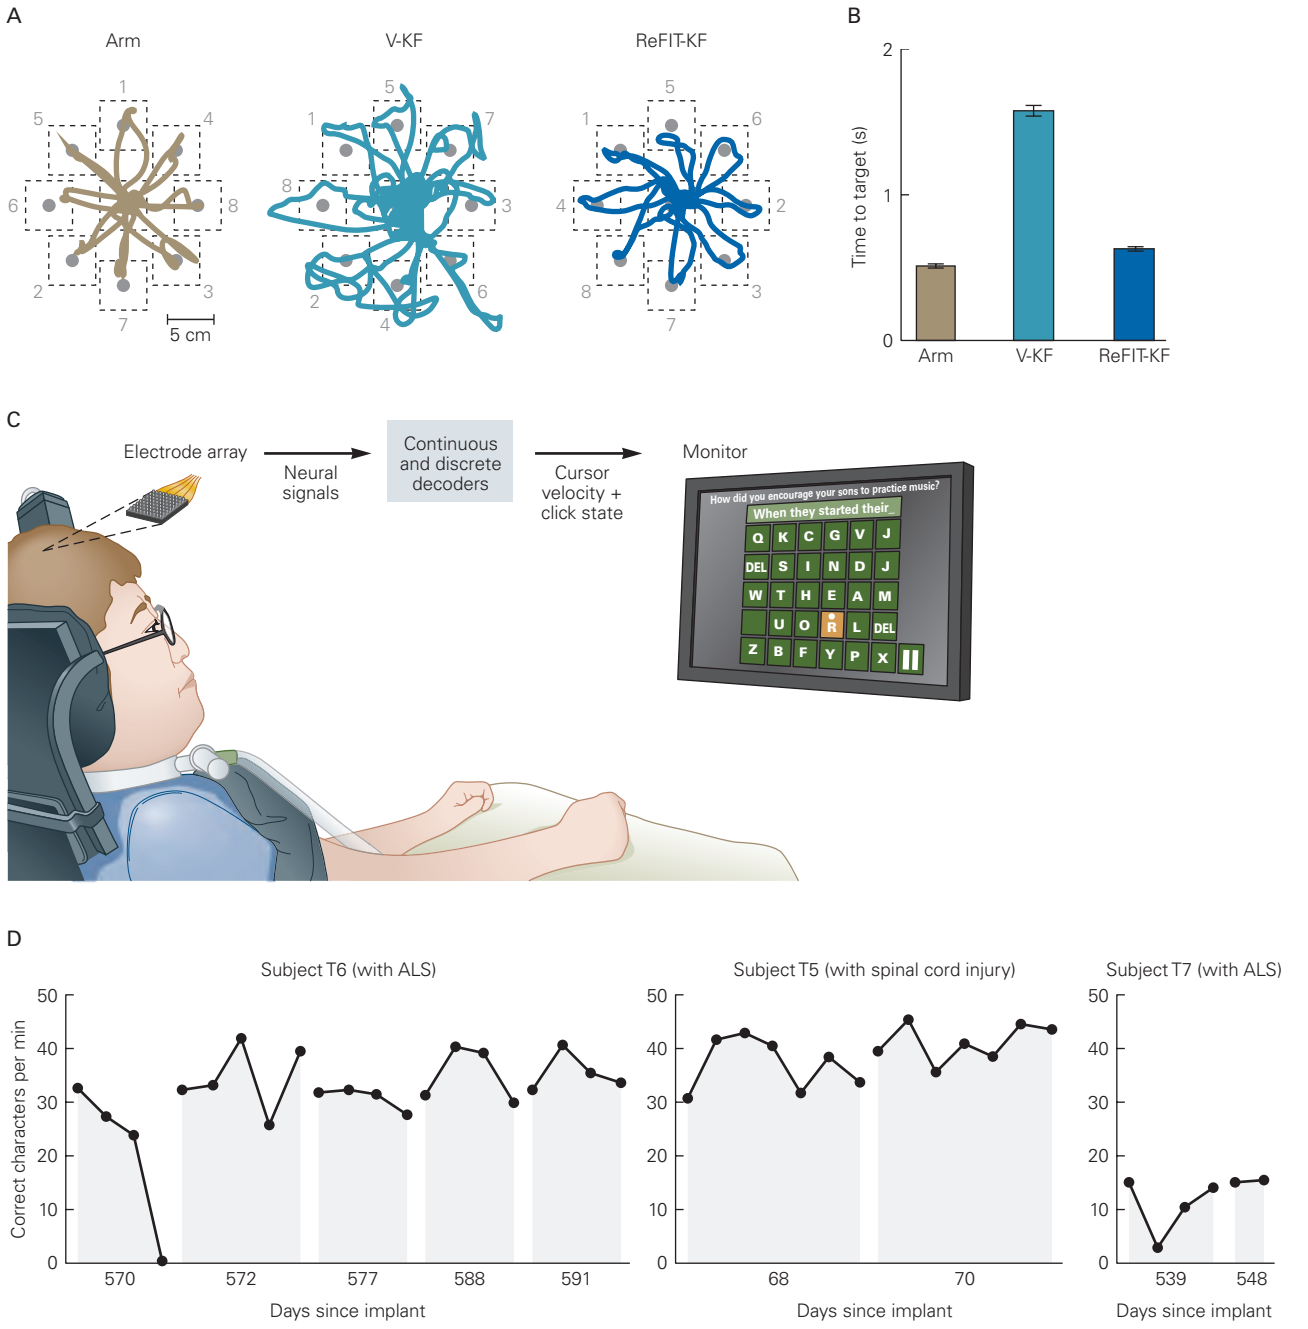

Figure 39–8 A communication brain–machine interface (BMI) can control a computer cursor using a continuous decoder based on neural activity during the execution epoch.

A. Comparison of cursor control by a monkey using its arm, a standard decoder that estimates velocity (BMI with Kalman filter decoding movement velocity [**V-KF**]), and a feedback intention-trained decoder (BMI with recalibrated feedback intention-trained Kalman filter [**ReFIT-KF**]). Traces show cursor movements to and from targets alternating in the sequence indicated by the numbers shown. Traces are continuous for the duration of all reaches. (Adapted, with permission, from Gilja et al. 2012.)

D. Performance in a typing task for three clinical trial participants. Performance can be sustained across days or even years after array implantation. (Adapted, with permission, from Pandarinath et al. 2017.)

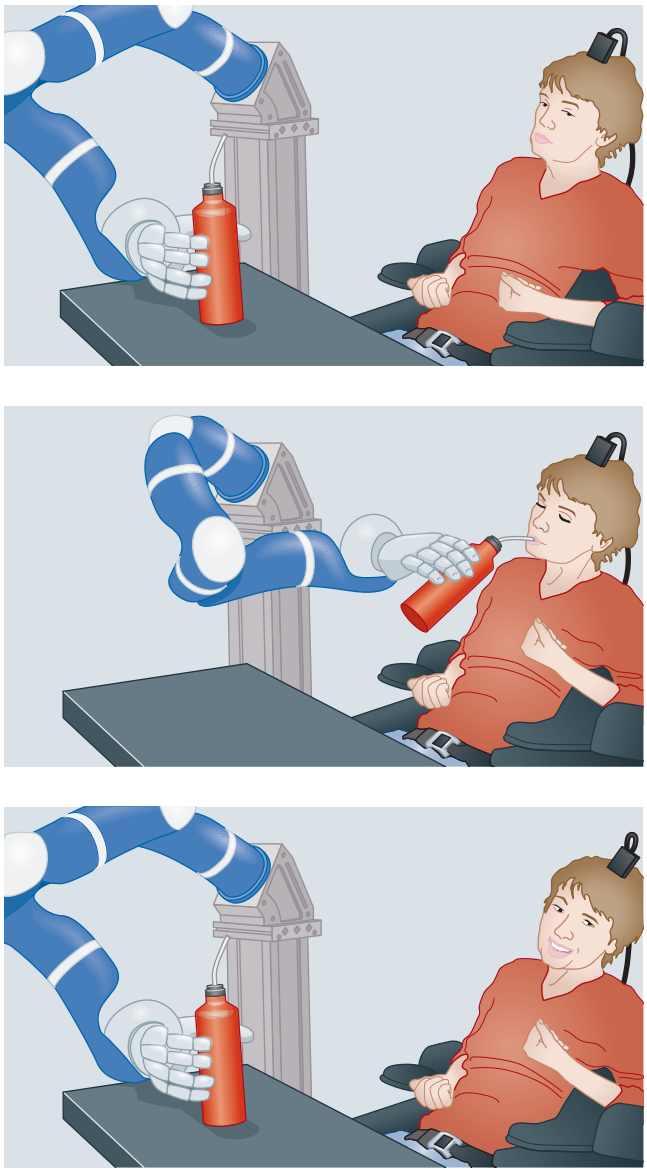

Figure 39–9 A subject with paralysis drinks from a bottle using a robotic arm controlled by a motor brain–machine interface using a continuous decoder. Three sequential images from the first successful trial show the subject using the robotic arm to grasp the bottle, bring it to her mouth and drink coffee through a straw, and place the bottle back on the table. (Adapted from Hochberg et al. 2012.)

It is implemented by calibrating a continuous decoder to predict the intended activity of each of several of the muscles, transiently paralyzed with a nerve block. These predictions are then used to control the intensity of stimulation of the same paralyzed muscles, which in turn controls motor outputs such as a grip angle and force. This process in effect bypasses the spinal cord and restores some semblance of voluntary control of the paralyzed arm and hand. Similar results have recently been demonstrated in patients with paralysis using either externally applied or fully implanted state-of-the-art FES electrodes. Intracortically recorded signals from motor cortex were decoded to restore movement via FES in a person with upper spinal cord injury (Figure 39–11). The subject was able to achieve control of different wrist and hand motions, including finger movements, and perform various activities of daily living.

Subjects Can Use Sensory Feedback Delivered by Cortical Stimulation During BMI Control

During arm movements, we rely on multiple sources of sensory feedback to guide the arm along a desired path or to a desired goal. These sources include visual, proprioceptive, and somatosensory feedback. However, in most current BMI systems, the user receives only visual feedback about the movements of the computer cursor or robotic limb. In patients with normal motor output pathways but lacking proprioception, arm movements are substantially less accurate than in healthy individuals, both in terms of movement direction and extent. Furthermore, in tests of BMI cursor control in healthy nonhuman primate subjects, the arm continues to provide proprioceptive feedback even though arm movements are not required to move the cursor. BMI cursor control is more accurate when the arm is passively moved together with the BMI cursor along the same path, rather than along a different path. This demonstrates the importance of "correct" proprioceptive feedback. Based on these two lines of evidence, it is perhaps not surprising that BMI-directed movements relying solely on visual feedback are slower and less accurate than normal arm movements. This has motivated recent attempts to demonstrate how providing surrogate (ie, artificial) proprioceptive or somatosensory feedback can improve BMI performance.

Several studies have attempted to write in sensory information by stimulating the brain using cortical electrical microstimulation. Laboratory animals can discriminate current pulses of different frequencies and amplitudes, and this ability can be utilized to provide proprioceptive or somatosensory information in BMIs by using different pulse frequencies to encode different physical locations (akin to proprioception) or different textures (akin to somatic sensation). Electrical microstimulation in the primary somatosensory cortex can be used by nonhuman primates to control a cursor on a moment-by-moment basis without vision. In these subjects, the use of electrical microstimulation

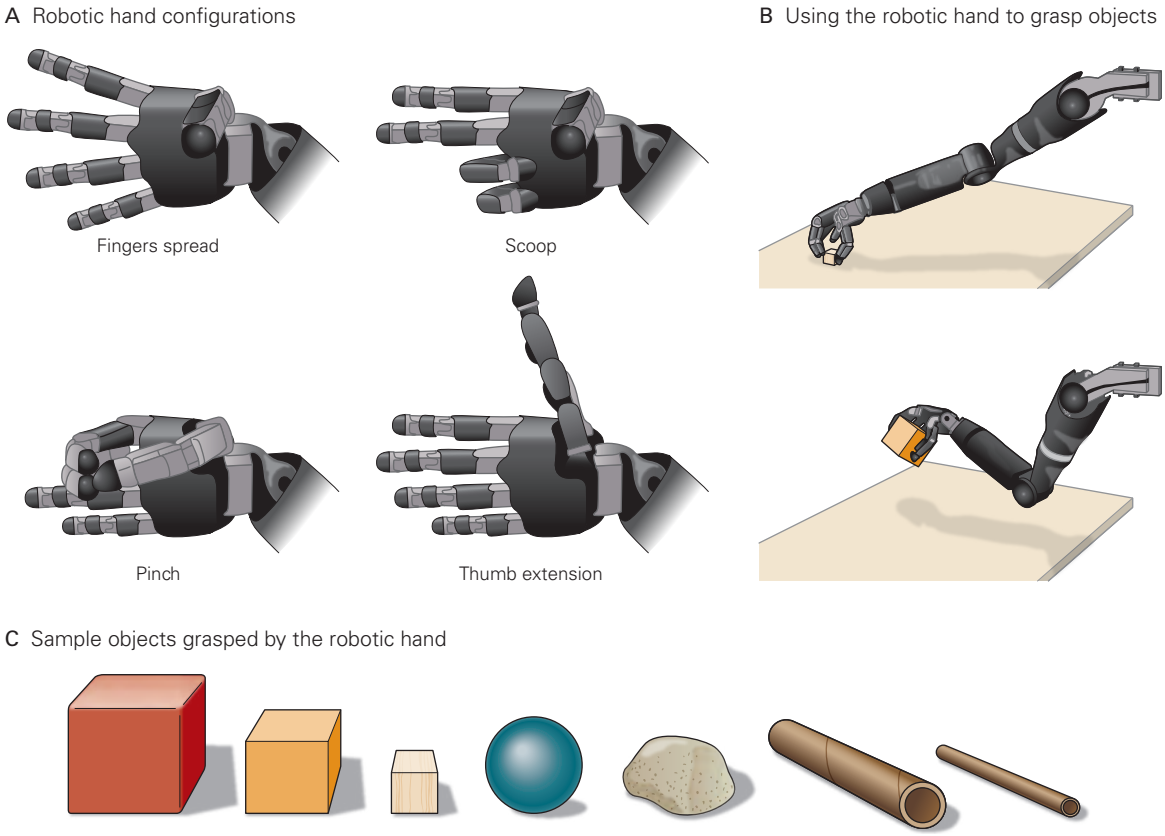

Figure 39–10 A motor brain–machine interface (BMI) can control a prosthetic arm with 10 degrees of freedom.

A. Examples of different hand configurations directed by the BMI. The 10 degrees of freedom are three-dimensional arm translation, three-dimensional wrist orientation, and four-dimensional hand shaping.

B. A subject uses the prosthetic arm to pick up an object and move it.

C. Objects of different shapes and sizes are used to test the generalization ability of the BMI. (Adapted from Wodlinger et al. 2015.)

and visual feedback together led to more accurate movements than either type of sensory feedback alone.

Furthermore, electrical microstimulation in the primary somatosensory cortex can also be used to provide tactile information. Nonhuman primates moved a BMI-directed cursor under visual feedback to hit different visual targets, each of which elicited a different stimulation frequency. Subjects learned to use differences in the stimulation feedback to distinguish the rewarded target from the unrewarded targets. This demonstrates that electrical microstimulation can also be used to provide somatosensory feedback during BMI control.

Finally, surrogate somatosensory information was delivered via electrical microstimulation to a person with paralysis and compromised sensory afferents. The person reported naturalistic sensations at different locations of his hand and fingers corresponding to different locations of stimulation in the primary somatosensory cortex.

BMIs Can Be Used to Advance Basic Neuroscience

BMIs are becoming an increasingly important experimental tool for addressing basic scientific questions about brain function. For example, cochlear implants have provided insight into how the brain processes sounds and speech, how the development of these mechanisms is shaped by language acquisition, and how neural plasticity allows the brain to interpret a few channels of stimulation carrying impoverished auditory information. Similarly, motor and communication BMIs are helping to elucidate the neural mechanisms underlying sensorimotor control. Such scientific findings can then be used to refine the design of BMIs.

The key benefit of BMIs for basic science is that they can simplify the brain's input and output interface with the outside world, without simplifying the complexities of brain processing that one wishes to study.

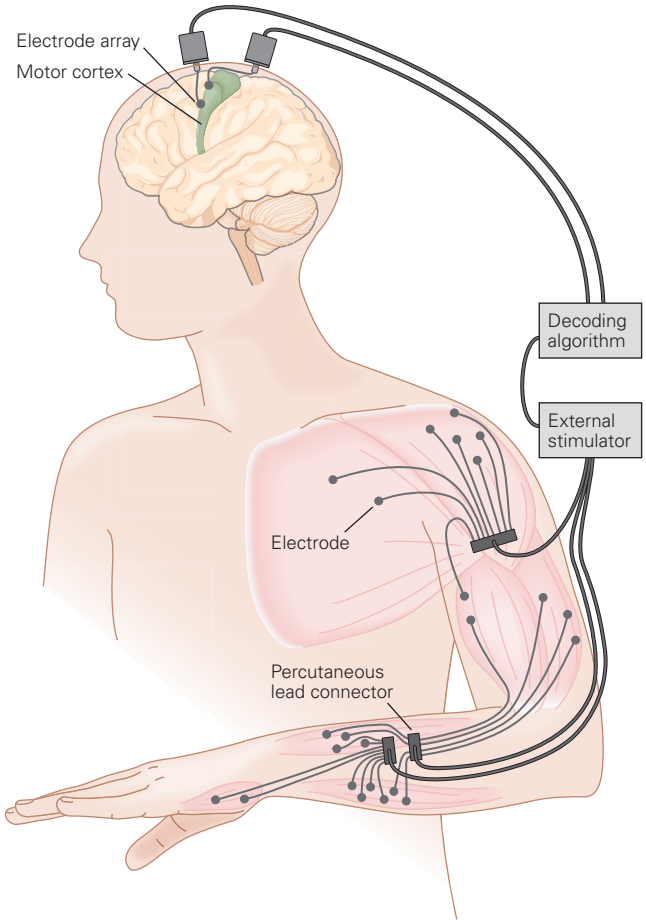

Figure 39–11 A motor brain–machine interface (BMI) can control the muscles of a paralyzed arm using a continuous decoder and functional electrical stimulation. Neural activity recorded in the motor cortex is decoded into command signals that control the stimulation of deltoid, pectoralis major, biceps, triceps, forearm, and hand muscles. This enables cortical control of whole-arm movements and grasping. Muscle stimulation is performed through percutaneous intramuscular fine-wire electrodes. (Adapted, with permission, from Ajiboye et al. 2017. Copyright © 2017 Elsevier Ltd.)

To illustrate this point, consider the output interface of the brain for controlling arm movements. Thousands of neurons from the motor cortex and other brain areas send signals down the spinal cord and to the arm, where they activate muscles that move the arm. Understanding how the brain controls arm movement is challenging because one can typically record from only a small fraction of the output neurons that send signals down the spinal cord, the relationship between the activity of the output neurons and arm movements is unknown, and the arm has nonlinear dynamics that are difficult to measure. Furthermore, it is usually difficult to determine which recorded neurons are output neurons.

One way to ease this difficulty is to use a BMI. Because of the way a BMI is constructed, only those neurons that are recorded can directly affect the movement of the cursor or robotic limb. Neurons throughout the brain are still involved, but they can influence the cursor movements only indirectly through the recorded neurons. Thus, in contrast to arm and eye movement studies, one can record from the entire set of output neurons in a BMI, and BMI-directed movements can be causally attributed to specific changes in the activity of the recorded neurons. Furthermore, the mapping between the activity of the recorded neurons and cursor movement is defined by the experimenter, so it is fully known. This mapping can be defined to be simple and can be easily altered by the experimenter during an experiment. In essence, a BMI defines a simplified sensorimotor loop, whose components are more concretely defined and more easily manipulated than for arm or eye movements.

These advantages of BMIs allow for studies of brain function that are currently difficult to perform using arm or eye movements. For example, one class of studies involves using BMIs to study how the brain learns. The BMI mapping defines which population activity patterns will allow the subject to successfully move the BMI-directed cursor to hit visual targets. By defining the BMI mapping appropriately, the experimenter can challenge the subject's brain to produce novel neural activity patterns.

A recent study explored what types of activity patterns are easier and more difficult for the brain to generate. They found that it was easier for subjects to learn new associations between existing activity patterns and cursor movements than to generate novel activity patterns. This finding has implications for our ability to learn everyday skills. A second class of studies involves asking how the activity of neurons that directly control movement differ from those that do not directly control movement. In a BMI, one can choose to use only a subset of the recorded neurons (the output neurons) for controlling movements. At the same time, other neurons (the nonoutput neurons) can be passively monitored without being used for controlling movements. Comparing the activity of output and nonoutput neurons can provide insight into how a network of neurons internally processes information and relays only some of that information to other networks.

Using this paradigm, a recent study recorded neural activity simultaneously in the primary cortex and striatum and designated a subset of the M1 neurons as the output neurons for controlling the BMI. They found that, during BMI learning, M1 neurons that were most relevant for behavior (the output neurons) preferentially increased their coordination with the striatum, which is known to play an important role during natural behavior (Chapter 38). Identifying output versus nonoutput neurons in a study using arm or eye movements would be challenging.

BMIs Raise New Neuroethics Considerations

A growing number of biomedical ethics considerations centered on the brain have arisen from the dramatic expansion in our understanding of neuroscience and our capabilities with neurotechnology. These advances are driven by society's curiosity about the functioning of the brain, the least-well understood organ in the body, as well as the desire to address the massive unmet need of those suffering from neurological disease and injury. The use of BMIs raises new ethical questions for four principal reasons.

First, recording high-fidelity signals (ie, spike trains) involves risk, including the risks associated with initial implantation of the electrodes as well as possible biological (immunological or infectious) responses during the lifetime of the electrodes and the associated implanted electronics. Electrodes implanted for long periods currently have functional lifetimes on the order of many months to a few years, during which time glial scar tissue can form around the electrodes and electrode materials can fail. Efforts to increase the functional lifetime of electrodes range from nanoscale flexible electrodes made with new materials to mitigating immunological responses, as is done with cardiac stents.

For these reasons, patients considering receiving implanted recording technologies will need to evaluate the risks and benefits of a BMI, as is the case for all medical interventions. It is important for patients to have options, as each person has personal preferences involving willingness to undergo surgery, desire for functional restoration and outcome, and cosmesis—be it while deliberating cancer treatment or BMI treatment. BMIs based on different neural sensors (Figure 39–2) have different risks and benefits.

Second, because BMIs can read out movement information from the brain at fine temporal resolution, it seems plausible that they will be able to read out more personal and private types of information as well. Future neuroethics questions that may arise as the technology becomes more sophisticated include whether it is acceptable, even with patient consent, to read out memories that may otherwise be lost to Alzheimer disease; promote long-term memory consolidation by recording fleeting short-term memories and playing them back directly into the brain; read out subconscious fears or emotional states to assist desensitization psychotherapy; or read out potential intended movements, including speech, that would not naturally be enacted.

Third, intracortical write-in BMIs, similar to DBS systems currently used to reduce tremor, may one day evoke naturalistic spatial-temporal activity patterns across large populations of neurons. In the extreme it may not be possible for a person to distinguish self-produced and volitional neural activity patterns from artificial or surrogate patterns. Although there are numerous therapeutic and beneficial reasons for embracing this technology, such as reducing tremor or averting an epileptic seizure, more dubious uses can be envisioned such as commandeering a person's motor, sensory, decision making, or emotional valence circuits.

Finally, ethical questions also involve the limits within which BMIs should operate. Current BMIs focus on restoring lost function, but it is possible for BMIs to be made to enhance function beyond natural levels. This is as familiar as prescribing a pair of glasses that confer better than normal vision, or overprescribing a pain medication, which can cause euphoria that is often addictive. Should BMIs be allowed, if and when it becomes technically possible,

to move a robotic arm faster and more accurately than a native arm? Should continuous neural recordings from BMIs, covering hours, days, or weeks, be saved for future analysis, and are the security and privacy issues the same or different from personal genomics data? Should BMIs with preset content be available for purchase, for example, to skip a grade of mathematics in high school? Should an able-bodied person be able to elect to receive an implanted motor BMI? While the safe and ethical limits of such sensory, motor, and cognitive BMI treatments might seem readily apparent, society continues to wrestle with these same questions concerning other currently available medical treatments. These include steroids that enhance musculature, energy drinks (eg, caffeine) that enhance alertness, and elective plastic surgery that alters appearance.

Although many of these ideas and questions may appear far-fetched at present, as mechanisms of brain function and dysfunction continue to be revealed, BMI systems could build on these discoveries and create even more daunting ethical quandaries. But equally important is the immediate need to help people suffering from profound neurological disease and injury through restorative BMIs. In order to achieve the right balance, it is imperative that physicians, scientists, and engineers proceed in close conversation and partnership with ethicists, government oversight agencies, and patient advocacy groups.

Highlights

1. Brain–machine interfaces (BMIs) are medical devices that read out and/or alter electrophysiological activity at the level of populations of neurons. BMIs can help to restore lost sensory, motor, or brain processing capabilities, as well as regulate pathological neural activity.
2. BMIs can help to restore lost sensory capabilities by stimulating neurons to convey sensory information to the brain. Examples include cochlear implants to restore audition or retinal prostheses to restore vision.
3. BMIs can help to restore lost motor capabilities by measuring the activity from many individual neurons, converting this neural information into control signals, and guiding a paralyzed limb, robotic limb, or computer cursor.
4. Whereas motor BMIs aim to provide control of a robotic limb or paralyzed limb, communication BMIs aim to provide a fast and accurate interface with a computer or other electronic devices.
5. BMIs can help to regulate pathological neural activity by measuring neural activity, processing the neural activity, and subsequently stimulating neurons. Examples include deep brain stimulators and antiseizure systems.
6. Neural signals can be measured using different technologies, including electroencephalography, electrocorticography, and intracortical electrodes. Intracortical electrodes record the activity of neurons near the electrode tip and can also be used to deliver electrical stimulation.
7. To study movement encoding, one usually considers the activity of an individual neuron across many experimental trials. In contrast, for movement decoding, one needs to consider the activity of many neurons across an individual experimental trial.
8. A discrete decoder estimates one of several possible movement goals from neural population activity. In contrast, a continuous decoder estimates the moment-by-moment details of a movement from neural population activity.
9. The field is making substantial progress in increasing the performance of BMIs, measured in terms of the speed and accuracy of the estimated movements. It is now possible to move a computer cursor in a way that approaches the speed and accuracy of arm movements.
10. In addition to controlling computer cursors, BMIs can also guide a robotic limb or a paralyzed limb using functional electrical stimulation. Developments from preclinical experiments with able-bodied, nonhuman primates have subsequently been tested in clinical trials with paralyzed people.
11. Future advances of BMI will depend, in part, on developments in neurotechnology. These include advances in hardware (eg, neural sensors and low-power electronics), software (eg, supervisory systems), and statistical methods (eg, decoding algorithms).
12. An important direction for improving BMI performance is to provide the user with additional forms of sensory feedback in addition to visual feedback. An area of current investigation uses stimulation of neurons to provide surrogate sensory feedback, representing somatosensation and proprioception, during ongoing use.
13. Beyond helping paralyzed patients and amputees, BMI is being increasingly used as a tool for understanding brain function. BMIs simplify the brain's input and output interfaces and allow the experimenter to define a causal relationship between neural activity and movement.

14. BMIs raise new neuroethics questions, which need to be considered together with the benefits provided by BMIs to people with injury or disease.

VI The Biology of Emotion, Motivation, and Homeostasis

Emotional and homeostatic behaviors all involve the coordination of one or more somatic, autonomic, hormonal, or cognitive processes. Subcortical brain regions concerned with a range of functions—including feeding, drinking, heart rate, breathing, temperature regulation, sleep, sex, and facial expressions—play a critical role in this coordination. Subcortical brain regions are bidirectionally connected with cortical brain areas, providing a means for reperesentations of internal state variables (eg, visceral information) to influence cognitive operations, such as subjective feelings, decision-making, and attention, and for cognitive functions to regulate or extinguish neural representations in subcortical brain areas that help coordinate behavior reflecting emotional states.

Our consideration of these systems begins with the brain stem, a structure critical for wakefulness and conscious attention on the one hand and sleep on the other. The significance of this small region of the brain—located between the spinal cord and the diencephalon—is disproportionate to its size. Damage to the brain stem can profoundly affect motor and sensory processes because it contains all of the ascending tracts that bring sensory information from the surface of the body to the cerebral cortex and all of the descending tracts from the cerebral cortex that deliver motor commands to the spinal cord. Finally, the brain stem contains neurons that control respiration and heartbeat as well as nuclei that give rise to most of the cranial nerves that innervate the head and neck.

Six neurochemical modulatory systems in the brain stem modulate sensory, motor, and arousal systems. The dopaminergic pathways that connect the midbrain to the limbic system and cortex are particularly important, because they are involved in processing stimuli and events in relation to reinforcement expectation, and therefore contribute to motivational state and learning. Addictive drugs such as nicotine, alcohol, opiates, and cocaine are thought to produce their actions by co-opting the same neural pathways that positively reinforce behaviors essential for survival. Other modulatory transmitters

regulate sleep and wakefulness, in part by controlling information flow between the thalamus and cortex. Disorders of electrical excitation in corticothalamic circuits can result in seizures and epilepsy.

Rostral to the brain stem lies the hypothalamus, which functions to maintain the stability of the internal environment by keeping physiological variables within the limits favorable to vital bodily processes. Homeostatic processes in the nervous system have profound consequences for behavior that have intrigued many of the founders of modern physiology, including Claude Bernard, Walter B. Cannon, and Walter Hess. Neurons controlling the internal environment are concentrated in the hypothalamus, a small area of the diencephalon that comprises less than 1% of the total brain volume. The hypothalamus, with closely linked structures in the brain stem and limbic system, acts directly on the internal environment, through its control of the endocrine system and autonomic nervous system, to achieve goal-directed behavior. It acts indirectly through its connections to higher brain regions to modulate emotional and motivational states. In addition to influencing motivated behaviors, the hypothalamus, together with the brain stem below and the cerebral cortex above, maintains a general state of arousal, which ranges from excitement and vigilance to drowsiness and stupor.

The neurobiological investigation of emotion has relied on experiments that define emotions in terms of specific measures ranging from subjective reports of feelings in humans, to approach or defensive behaviors, to physiological responses such as autonomic reactivity. Charles Darwin observed in his seminal book *The Expression of the Emotions in Man and Animals* that many emotions are conserved across species, making clear the relevance of studying emotions by using animal models to probe neural mechansisms. In experimental frameworks, emotional states are thereby considered to be central brain states that can cause coordinated behavioral, physiological, and cognitive responses across species.

In recent years, much work on emotion has focused on the amygdala, which can orchestrate different responses via its connections to the cortex, hypothalamus, and brain stem. Lesions of the amygdala in humans impair fear learning and expression, as well as fear recognition in others, due to decreased allocation of attention to features of faces that communicate fear. Symptoms in a variety of psychiatric disorders—ranging from addiction to anxiety to social deficits—likely involve amygdala dysfunction. However, the amygdala is only one component of a larger set of brain regions that includes parts of the hypothalamus, the brain stem, and cortical areas also responsible for coordinating emotional responses. In particular, the medial and ventral prefrontal cortex and amygdala are closely interconnected. Dynamic processing within and between these structures likely subserves many functions beyond coordinated emotional behavior, including extinction, the cognitive regulation of emotional

states, interactions between social and emotional domains, and the influence of the amgydalar representations on decision-making and subjective feelings.

The Brain Stem

In primitive vertebrates—reptiles, amphibians, and fish—the forebrain is only a small part of the brain and is devoted mainly to olfactory processing and to the integration of autonomic and endocrine function with the basic behaviors necessary for survival. These basic behaviors include feeding, drinking, sexual reproduction, sleep, and emergency responses. Although we are accustomed to thinking that the forebrain orchestrates most human behaviors, many complex responses, such as feeding—the coordination of chewing, licking, and swallowing—are actually made up of relatively simple, stereotypic motor responses governed by ensembles of neurons in the brain stem.

The importance of this pattern of organization in human behavior is clear from observing infants born without a forebrain (hydranencephaly). Hydranencephalic infants are surprisingly difficult to distinguish from normal babies. They cry, smile, suckle, and move their eyes, face, arms, and legs. As these sad cases illustrate, the brain stem can organize virtually all of the behavior of the newborn.

In this chapter, we describe the functional anatomy of the brain stem, particularly the cranial nerves, as well as the ensembles of local circuit neurons that organize the simple behaviors of the face and head. Finally, we consider the modulatory functions of nuclei in the brain stem that adjust the sensitivity of sensory, motor, and arousal systems.

The brain stem is the rostral continuation of the spinal cord, and its motor and sensory components are similar in structure to those of the spinal cord. But the portions of the brain stem that control the cranial nerves are much more complex than the corresponding parts of the spinal cord that control the spinal nerves because cranial nerves mediate more complex behaviors. The core of the brain stem, the *reticular formation*, is homologous to the intermediate gray matter of the spinal cord but is also more complex. Like the spinal cord, the reticular formation contains ensembles of local-circuit interneurons that generate motor and autonomic patterns and coordinate reflexes and simple behaviors. In addition, the brain stem contains glutamatergic and GABAergic circuitry that regulates arousal, wake–sleep cycles, breathing, and other vital functions, as well as monoaminergic modulatory neurons that act to optimize the functions of the nervous system.

The Cranial Nerves Are Homologous to the Spinal Nerves

Because the spinal nerves reach only as high as the first cervical vertebra, the cranial nerves provide the somatic and visceral, sensory and motor innervation for the head. Two cranial nerves, the glossopharyngeal and vagus nerves, also supply visceral sensory and motor innervation of the neck, chest, and most of the abdominal organs with the exception of the pelvis. In addition, some cranial nerves are associated with specialized functions, such as vision or hearing, that go beyond the sensory and motor plan of the spinal cord.

Assessment of the cranial nerves is an important part of the neurological examination because abnormalities of function can pinpoint a site in the brain stem that has been damaged. Therefore, it is important to know the origins of the cranial nerves, their intracranial course, and where they exit from the skull.

The cranial nerves are traditionally numbered I through XII in rostrocaudal sequence. Cranial nerves I and II enter at the base of the forebrain. The other cranial nerves arise from the brain stem at characteristic locations (Figure 40–1). All but one exit from the ventral surface of the brain stem (Figure 40–2). The exception is the trochlear (IV) nerve, which leaves the midbrain from its dorsal surface just behind the inferior colliculus and wraps around the lateral surface of the brain stem to join the other cranial nerves concerned with eye movements. The cranial nerves with sensory functions (V, VII, VIII, IX, and X) have associated sensory ganglia that operate much as dorsal root ganglia do for spinal nerves. These ganglia are located along the course of individual nerves as they enter the skull.

The olfactory (I) nerve, which is associated with the forebrain, is described in detail in Chapter 29; the optic (II) nerve, which is associated with the diencephalon, is described in Chapters 21 and 22. The spinal accessory (XI) nerve can be considered a cranial nerve anatomically but actually is a spinal nerve originating from the higher cervical motor rootlets. It runs up into the skull before exiting through the jugular foramen to innervate the trapezius and sternocleidomastoid muscles in the neck.

Cranial Nerves Mediate the Sensory and Motor Functions of the Face and Head and the Autonomic Functions of the Body

Three ocular motor nerves control movements of the eyes. The *abducens (VI) nerve* has the simplest action; it contracts the lateral rectus muscle to move the globe laterally. The *trochlear (IV) nerve* also innervates a single muscle, the superior oblique, which both depresses the eye and rotates it inward depending on the eye's position. The *oculomotor (III) nerve* supplies all of the other muscles of the orbit, including the retractor of the lid. It also provides the parasympathetic innervation responsible for pupillary constriction in response to light and accommodation of the lens for near vision. The ocular motor system is considered in detail in Chapter 35.

The *trigeminal (V) nerve* is a mixed nerve (containing both sensory and motor axons) that leaves the brain stem in two roots. The motor root innervates the muscles of mastication (the masseter, temporalis, and pterygoids) and a few muscles of the palate (tensor veli palatini), inner ear (tensor tympani), and upper neck (mylohyoid and anterior belly of the digastric muscle). The sensory fibers arise from neurons in the trigeminal ganglion, located at the floor of the skull in the middle cranial fossa.

Three branches emerge from the trigeminal ganglion. The *ophthalmic division* (V_1) runs with the ocular motor nerves through the superior orbital fissure (Figure 40–2A) to innervate the orbit, nose, and forehead and scalp back to the vertex of the skull (Figure 40–3). Some fibers from this division also innervate

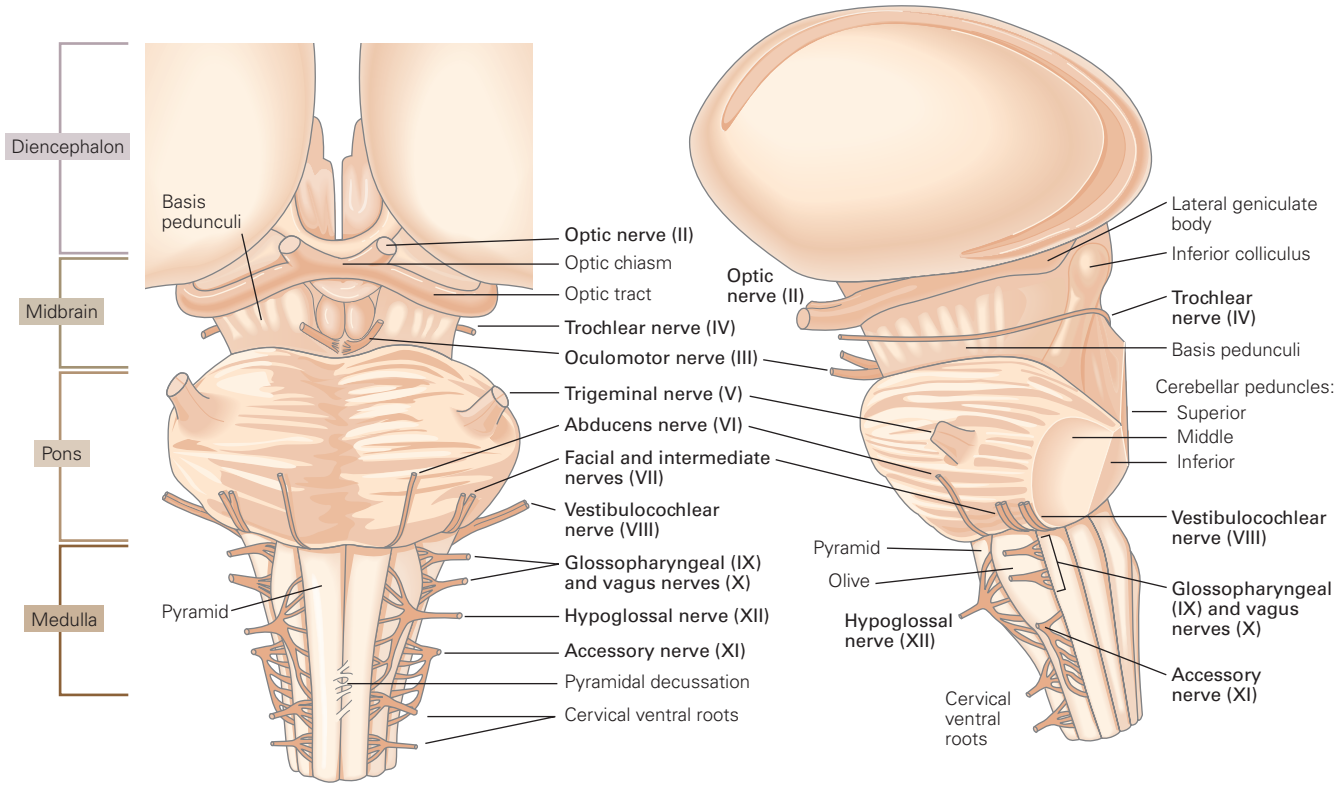

Figure 40–1 The origins of cranial nerves in the brain stem (ventral and lateral views). The olfactory (I) nerve is not shown because it terminates in the olfactory bulb in the forebrain. All of the cranial nerves except one emerge from the ventral surface of the brain; the trochlear (IV) nerve originates from the dorsal surface of the midbrain.

the meninges and blood vessels of the anterior and middle intracranial fossas. The *maxillary division* (V_2) runs through the round foramen of the sphenoid bone to innervate the skin over the cheek and the upper portion of the oral cavity. The *mandibular division* (V_3), which also contains the motor axons of the trigeminal nerve, leaves the skull through the oval foramen of the sphenoid bone. It innervates the skin over the jaw, the area above the ear, and the lower part of the oral cavity, including the tongue.

Complete trigeminal sensory loss results in numbness of the entire face and the inside of the mouth. One-sided trigeminal motor weakness does not cause much weakness of jaw closure because the muscles of mastication on either side are sufficient to close the jaw. Nevertheless, the jaw tends to deviate toward the side of the lesion when the mouth is opened because the internal pterygoid muscle on the opposite side, when unopposed, pulls the jaw toward the weak side.

The *facial (VII) nerve* is also a mixed nerve. Its motor root innervates the muscles of facial expression as well as the stapedius muscle in the inner ear, stylohyoid muscle, and posterior belly of the digastric muscle in the upper neck. The sensory root runs as a separate bundle, the intermediate nerve, through the internal auditory canal and arises from neurons in the geniculate ganglion, located near the middle ear. Distal to the geniculate ganglion, the sensory fibers diverge from the motor branch. Some innervate skin of the external auditory canal while others form the chorda tympani, which joins the lingual nerve and conveys taste sensation from the anterior two-thirds of the tongue. The *autonomic component* of the facial nerve includes parasympathetic fibers that travel through the motor root to the sphenopalatine and submandibular ganglia, which innervate lacrimal and salivary glands (except the parotid gland) and the cerebral vasculature.

The facial nerve may suffer isolated injury in Bell palsy, a common complication of certain viral infections. Early on, the patient may complain mainly of the face pulling toward the unaffected side because of the weakness of the muscles on the side of the lesion. Later, the ipsilateral corner of the mouth droops, food falls out of the mouth, and the eyelids no longer close on that side. Loss of blinking may result in drying

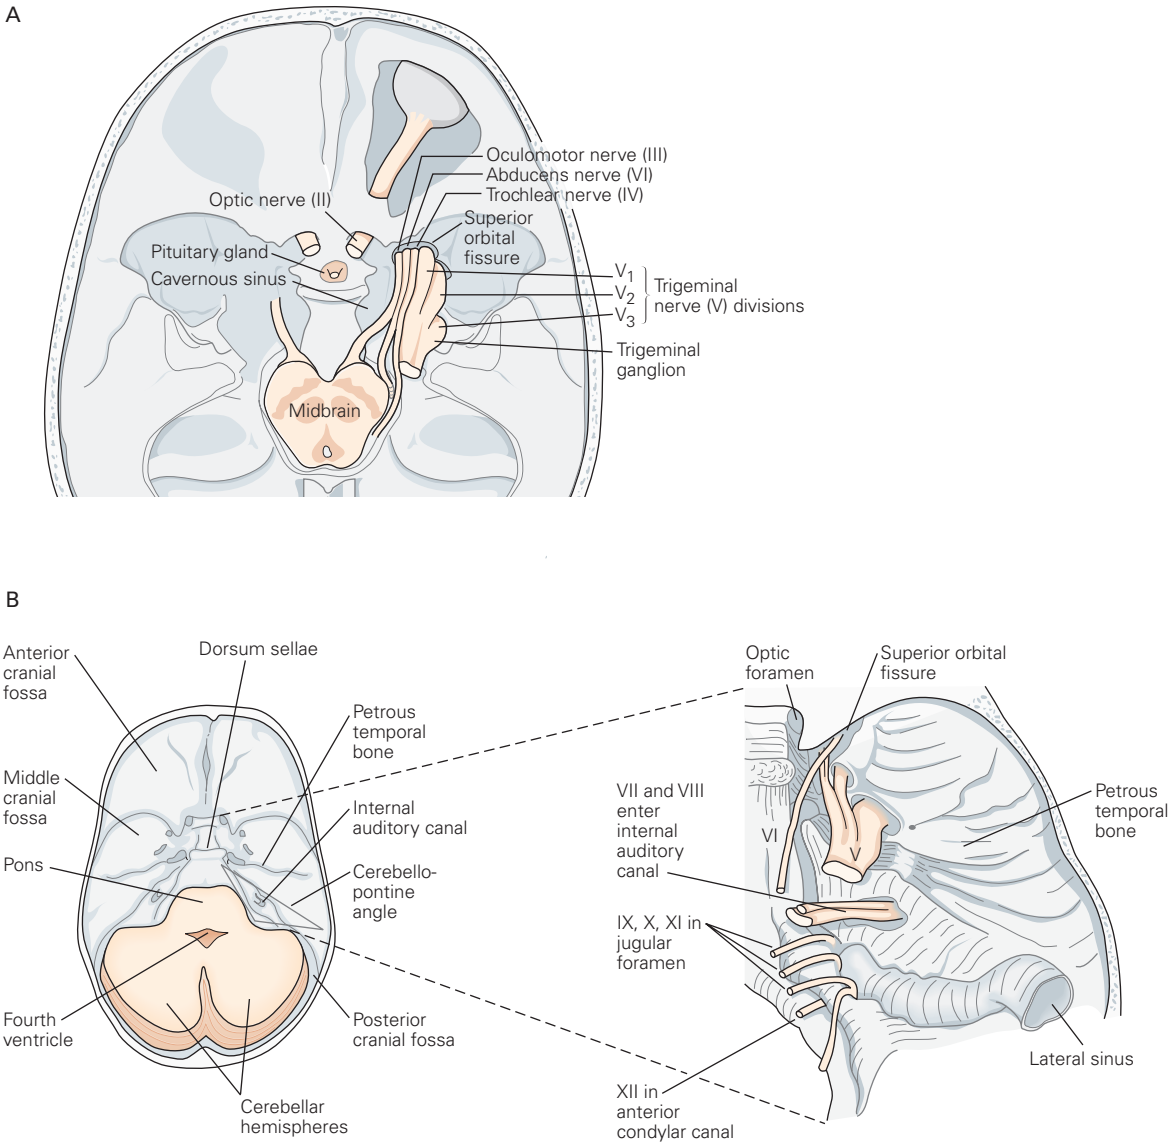

Figure 40–2 The cranial nerves exit the skull in groups.

A. Cranial nerves II, III, IV, V, and VI exit the skull near the pituitary fossa. The optic (**II**) nerve enters the optic foramen, but the oculomotor (**III**), trochlear (**IV**), and abducens (**VI**) nerves, and the first division of the trigeminal (**V**) nerve leave through the superior orbital fissure. The second and third divisions of the trigeminal nerve exit through the round and oval foramina, respectively.

B. In the posterior fossa, the facial (**VII**) and vestibulocochlear (**VIII**) nerves exit through the internal auditory canal, whereas the glossopharyngeal (**IX**), vagus (**X**), and accessory (**XI**) nerves leave through the jugular foramen. The hypoglossal nerve (**XII**) has its own foramen.

and injury to the cornea. The patient may complain that sound has a booming quality in the ipsilateral ear because the stapedius muscle fails to tense the ossicles in response to a loud sound (the stapedial reflex). Taste may also be lost on the anterior two-thirds of the tongue on the ipsilateral side. If the Bell palsy is caused by a herpes zoster infection of the geniculate ganglion, small blisters may form in the outer ear canal, the ganglion's cutaneous sensory field.

The *vestibulocochlear (VIII) nerve* contains two main bundles of sensory axons from two ganglia. Fibers from the vestibular ganglion relay sensation of angular and linear acceleration from the semicircular canals, utricle, and saccule in the inner ear. Fibers from the cochlear ganglion relay information from the cochlea concerning sound. A vestibular schwannoma, one of the most common intracranial tumors, may form along the vestibular component of cranial nerve VIII

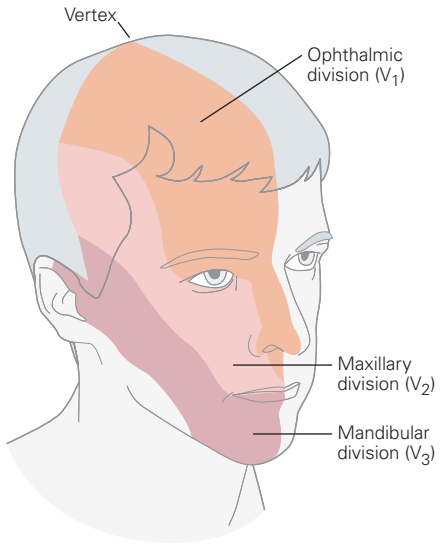

Figure 40–3 The three sensory divisions of the trigeminal (V) nerve innervate the face and scalp. The V_2 and V_3 divisions also innervate the upper and lower parts of the oral cavity, including the tongue. The C2 cervical root innervates the back of the head. The area around the ear is innervated by branches of the VII and X nerve.

as it runs within the internal auditory meatus. Most patients complain only about hearing loss, as the brain is usually able to adapt to the gradual loss of vestibular input from one side.

The *glossopharyngeal (IX) nerve* and *vagus (X) nerve* are mixed nerves and provide parasympathetic autonomic input to thoracic and visceral organs. These closely related nerves transmit sensory information from the pharynx and upper airway as well as taste from the posterior third of the tongue and oral cavity. The glossopharyngeal nerve transmits visceral information from the neck (for example, information on blood oxygen and carbon dioxide from the carotid body, and arterial pressure from the carotid sinus), whereas the vagus nerve transmits visceral information from the thoracic and abdominal organs except for the distal colon and pelvic organs. Both nerves include parasympathetic motor fibers. The glossopharyngeal nerve provides parasympathetic control of the parotid salivary gland, whereas the vagus nerve innervates the rest of the internal organs of the neck, thorax, and abdomen. The glossopharyngeal nerve innervates only one muscle of the palate, the stylopharyngeus, which raises and dilates the pharynx. The remaining striated muscles of the larynx and pharynx are under control of the vagus nerve.

The vagal sensory neurons innervate the length of the gastrointestinal tract and thus are able to regulate multiple postprandial functions. One excellent example is the role of vagal afferents in regulating food intake following a meal. Cholecystokinin (CCK) is an endogenous peptide secreted by duodenal enteroendocrine cells during meals, which helps to induce satiety. CCK acts (at least in part) via action on vagal afferents in the gut, stimulating a feeling of fullness. Exogenous electrical stimulation of the vagus nerve is now being used clinically to treat a wide variety of conditions including obesity, intractable epilepsy, and even depression. However, the neuroanatomic and molecular mechanisms underlying these effects remain poorly understood. Similarly, bariatric surgery remains one of the most widely used and effective strategies to combat obesity. Some studies have suggested that surgical alterations in the responsiveness of vagal afferents to gut signals may contribute to the sustained weight loss following these surgeries.

Because many of the functions of nerves IX and X are bilateral and partially overlapping, unilateral injury of nerve IX may be difficult to detect. Patients with unilateral cranial nerve X injury are hoarse, because one vocal cord is paralyzed, and they may have some difficulty swallowing. Examination of the oropharynx shows weakness and numbness of the palate on one side.

The *spinal accessory (XI) nerve* is purely motor and originates from motor neurons in the upper cervical spinal cord. It innervates the trapezius and sternocleidomastoid muscles on the same side of the body. Because the mechanical effect of the sternocleidomastoid is to turn the head toward the opposite side, an injury of the left nerve causes weakness in turning the head to the right. A lesion of the cerebral cortex on the left will cause weakness of voluntary muscles on the entire right side of the body except for the sternocleidomastoid; instead, the ipsilateral sternocleidomastoid will be weak (because the left cerebral cortex is concerned with muscles that interact with the right side of the world, and the left sternocleidomastoid turns the head to the right).

The *hypoglossal (XII) nerve* is also purely motor, innervating the muscles of the tongue. When the nerve is injured, for example during surgery for head and neck cancer, the tongue atrophies on that side. The muscle fibers exhibit twitches of muscle fascicles (fasciculations), which may be seen clearly through the thin mucosa of the tongue.

Cranial Nerves Leave the Skull in Groups and Often Are Injured Together

In assessing dysfunction of the cranial nerves, it is important to determine whether the injury is within

the brain or further along the course of the nerve. As cranial nerves leave the skull in groups through specific foramina, damage at these locations can affect several nerves.

The cranial nerves concerned with orbital sensation and movement of the eyes—the oculomotor, trochlear, and abducens nerves, as well as the ophthalmic division of the trigeminal nerve—are gathered together in the *cavernous sinus*, along the lateral margins of the sella turcica, and then exit the skull through the *superior orbital fissure* adjacent to the optic foramen (Figure 40–2A). Tumors in this region, such as those arising from the pituitary gland, often make their presence known first by pressure on these nerves or the adjacent optic chiasm.

Cranial nerves VII and VIII exit the brain stem at the *cerebellopontine angle*, the lateral corner of the brain stem at the juncture of the pons, medulla, and cerebellum (Figure 40–2B), and then leave the skull through the internal auditory meatus. A common tumor of the cerebellopontine angle is the vestibular schwannoma (sometimes erroneously called an "acoustic neuroma"), which derives from Schwann cells in the vestibular component of nerve VIII. A large tumor of the cerebellopontine angle may not only impair the function of nerves VII and VIII but may also press on nerve V near its site of emergence from the middle cerebellar peduncle, causing facial numbness, or compress the cerebellum or its peduncles on the same side, causing ipsilateral clumsiness.

The lower cranial nerves (IX, X, and XI) exit through the *jugular foramen* (Figure 40–2B) and are vulnerable to compression by tumors at that site. Nerve XII leaves the skull through its own (hypoglossal) foramen and is generally not affected by tumors located in the adjacent jugular foramen, unless the tumor becomes quite large. If a tumor involves nerves IX and X, but nerve XI is spared, it is generally within or near the brain stem rather than near the jugular foramen.

The Organization of the Cranial Nerve Nuclei Follows the Same Basic Plan as the Sensory and Motor Areas of the Spinal Cord

Cranial nerve nuclei are organized in rostrocaudal columns that are homologous to the sensory and motor laminae of the spinal cord (Chapters 18 and 31). This pattern is best understood from the developmental plan of the caudal neural tube that gives rise to the brain stem and spinal cord.

The transverse axis of the embryonic caudal neural tube is subdivided into alar (dorsal) and basal (ventral) plates by the sulcus limitans, a longitudinal groove along the lateral walls of the central canal, fourth ventricle, and cerebral aqueduct (Figure 40–4). The alar plate forms the sensory components of the dorsal horn of the spinal cord, whereas the basal plate forms the motor components of the ventral horn. The intermediate gray matter is made up primarily of the interneurons that coordinate spinal reflexes and motor responses.

The brain stem shares this basic plan. As the central canal of the spinal cord opens into the fourth ventricle, the walls of the neural tube are splayed outward

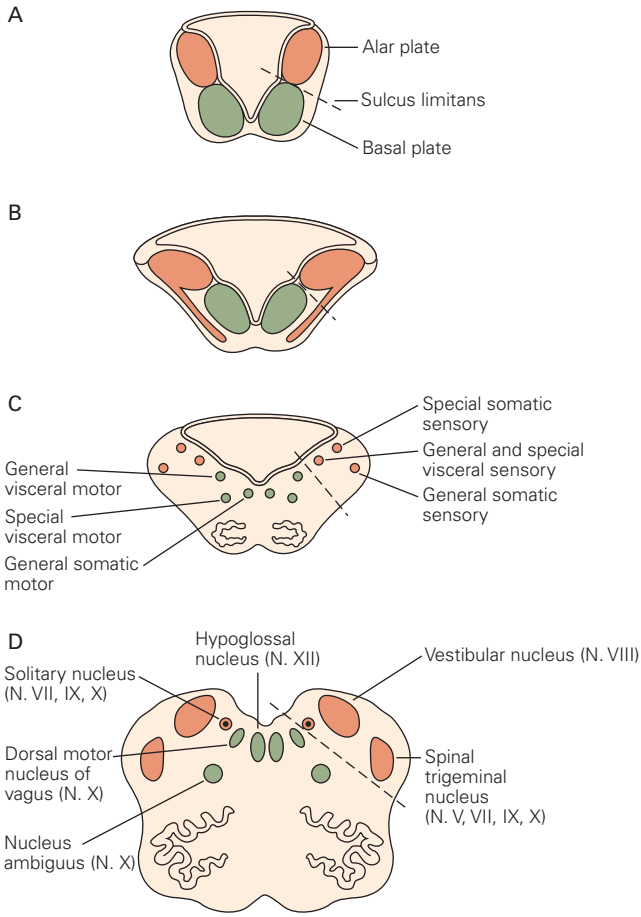

Figure 40–4 The developmental plan of the brain stem is the same general plan as that of the spinal cord.

A. The neural tube is divided into a dorsal sensory portion (the alar plate) and a ventral motor portion (the basal plate) by a longitudinal groove, the sulcus limitans.

B–D. During development, the sensory and motor cell groups migrate into their adult positions but largely retain their relative locations. In maturity (part **D**), the sulcus limitans (**dashed line**) is still recognizable in the walls of the fourth ventricle and the cerebral aqueduct, demarcating the border between dorsal sensory (**orange**) and ventral motor (**green**) structures. The section in part D is from the rostral medulla.

so that the dorsal sensory structures (derived from the alar plate) are displaced laterally, whereas the ventral motor structures (derived from the basal plate) remain more medial. The nuclei of the brain stem are divided into *general nuclei*, which serve functions similar to those of the spinal cord laminae, and *special nuclei*, which serve functions unique to the head, such as hearing, balance, taste, and control of the musculature related to the jaw, face, oropharynx, and larynx.

Embryonic Cranial Nerve Nuclei Have a Segmental Organization

Although the columns of sensory and motor nuclei in the adult hindbrain are organized rostrocaudally, the arrangement of neurons at each level derives from a strikingly segmental pattern in the early embryo. Before neurons appear, the future hindbrain region of the neural plate becomes subdivided into a series of eight segments of approximately equal size, known as *rhombomeres* (Figure 40–5A).

Each rhombomere develops a similar set of differentiated neurons, as if the developing hindbrain is made up of series of modules. Pairs of rhombomeres are associated with specific sets of muscles derived from the embryonic branchial arches (eg, rhombomeres 2 and 3 with the muscles of mastication and 4 and 5 with the muscles of facial expression) (Figure 40–5A). The even-numbered rhombomeres differentiate ahead of the odd-numbered ones. Rhombomeres 2, 4, and 6 form the branchial motor nuclei of the trigeminal, facial, and glossopharyngeal nerves, respectively. Later, rhombomeres 3, 5, and 7 contribute motor neurons to these nuclei, again respectively; in each case, the axons of individual motor neurons from odd-numbered rhombomeres extend rostrally as they join those of their even-numbered neighbors.

At this developmental stage, each of these nuclei is composed of homologous neurons derived from two adjacent segments. This early transverse segmental organization changes later in development, as rhombomere boundaries disappear and the dorsolateral migration of the cell bodies aligns the cells into rostrocaudal columns. Ultimately, some somatic and parasympathetic motor neurons migrate into the ventrolateral tegmentum; for example, the migration of the facial motor neurons of rhombomere 4 around the abducens nucleus generates the internal genu of the facial nerve (Figure 40–5A). Furthermore, neural crest cells from each rhombomere migrate into the corresponding branchial arches where they provide sensory and autonomic ganglion cells, as well as positional cues for the development of the arch muscles.

Adult Cranial Nerve Nuclei Have a Columnar Organization

Overall, the brain stem nuclei on each side are organized in six rostrocaudal columns, three of sensory nuclei and three of motor nuclei (Figure 40–6). These are considered later, in dorsolateral to ventromedial sequence. Although the columns are discontinuous along the rostrocaudal axis of the brain stem, nuclei with similar functions (sensory or motor, somatic or visceral) have similar dorsolateral-ventromedial positions at each level of the brain stem.

Within each motor nucleus, motor neurons for an individual muscle are also arranged in a cigar-shaped longitudinal column. Thus, each motor nucleus in cross section forms a mosaic map of the territory that is innervated. For example, in a cross section through the facial nucleus, the clusters of neurons that innervate the different facial muscles form a topographic map of the face.

General Somatic Sensory Column

The general somatic sensory column occupies the most lateral region of the alar plate and includes the trigeminal sensory nuclei (N. V). The *spinal trigeminal nucleus* is a continuation of the dorsal-most laminae of the spinal dorsal horn (Figure 40–5A) and is sometimes called the medullary dorsal horn. Along its outer surface lies the spinal trigeminal tract, a direct continuation of Lissauer's tract of the spinal cord (Chapter 20), thus allowing some cervical sensory fibers to reach the trigeminal nuclei and some trigeminal sensory axons to reach the dorsal horn in upper cervical segments. This arrangement allows dorsal horn sensory neurons to have a range of inputs that are much broader than that of individual spinal or trigeminal segments and ensures the integration of trigeminal and upper cervical sensory maps.

The spinal trigeminal nucleus receives sensory axons from the trigeminal ganglion (N. V) and from all cranial nerve sensory ganglia concerned with pain and temperature in the head, including geniculate ganglion (N. VII) neurons that relay information from the external auditory meatus, petrosal ganglion (N. IX) cells that convey information from the posterior part of the palate and tonsillar fossa, and nodose ganglion (N. X) axons that relay information from the posterior wall of the pharynx. The spinal trigeminal nucleus thus represents the entire oral cavity as well as the surface of the face.

The somatotopic organization of the afferent fibers in the spinal trigeminal nucleus is inverted: The forehead

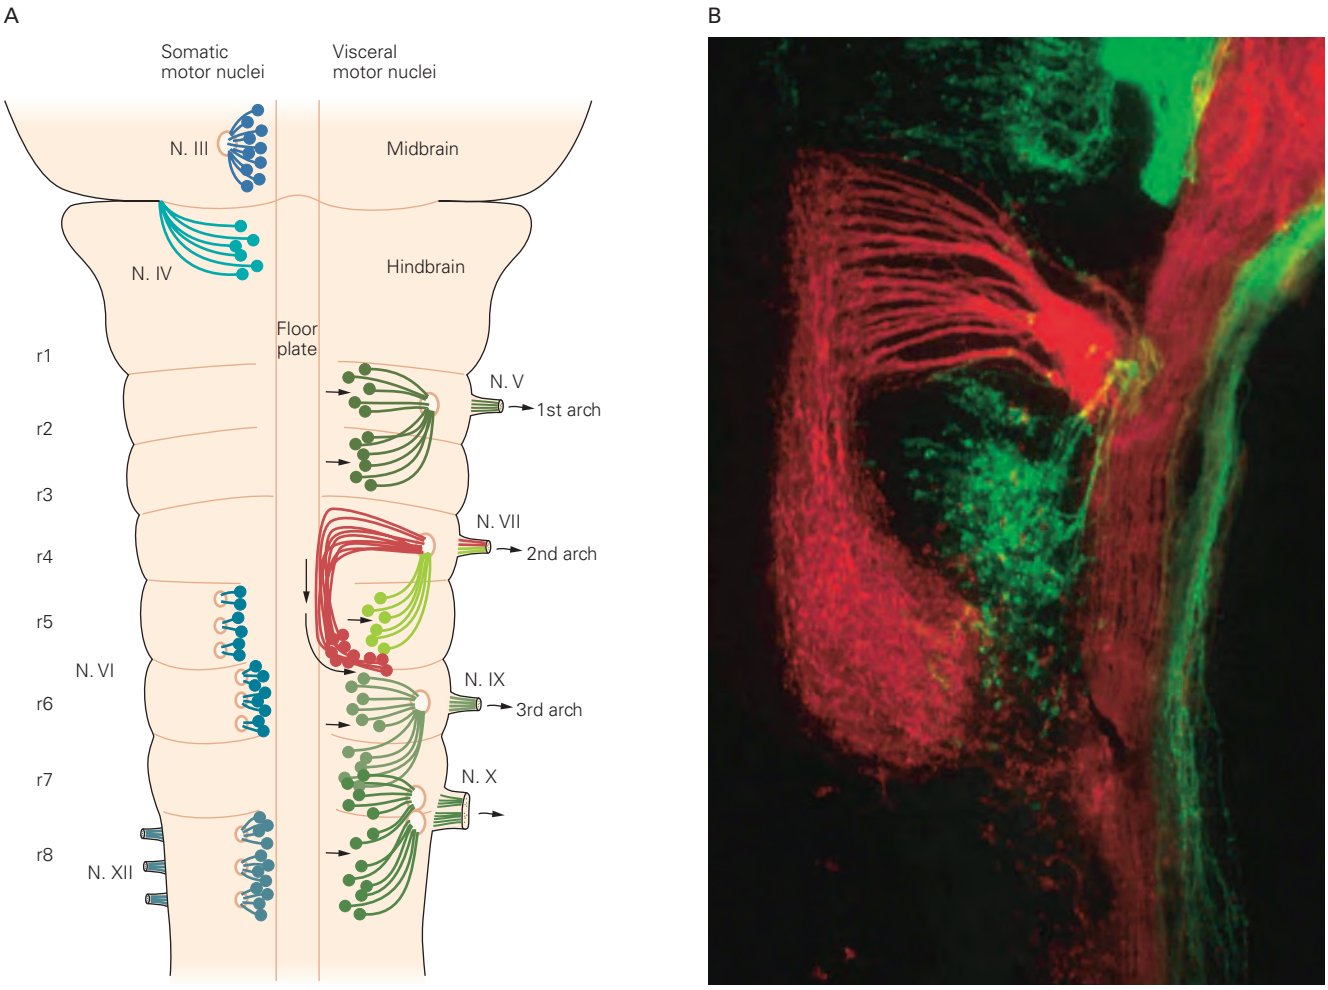

Figure 40–5 Embryonic cranial nerve nuclei are organized segmentally.

A. In the developing hindbrain (seen here from the ventral side), special and general visceral motor neurons (represented on the right side of the brain stem) form in each hindbrain segment (rhombomere) except rhombomere 1 (**r1**). Each special visceral motor nucleus comprises neurons in two rhombomeres: the trigeminal motor nucleus is formed by neurons in r2 and r3, the facial nucleus by neurons in r4 and r5, the glossopharyngeal nucleus by neurons in r6 and r7, and the motor nuclei of the vagus by neurons in r7 and r8. Axons of neurons in each of these nuclei course laterally within the brain, leaving the brain through exit points in the lateral neuroepithelium (of r2, r4, r6, and r7) and running together outside the brain to form the respective cranial motor nerves (V, VII, IX, X). The trigeminal (**V**) nerve innervates muscles in the 1st branchial arch, the facial (**VII**) nerve innervates muscles in the 2nd branchial arch, and the glossopharyngeal (**IX**) nerve innervates muscles in the 3rd branchial arch.

All of the visceral motor neurons (various shades of **green**, represented on the right side of the brain stem) develop initially next to the floor plate at the ventral midline; after extending their axons toward their respective exit points, the cell bodies then migrate laterally (**arrows**). Exceptions are the facial motor neurons formed in r4 (**red**); the cell bodies, after extending their axons toward the exit point, migrate caudally to the axial level of r6 before migrating laterally. General visceral (parasympathetic) motor neurons associated with nerve VII (**light green**) take a more conventional course (see panel **B**).

General somatic motor nuclei (**various shades of blue**, represented on the left side of the brain stem) are formed in r1 (trochlear nucleus), r5 and r6 (abducens nucleus), and r8 (hypoglossal nucleus). The cell bodies of these neurons remain close to their place of birth, next to the floor plate. The axons of abducens and hypoglossal neurons exit the brain directly ventrally, without coursing laterally. The axons of trochlear neurons (**light blue**) extend laterally and dorsally within the brain until, caudal to the inferior colliculus, they turn medially, decussate just behind the inferior colliculus, and exit near the midline of the opposite side.

B. The brain stem of a mouse embryo in which fluorescent dyes label different populations of cranial nerve VII motor neurons. A red-fluorescing dye fills the cell bodies of facial motor neurons via retrograde transport from the motor root of the facial nerve. These neurons develop initially in r4 and then migrate posteriorly, alongside the floor plate, to r6 (see **red** neurons in part **A**). A green-fluorescing dye fills the cell bodies of general visceral motor neurons in r5 (see **light green** neurons in part **A**) via retrograde transport from the root of the intermediate nerve (sensory and preganglionic general visceral motor axons). (Micrograph reproduced, with permission, from Dr. Ian McKay.)

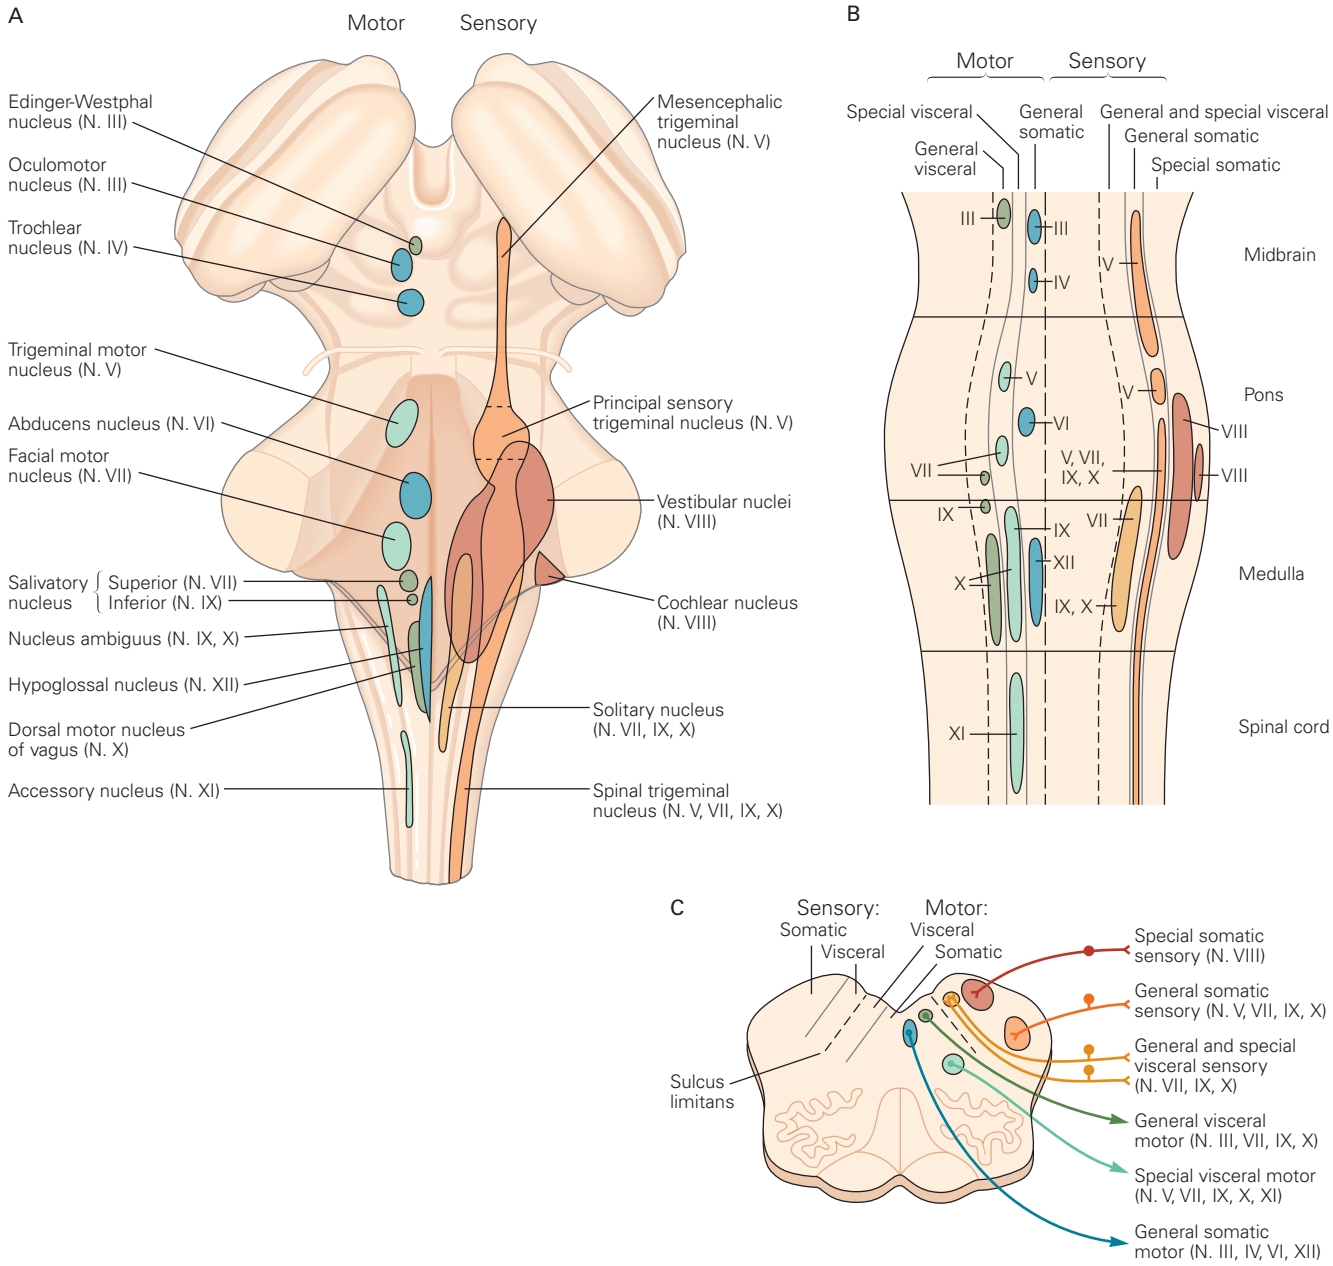

Figure 40–6 Adult cranial nerve nuclei are organized in six functional columns on the rostrocaudal axis of the brain stem.

A. This dorsal view of the human brain stem shows the location of the cranial nerve sensory nuclei (*right*) and motor nuclei (*left*).

B. A schematic view of the functional organization of the cranial nerve nuclei makes it clearer that they form motor and sensory columns.

C. The medial-lateral arrangement of the cranial nerve nuclei is shown in a cross section at the level of the medulla (compare with Figure 40–4D).

is represented ventrally and the oral region dorsally, with the tongue extending medially toward the taste region of the nucleus of the solitary tract, with which it shares some afferent information concerning food texture and temperature. Axons from the spinal trigeminal nucleus descend on the same side of the brain stem into the cervical spinal cord, where they cross the midline in the anterior commissure with spinothalamic axons and join the opposite spinothalamic tract. (For this reason, upper cervical spinal cord injury may cause facial numbness.) The trigeminothalamic axons then ascend back through the brain stem in close association with the spinothalamic tract, providing inputs to brain stem nuclei for reflex motor and autonomic responses in addition to carrying pain and temperature information to the thalamus.

The *principal sensory trigeminal nucleus* lies in the mid-pons just lateral to the trigeminal motor nucleus. It receives the axons of neurons in the trigeminal ganglion concerned with position sense and fine touch discrimination, the same types of sensory information carried from the rest of the body by the dorsal columns. The axons from this nucleus are bundled just medial to those from the dorsal column nuclei in the medial lemniscus, through which they ascend to the ventroposterior medial thalamus.

The *mesencephalic trigeminal nucleus*, located at the midbrain level in the lateral surface of the periaqueductal gray matter, relays mechanosensory information from the muscles of mastication and the periodontal ligaments. The large cells of this nucleus are not central neurons but primary sensory ganglion cells that derive from the neural crest and, unlike their relatives in the trigeminal ganglion, migrate into the brain during development. The central branches of the axons of these pseudo-unipolar cells contact motor neurons in the trigeminal motor nucleus, providing monosynaptic feedback to the jaw musculature, critical for rapid and precise control of chewing movements.

Special Somatic Sensory Column

The special somatic sensory column has inputs from the acoustic and vestibular nerves and develops from the intermediate region of the alar plate. The *cochlear nuclei* (N. VIII), which lie at the lateral margin of the brain stem at the pontomedullary junction, receive afferent fibers from the spiral ganglion of the cochlea. The output of the cochlear nuclei is relayed through the pons to the superior olivary and trapezoid nuclei and bilaterally on to the inferior colliculus (Chapter 28). The *vestibular nuclei* (N. VIII) are more complex. They include four distinct cell groups that relay information from the vestibular ganglion to various motor sites in the brain stem, cerebellum, and spinal cord concerned with maintaining balance and coordination of eye and head movements (Chapter 27).

Visceral Sensory Column

The visceral sensory column is concerned with special visceral information (taste) and general visceral information from the facial (VII), glossopharyngeal (IX), and vagus nerves (X). It is derived from the most medial tier of neurons in the alar plate. All of the afferent axons from these sources terminate in the *nucleus of the solitary tract*. The solitary tract is analogous to the spinal trigeminal tract or Lissauer's tract, bundling afferents from different cranial nerves as they course rostrocaudally along the length of the nucleus. As a result, sensory information from different regions of the viscera produces a unified map of the internal body in the nucleus.

Special visceral afferents from the anterior two-thirds of the tongue travel to the nucleus of the solitary tract through the chorda tympani branch of the facial nerve, whereas those from the posterior parts of the tongue and oral cavity arrive through the glossopharyngeal and vagus nerves. These afferents terminate in roughly somatotopic fashion in the anterior third of the nucleus of the solitary tract (or solitary nucleus). General visceral afferents are relayed through the glossopharyngeal and vagus nerves. Those from the rest of the gastrointestinal tract (down to the transverse colon) terminate in the middle portion of the solitary nucleus in topographic order, whereas those from the cardiovascular and respiratory systems terminate in the caudal and lateral portions.

The solitary nucleus projects directly to parasympathetic and sympathetic preganglionic motor neurons in the medulla and spinal cord that mediate various autonomic reflexes, as well as to parts of the reticular formation that coordinate autonomic and respiratory responses. Most ascending projections from the solitary nucleus that carry information from the viscera to the forebrain are relayed through the parabrachial nucleus in the pons, although some reach the forebrain directly. Together, the solitary and parabrachial nuclei supply visceral sensory information to the hypothalamus, basal forebrain, amygdala, thalamus, and cerebral cortex.

General Visceral Motor Column

All motor neurons initially develop adjacent to the floor plate, a longitudinal strip of non-neuronal cells

at the ventral midline of the neural tube (Chapter 45). Neurons fated to become the three types of brain stem motor neurons migrate dorsolaterally, settling in three distinct rostrocaudal columns. The neurons that form the general visceral motor column take up a position along the most lateral region of the basal plate, just medial to the sulcus limitans. During development, the parasympathetic motor neurons destined to join the superior salivatory nucleus (part of the facial nerve) and nucleus ambiguus (part of the vagus nerve) migrate ventrolaterally, leaving behind axons that ascend medially before turning laterally to exit the brain stem, in a course similar to the facial motor neurons.

The *Edinger-Westphal nucleus* (N. III) lies in the midline separating the somatic oculomotor neurons just below the floor of the cerebral aqueduct. It contains preganglionic neurons that control pupillary constriction and lens accommodation through the ciliary ganglion.

The *superior salivatory nucleus* (N. VII) lies just dorsal to the facial motor nucleus and comprises parasympathetic preganglionic neurons that innervate the sublingual and submandibular salivary glands and the lacrimal glands and intracranial circulation through the sphenopalatine and submandibular parasympathetic ganglia.

Parasympathetic preganglionic neurons associated with the gastrointestinal tract form a column at the level of the medulla just dorsal to the hypoglossal nucleus and ventral to the nucleus of the solitary tract. At the most rostral end of this column is the *inferior salivatory nucleus* (N. IX) comprising the preganglionic neurons that innervate the parotid gland through the otic ganglion. The rest of this column constitutes the *dorsal motor vagal nucleus* (N. X). Most of the preganglionic neurons in this nucleus innervate the gastrointestinal tract below the diaphragm; a few are cardiomotor neurons.

The *nucleus ambiguus* (N. X) runs the rostrocaudal length of the ventrolateral medulla and contains parasympathetic preganglionic neurons that innervate thoracic organs, including the esophagus, heart, and respiratory system, as well as special visceral motor neurons that innervate the striated muscle of the larynx and pharynx, and neurons that generate respiratory motor patterns (see later in chapter). The parasympathetic preganglionic neurons are organized in topographic fashion, with the esophagus represented most rostrally and dorsally.

Special Visceral Motor Column

The special visceral motor column includes motor nuclei that innervate muscles derived from the branchial (pharyngeal) arches. Because these arches are homologous to the gills in fish, the muscles are considered special visceral muscles, even though they are striated. During development, these cell groups migrate to an intermediate position in the basal plate and are eventually located ventrolaterally in the tegmentum.

The *trigeminal motor nucleus* (N. V) lies at midpontine levels and innervates the muscles of mastication. Nearby in separate clusters are located the *accessory trigeminal nuclei* that innervate the tensor tympani, tensor veli palatini, and mylohyoid muscles, and the anterior belly of the digastric muscle.

The *facial motor nucleus* (N. VII) lies caudal to the trigeminal motor nucleus at the level of the caudal pons and innervates the muscles of facial expression. During development, facial motor neurons migrate medially and rostrally around the medial margin of the abducens nucleus before turning laterally, ventrally, and caudally toward their definitive position at the pontomedullary junction (Figure 40–5A). This sinuous course that the axons leave behind forms the *internal genu of the facial nerve*. The adjacent *accessory facial motor nuclei* innervate the stylohyoid and stapedius muscles and the posterior belly of the digastric muscle.

The nucleus ambiguus contains branchial motor neurons with axons that run in the glossopharyngeal and vagus nerves. These neurons innervate the striated muscles of the larynx and pharynx. During development, these motor neurons migrate into the ventrolateral medulla, and as a consequence, their axons run dorsomedially toward the dorsal motor vagal nucleus, then turn sharply within the medulla to exit laterally, similar to the course of the facial motor axons.

General Somatic Motor Column

The neurons of the somatic motor column migrate the least during development, remaining close to the ventral midline. The *oculomotor nucleus* (N. III) lies at the midbrain level; it consists of five rostrocaudal columns of motor neurons innervating the medial, superior, and inferior rectus muscles, the inferior oblique muscle, and the levator of the eyelids. The motor neurons for the medial and inferior rectus and inferior oblique muscles are on the side of the brain stem from which the nerve exits, whereas those for the superior rectus are on the opposite side. The levator motor neurons are bilateral.

The *trochlear nucleus* (N. IV), which innervates the trochlear muscle, lies at the midbrain/rostral pontine level on the side of the brain stem opposite from

which the nerve exits. The *abducens nucleus* (N. VI), which innervates the lateral rectus muscle, is located at the midpontine level. The *hypoglossal nucleus* (N. XII) in the medulla consists of several columns of neurons, each of which innervates a single muscle of the tongue.

The Organization of the Brain Stem Differs From the Spinal Cord in Three Important Ways

One major difference between the organization of the brain stem and that of the spinal cord is that many long ascending and descending sensory tracts that run along the outside of the spinal cord are incorporated within the interior of the brain stem. Thus, the ascending sensory tracts (the medial lemniscus and spinothalamic tract) run through the reticular formation of the brain stem, as do the auditory, vestibular, and visceral sensory pathways.

A second major difference is that in the brain stem, the cerebellum and its associated pathways form additional structures that are superimposed on the basic plan of the spinal cord. Fibers of the cerebellar tracts and nuclei are bundled with those of the pyramidal and extrapyramidal motor systems to form a large ventral portion of the brain stem. Thus, from the midbrain to the medulla, the brain stem is divided into a dorsal portion, the tegmentum, which follows the basic segmental plan of the spinal cord, and a ventral portion, which contains the structures associated with the cerebellum and the descending motor pathways. At the level of the midbrain, the ventral (motor) portion includes the cerebral peduncles, substantia nigra, and red nuclei. The base of the pons includes the pontine nuclei, corticospinal tract, and middle cerebellar peduncle. In the medulla, the ventral motor structures include the pyramidal tracts and inferior olivary nuclei.

A third major difference is that, although the hindbrain is segmented into rhombomeres during development, there is no clear repeating pattern in the adult brain. In contrast, the spinal cord is not segmented during development, but the final pattern consists of repeating segments. The prominent ladder-like arrays of ventral root axons and dorsal root ganglia suggest that segmentation is imposed by a polarizing effect of the adjacent body segments, or somites into which they migrate—in each somite, the rostral part attracts axonal growth cones and neural crest cells, whereas the caudal part is repulsive. In the head, such patterning is lacking as the cranial mesoderm is not segmented into somites but rather develops under the influence of the rhombomeres.

Neuronal Ensembles in the Brain Stem Reticular Formation Coordinate Reflexes and Simple Behaviors Necessary for Homeostasis and Survival

In the 19th century, Charles Darwin pointed out in his book *The Expression of the Emotions in Man and Animals* that the muscles of facial expression are activated in similar patterns in all mammals during similar emotional situations (fear, anger, disgust, happiness). He hypothesized that the patterns of facial expression must be deeply embedded in the organization of the brain stem. We now recognize that a wide range of reflexes and simple, repetitive, coordinated behaviors, such as facial emotional expression, breathing, and eating, are controlled by neurons in the brain stem reticular formation called *pattern generators*, which produce stereotyped innate responses. Impairment of cranial nerve reflexes and motor patterns in patients with neurological disease can indicate the precise site of brain stem damage.

Cranial Nerve Reflexes Involve Mono- and Polysynaptic Brain Stem Relays

The responses of the pupils to light (*pupillary light reflexes*) are determined by the balance between sympathetic tone in the pupillodilator muscles and parasympathetic tone in the pupilloconstrictor muscles of the iris. Sympathetic tone is maintained by postganglionic neurons in the superior cervical ganglion, which in turn are innervated by preganglionic neurons in the first and second thoracic spinal segments. Parasympathetic tone is supplied by postganglionic ciliary ganglion cells under the control of preganglionic neurons in the Edinger-Westphal nucleus and adjacent areas of the midbrain.

Light impinging on the retina activates a special class of retinal ganglion cells that act as brightness detectors. These cells receive inputs from photopigment-containing rod and cone cells, but they also have their own photopigment, melanopsin, which allows them to respond to light even when the rods and cones have degenerated. These cells send their axons through the optic nerve, chiasm, and tract to the olivary pretectal nucleus, where they terminate on neurons whose axons project to preganglionic neurons in the Edinger-Westphal nucleus (Figure 40–7). Thus, injury to the dorsal midbrain in the region of the posterior commissure can prevent pupillary light responses (midposition, fixed pupils), whereas injury to the oculomotor nerve eliminates parasympathetic tone to that pupil (fixed and dilated pupil). The melanopsin-containing

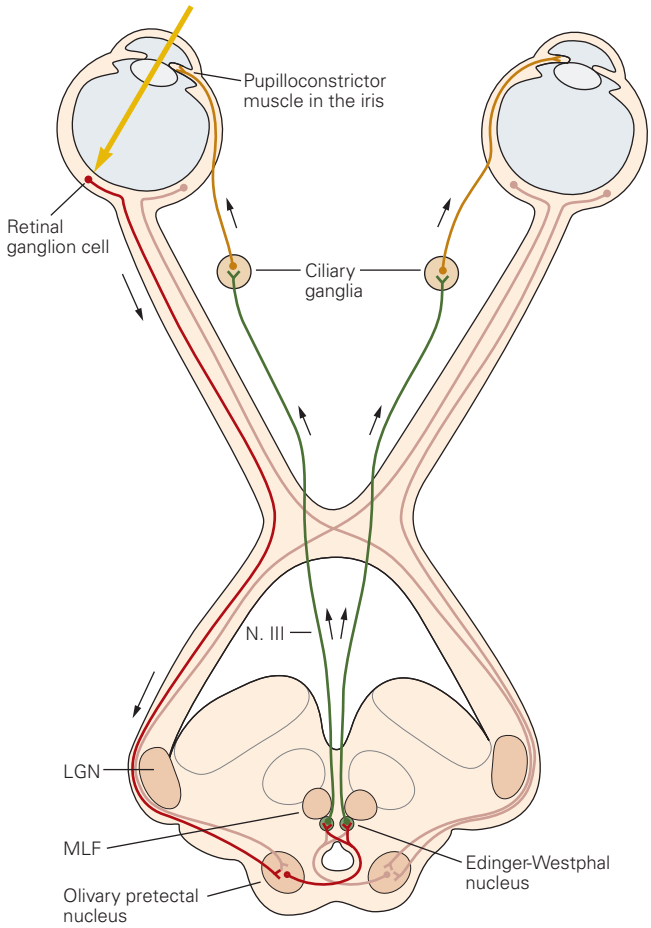

Figure 40–7 The pupillary response to light is mediated by parasympathetic innervation of the iris. Retinal ganglion cells that contain the photopigment melanopsin act as luminance detectors, sending their axons through the optic tract to the olivary pretectal nucleus, at the junction of the midbrain and the thalamus. Neurons in this nucleus project through the posterior commissure to parasympathetic preganglionic neurons in and around the Edinger-Westphal nucleus. The axons of the preganglionic cells exit with the oculomotor (III) nerve and contact ciliary ganglion cells, which control the pupilloconstrictor muscle in the iris. (Abbreviations: LGN, lateral geniculate nucleus; MLF, medial longitudinal fasciculus.)

retinal ganglion cells also project to the suprachiasmatic nucleus of the hypothalamus, where they entrain circadian rhythms to the day–night cycle (Chapter 44).

Vestibulo-ocular reflexes stabilize the image on the retina during head movement by rotating the eyeballs counter to the rotation of the head. These reflexes are activated by pathways from the vestibular ganglion and nerve to the medial, superior, and lateral vestibular nuclei, and from there to neurons in the reticular formation and ocular motor nuclei that coordinate eye movements. The reflex movements are seen most clearly in comatose patients, in whom turning the head will elicit counter-rotational movements of the eyes (so-called doll's eye movements). Damage to these pathways in the pons impairs these movements.

The *corneal reflex* involves closure of both eyelids as well as upward turning of the eyes (Bell phenomenon) when the cornea is gently stimulated (eg, with a wisp of cotton). The sensory axons from the first division of the trigeminal nerve terminate in the spinal trigeminal nucleus, which relays the sensory signals to pattern generator neurons in the reticular formation adjacent to the facial motor nucleus. The pattern generator neurons provide bilateral inputs to the motor neurons that protect the cornea from damage by causing the orbicularis oculi muscle to close the eyelid and the oculomotor nuclei to roll the eyes upward and back in the orbit. Because the output of the pattern generator is bilateral, damage along the sensory pathway prevents the reflex in both eyes, whereas damage to the facial nerve prevents closure on the same side only.

The *stapedial reflex* contracts the stapedius muscle in response to a loud sound, thus damping movement of the ossicles. The sensory pathway is through the cochlear nerve and nucleus to the reticular formation adjacent to the facial motor nucleus and from there to the stapedial motor neurons, which run in the facial nerve. As described earlier, in patients with injury to the facial nerve (eg, Bell palsy), the stapedial reflex is impaired, and the patient complains that sounds in that ear have a "booming" quality (hyperacusis).

A variety of gastrointestinal reflexes are controlled by multisynaptic brain stem relays. For example, the tasting of food causes neurons in the solitary nucleus that project to the reticular formation adjacent to the motor facial and dorsal motor vagal nuclei to stimulate the preganglionic salivary neurons. The contact of food in the mouth can also elicit gastric contractions and acid secretion, presumably through inputs from the solitary nucleus directly to parasympathetic preganglionic gastric neurons in the dorsal motor vagal nucleus. In patients who have had Bell palsy, the damaged VII nerve parasympathetic axons may regrow aberrantly so that salivary axons reach the lacrimal gland in error, causing tasty food to initiate reflex tearing (crocodile tears).

The *gag reflex* protects the airway in response to stimulation of the posterior oropharynx. The afferent sensory fibers in the glossopharyngeal and vagus nerves terminate in the spinal trigeminal nucleus, whose axons project to the reticular formation adjacent to the nucleus ambiguus. Branchial motor neurons in the nucleus ambiguus innervate the posterior pharyngeal muscles, resulting in elevation of the

palate, constriction of pharyngeal muscles (to expel the offending stimulus), and closure of the airway. Loss of the gag reflex on one side of the throat indicates injury to the medulla or to cranial nerve X on that side (cranial nerve IX has such a small territory of sensory and motor innervations in the pharynx that transection of this nerve does not cause a noticeable deficit).

Pattern Generators Coordinate More Complex Stereotypic Behaviors

As Darwin proposed, pools of pattern generator neurons in the reticular formation adjacent to the facial nucleus control facial emotional expression through stereotypic patterns of contraction of facial muscles simultaneously on the two sides of the face. Pattern generator neurons on each side of the brain stem project to the facial motor neurons on both sides of the brain, so that spontaneous facial expressions are virtually always symmetric. Even patients who have had major strokes in the cerebral hemispheres and cannot voluntarily move the contralateral orofacial muscles still tend to smile symmetrically when they hear a joke and can raise their eyebrows symmetrically, both of which are initiated by facial pattern generators.

Similarly, orofacial movements involved in eating are produced by pattern generator neurons in the reticular formation near the cranial motor nuclei that mediate the behaviors. Licking movements are organized in the reticular formation near the hypoglossal nucleus, chewing movements near the trigeminal motor nucleus, sucking movements near the facial and ambiguus nuclei, and swallowing near the nucleus ambiguus. Not surprisingly, neurons in these reticular areas are closely interconnected with each other and receive inputs from the part of the nucleus of the solitary tract concerned with taste and from the part of the spinal trigeminal nucleus concerned with tongue and oral sensation, as well as from neurons in the adjacent reticular formation that respond to more complex combinations of taste, texture, and temperature of food. As a result, even a decerebrate rat is able to make appropriate choices of which foods to swallow and which to reject.

Vomiting is another example of a coordinated response mediated by pattern generator neurons. Toxic substances in the blood stream can be detected by nerve cells in the area postrema, a small region adjacent to the nucleus of the solitary tract along the floor of the fourth ventricle. Unlike most of the brain, which is protected by a blood–brain barrier, the area postrema contains fenestrated capillaries that allow its neurons to sample the contents of the blood stream. These neurons, when they detect a toxin, activate a pool of neurons in the ventrolateral medulla that control a pattern of responses that clears the digestive tract of any poisonous substances. These responses include reversal of peristalsis in the stomach and esophagus, increased abdominal muscle contraction, and activation of the same motor patterns used in the gag reflex to clear the oropharynx of unwanted material.

A variety of responses organized by the brain stem require coordination of cranial motor patterns with autonomic and sometimes endocrine responses. A good example is the *baroreceptor reflex*, which ensures an adequate blood flow to the brain (Chapter 41). The nucleus of the solitary tract receives information about stretch of the aortic arch through the vagus (X) nerve and stretch of the carotid sinus through the glossopharyngeal (IX) nerve. This information is relayed to neurons in the ventrolateral medulla that produce a coordinated response that protects the brain against a fall in blood pressure.

Reduced stretch of the aortic arch and carotid sinus reduces drive to the parasympathetic preganglionic cardiac-vagal neurons in the nucleus ambiguus, resulting in reduced vagal tone and increased heart rate. Simultaneously, increased firing of neurons in the rostral ventrolateral medulla drives sympathetic preganglionic vasoconstrictor and cardioaccelerator neurons. This combination of increased cardiac output and increased vascular resistance elevates blood pressure. Meanwhile, other neurons in the ventrolateral medulla increase the firing of hypothalamic neurons that secrete vasopressin from their terminals in the posterior pituitary gland. Vasopressin also has a direct vasoconstrictor effect, and it maintains blood volume by reducing water excretion through the kidney.

Control of Breathing Provides an Example of How Pattern Generators Are Integrated Into More Complex Behaviors

One of the most important functions of the brain stem is control of breathing. The brain stem automatically generates breathing movements beginning in utero at 11 to 13 weeks of gestation in humans, and continues nonstop from birth until death. This behavior does not require any conscious effort, and in fact, it is rare for us to even think about the need to breathe. The primary purpose of breathing is to ventilate the lungs to control blood levels of oxygen, carbon dioxide, and hydrogen ions (pH). (These are often measured together clinically and referred to as "blood gases.") Breathing movements involve contraction of the diaphragm, activated by the phrenic nerve. The diaphragm is assisted

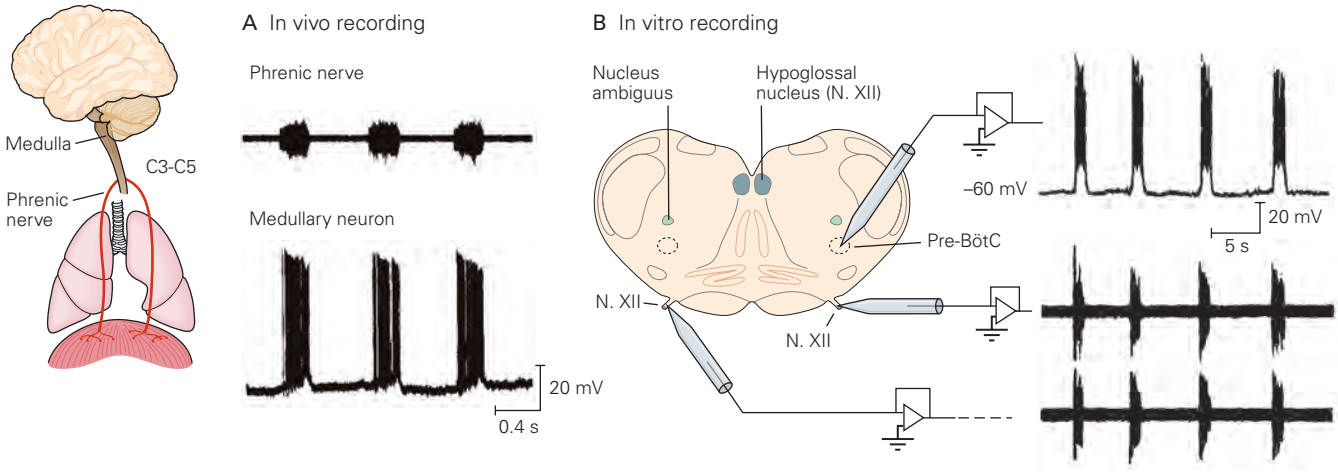

Figure 40–8 Rhythmic breathing is generated within the medulla.

A. Rhythmic activity in the phrenic motor nerve of a guinea pig causes contraction of the diaphragm. The firing of the phrenic nerve is phase-locked to bursts of firing by neurons in the medulla. The activity in a single medullary neuron, recorded intracellularly, is shown. (Reproduced, with permission, from Richerson and Getting 1987. Copyright © 1987. Published by Elsevier B.V.)

B. Similar rhythmic firing can be recorded in vitro from accessory respiratory nerves, such as the hypoglossal (**XII**) nerve. The minimal tissue necessary to support this rhythm is a slice about 0.5 mm thick at the level of the rostral medulla. Neurons in the pre-Bötzinger complex (**Pre-BötC**) near the nucleus ambiguus fire bursts that are phase-locked to the motor rhythm. (Reproduced, with permission, from Smith et al. 1991. Copyright © 1991 AAAS.)

when necessary by accessory muscles of respiration, including the intercostal muscles, pharyngeal muscles (to change airway diameter), some neck muscles (which help expand the chest), the tongue protruder muscles (to open the airway), and even some facial muscles (which flare the nares).

Respiratory activity can be generated by the medulla even when it is isolated from the rest of the nervous system. Many medullary neurons have patterns of firing that correlate with inspiration or expiration (Figure 40–8A). Some have more refined patterns, such as firing only during early inspiration or late inspiration. These respiratory neurons are concentrated in two regions, the dorsal and ventral respiratory groups.

The *dorsal respiratory group* is located bilaterally in and around the ventrolateral part of the nucleus of the solitary tract. Neurons in this group receive respiratory sensory input, including afferents from stretch receptors in the lungs and peripheral chemoreceptors, and participate in such reflex actions as limitation of lung inflation at high volume (the Hering-Breuer reflex) and the ventilatory response to low oxygen (*hypoxia*). The *ventral respiratory group*, a column of neurons in and around the nucleus ambiguus, coordinates respiratory motor output. Some of these neurons are motor neurons with axons that leave the brain through the vagus nerve and innervate accessory muscles of respiration or premotor neurons that innervate the phrenic motor nucleus, whereas others form a pattern generator, the *pre-Bötzinger complex*, that generates respiratory rhythm.

The intrinsic rhythmicity of the pre-Bötzinger complex is so resilient that, even in a transverse brain slice from the rostral medulla, neurons in the pre-Bötzinger complex are able independently to generate a respiratory rhythm that can be recorded in the rootlets of the hypoglossal (XII) nerve that emerge from the ventral surface of the slices (Figure 40–8B). Acute destruction of this cell group in an intact animal results in inability to maintain a normal respiratory rhythm.

The most important inputs to the respiratory pattern generator come from chemoreceptors that sense oxygen and carbon dioxide. Under normal conditions, ventilation is primarily regulated by the levels of CO_2 rather than O_2 (Figure 40–9A). However, breathing is also strongly stimulated if O_2 becomes sufficiently low, such as at high altitude or in people with lung disease. The peripheral chemoreceptors in the carotid and aortic bodies normally respond primarily to a decrease in blood oxygen, but during hypoxia, they also become more sensitive to elevated levels of CO_2 (*hypercapnia*). Afferent fibers from the carotid sinus nerve travel in the glossopharyngeal nerve and activate neurons in the dorsal respiratory group.

The response to hypercapnia is largely driven by *central chemoreceptors* in the brain stem that sense the

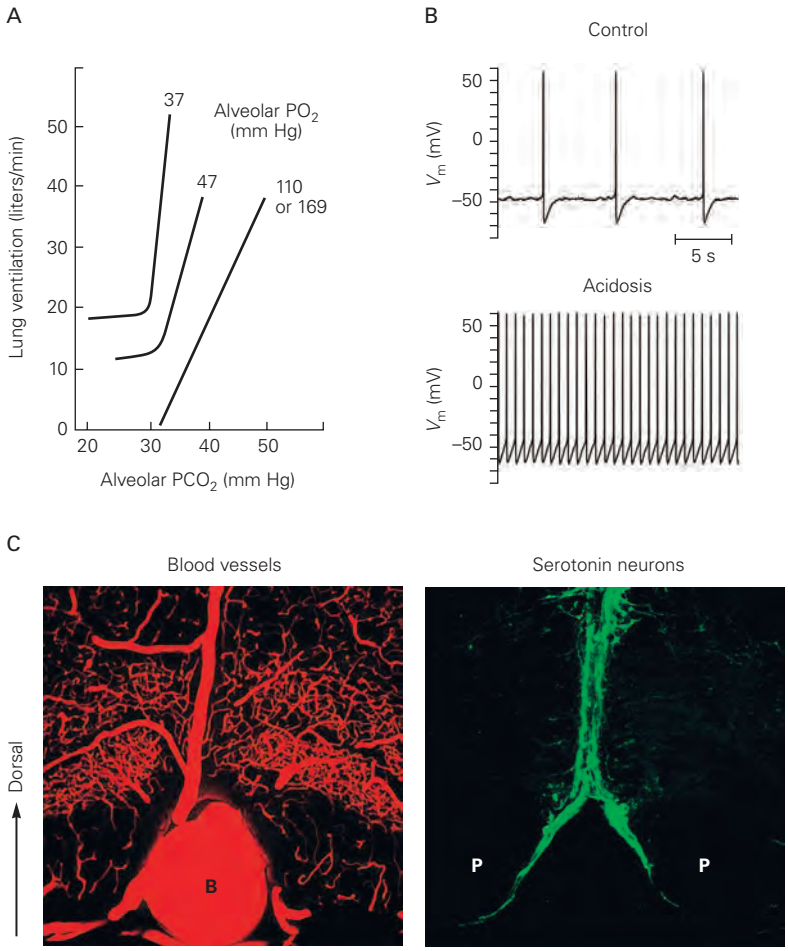

Figure 40–9 Respiratory motor output is regulated by carbon dioxide in the blood.

A. Lung ventilation (determined by the rate and depth of breathing) in humans is steeply dependent on the partial pressure of carbon dioxide (PCO_2) at normal levels of the partial pressure of oxygen (PO_2) (>100 mm Hg). When PO_2 drops to very low values (<50 mm Hg), breathing is stimulated directly and also becomes more sensitive to an increase in PCO_2 (seen here as an increase in the slope of the curves for alveolar PO_2 of 37 and 47 mm Hg). (Reproduced, with permission, from Nielsen and Smith 1952.)

B. Central chemoreceptors in the medulla control ventilatory motor output to maintain normal blood CO_2. The firing rate of serotonergic neurons within the raphe nuclei of the medulla increases when elevated PCO_2 causes a pH decrease. The records shown here are from in vitro recordings of a neuron in the raphe nuclei of a rat at two different levels of pH (7.4, control, and 7.2, acidosis). (Reproduced, with permission, from Wang et al. 2002.)

C. Serotonergic neurons are closely associated with large arteries in the ventral medulla where they can monitor local changes in PCO_2. Two images of the same transverse section of the rat medulla show blood vessels after injection of a red fluorescent dye into the arterial system (*left*) and green antibody staining for tryptophan hydroxylase, the enzyme that synthesizes serotonin (*right*). The basilar artery (**B**) is on the ventral surface of the medulla between the pyramidal tracts (**P**). (Reproduced, with permission, from Bradley et al. 2002. Copyright © 2002 Springer Nature.)

accompanying decrease in pH. The most sensitive area for this is along the ventral surface of the medulla lateral to the pyramidal tract. This region contains at least two sets of neurons that respond to elevated CO_2. Glutamatergic neurons in the retrotrapezoid nucleus in the rostral ventrolateral medulla, near the facial motor nucleus, are highly sensitive to CO_2 levels. Absence of these neurons, due to a mutation in the phox2b transcription factor required for their development, causes congenital central hypoventilation syndrome, in which there is failure to breathe adequately, particularly during sleep. In addition, serotonergic neurons in the rostral ventrolateral medulla, like retrotrapezoid neurons, lie along penetrating arteries and are sensitive to acidosis (Figure 40–9B,C). Genetic deletion of these neurons reduces the ventilatory response to hypercapnia, especially during sleep. Recent studies demonstrate that a serotonin 5-HT_{2A} agonist can restore arousal responses to CO_2, suggesting that the serotonergic neurons play a modulatory role, increasing the sensitivity of the CO_2 reflexes during hypercapnia, and that this may be especially important during sleep.

The motor pattern generated by the respiratory system is remarkably stable in healthy people, but a variety of diseases can alter these patterns. One of the most common and easily recognized patterns is Cheyne-Stokes respiration, which is characterized by repeated cycles of gradually increasing then decreasing ventilation, alternating with cessation of breathing (apnea). This periodic breathing is seen, for example, in congenital central hypoventilation syndrome, where the central neurons are not sufficiently sensitive to rising CO_2, particularly during sleep. By the time they begin to respond, CO_2 levels may already be quite high. This causes hyperventilation, which reduces CO_2 levels below the threshold where breathing is required. The result is a period of apnea, until the CO_2 levels again become quite high (Figure 40–10).

A similar pattern is seen in people who have cardiac or pulmonary disease that increases the time it takes for the change in alveolar CO_2 to register with the medulla. Cheyne-Stokes respiration often occurs in hospitalized patients with marginal cardiac or respiratory reserve when they fall asleep, thus reducing

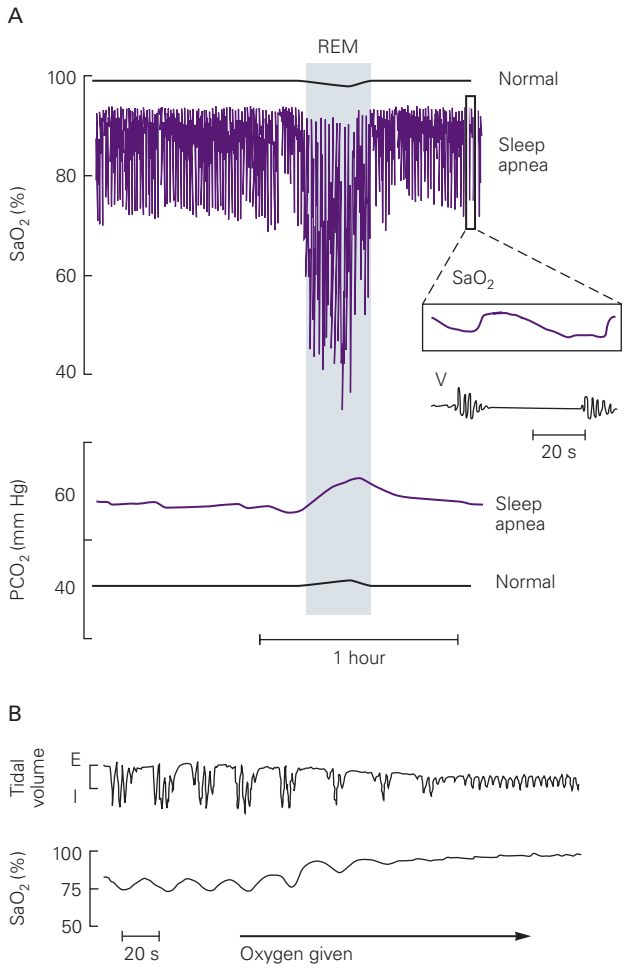

Figure 40–10 Respiratory motor patterns can become unstable during sleep.

A. Sleep apnea (cessation of breathing) is a common problem that often goes undetected. The records here show blood oxygen saturation (SaO_2) and CO_2 partial pressure (PCO_2) during sleep in a healthy person and a patient with obstructive sleep apnea. In the healthy person, SaO_2 remains near 100%, and PCO_2 remains near 40 mm Hg during both rapid eye movement (REM) and non-REM sleep. In the patient with sleep apnea, reduced muscle tone (hypotonia) during sleep leads to collapse of the upper airway, resulting in obstruction and apnea. Repetitive apnea at the rate of approximately once per minute causes the patient's SaO_2 to fall repetitively and dramatically. (The inset shows a period of approximately 80 seconds on an expanded scale. Ventilation [V] begins at the nadir of the SaO_2 and again ceases when the blood oxygen increases.) During non-REM sleep, the patient's PCO_2 increases to near 60 mm Hg. During REM sleep, the SaO_2 and PCO_2 become even more abnormal, as worsening airway hypotonia causes greater obstruction. Many people with sleep apnea wake up repeatedly during the night because of the apnea, but the arousals are too brief for them to be aware that their sleep is interrupted. (Adapted, with permission, from Grunstein and Sullivan 1990.)

B. Breathing in most normal individuals becomes unstable during sleep at high altitudes. The upper trace shows an example of a Cheyne-Stokes breathing pattern in a healthy person, during the first night after arriving at an altitude of 17,700 feet, where the low partial pressure of oxygen in the air reduces the blood SaO_2 to approximately 75% to 80%. Repeated cycles of waxing and waning ventilation are separated by periods of apnea. Administration of supplemental oxygen results in a rapid return to a normal respiratory pattern. This abnormal pattern disappears in most people after they have acclimated to the altitude. (Reproduced, with permission, from Lahiri et al. 1984.)

other behavioral drives for respiration. Although not dangerous in itself, it can indicate that there is a serious underlying cardiorespiratory problem that needs to be corrected.

Other inputs to the respiratory pattern generator come from the circuitry mediating particular behaviors, as breathing must be coordinated with many motor actions that share the same muscles. To accomplish this coordination, respiratory neurons in the medulla receive input from neuronal networks concerned with vocalization, swallowing, sniffing, vomiting, and pain. For example, the ventral respiratory group is connected with a part of the parabrachial complex in the pons termed the *pontine respiratory group* or *pneumotaxic center*. These pontine neurons coordinate breathing with behaviors such as chewing and swallowing. They can cause holding of the breath at full inspiration (called *apneusis*), which is required during eating and drinking. The reserve of air in the lungs permits a cough, if necessary, to expel any food or drink that may enter the airway. Other neurons in the intertrigeminal zone, between the motor and principal sensory trigeminal nuclei, receive facial and upper airway sensory inputs and project to the ventrolateral medulla to temporarily stop breathing to protect against accidental inspiration of dust or water.

Voluntary motor pathways can take over the control of breathing during talking, eating, singing, swimming, or playing a wind instrument. Descending inputs cause hyperventilation at the onset of exercise, in anticipation of an increase in oxygen demand. In fact, this leads to a sustained drop in blood CO_2 during exercise—the opposite of what would be expected for a negative feedback control system. Other descending inputs from the limbic system produce hyperventilation in connection with pain or anxiety and, in some people, may be responsible for causing spontaneous panic attacks, characterized by hyperventilation and a feeling of suffocation. These various descending inputs allow efficient integration of breathing with

other behaviors, but they ultimately must yield to the need to maintain blood gas homeostasis, as even a small increase in CO_2 produces severe air hunger or *dyspnea*. Thus, the respiratory control system is a fascinating example of a brain stem pattern generator that must be sufficiently stable to ensure survival yet flexible enough to accommodate a wide variety of behaviors.

Monoaminergic Neurons in the Brain Stem Modulate Sensory, Motor, Autonomic, and Behavioral Functions

In addition to containing the primary sensory and motor nuclei of the cranial nerves and the reflex and pattern generator mechanisms that control basic behaviors, the brain stem also contains a set of modulatory cell groups. In a groundbreaking series of experiments in the 1970s, Hans Kuypers used the newly discovered method of retrograde transport of axonal tracers to identify the cell groups in the brain stem and diencephalon that contribute to modulation of spinal cord sensory and motor systems and those that send inputs directly to the cerebral cortex. To a surprising extent, these two sets of experiments, starting at opposite ends of the neuraxis, identified a common substrate whose role it is to modulate circuitry at other levels of the nervous system, almost as if it were an "autonomic system" for the brain.

These cell groups have direct connections to the forebrain, brain stem, and spinal cord that regulate the overall level of function of their targets. Like the way serotonergic neurons set the overall sensitivity of CO_2 reflexes, brain stem monoaminergic modulatory systems adjust the overall responsiveness of a wide variety of sensory systems by means of projections to sensory neurons in the spinal cord and brain stem, including nociceptive systems. Descending projections from these modulatory systems also control motor tone, which is critical for adjusting posture and gait as well as initiating finer movements. Ascending inputs to the forebrain control overall arousal as well as responses to rewarding situations. While these modulatory systems are not sufficient to accomplish motor, sensory, or cognitive tasks on their own, their ability to adjust the responsiveness of these systems plays an enormously influential role in overall behavior.

Many Modulatory Systems Use Monoamines as Neurotransmitters

The monoaminergic systems use decarboxylated derivatives of the cyclic amino acids tyrosine, tryptophan, and histidine as neurotransmitters. They were among the first in the brain to be identified and mapped due to the property that some of them possess to fluoresce when exposed to formaldehyde. In the 1960s, Dahlstrom and Fuxe used this property to identify serotonergic, noradrenergic, and dopaminergic cell groups in the brain stem. In the 1970s, with the development of immunohistochemical methods able to map the enzymes that synthesize monoamines, other investigators mapped neurons containing epinephrine and histamine.

The cell groups of these modulatory systems in general were unlike earlier identified nuclei in the brain. Rather than forming compact clusters of cell bodies, the monoaminergic cell groups tended to form columns that extended longitudinally through the brain stem and hypothalamus (see Figure 40–6). The monoamine systems were therefore designated with letters and numbers, to avoid confusion with other systems of nomenclature for the brain (Figure 40–11).

The first cell groups identified by Dahlstrom and Fuxe were simply identified alphabetically as the "A" cell groups, and then numbered sequentially from caudal to rostral. It was later determined that the A1–A7 cell groups produce norepinephrine and the A8–A14 groups produce dopamine. The A1, A3, and A5 designations were applied to neurons located in the ventrolateral corner of the medullary and pontine tegmentum (the A3 group was quite small and the term is no longer used), while the A2, A4, A6, and A7 names were applied to cell groups located more dorsally, similar to the columns of motor neurons in the brain stem (Figure 40–11A). The A1 and A2 groups, located among the neurons of the nucleus ambiguus and the nucleus of the solitary tract (respectively), are mainly concerned with autonomic functions. Together, they modulate hypothalamic and brain stem systems that regulate the autonomic nervous system. The noradrenergic A4–A7 cell groups have widespread influence over sensory and motor systems, ranging from the cerebral cortex to the spinal cord, and provide important modulation of arousal and wakefulness.

The dopaminergic systems (Figure 40–11E) include the A8–A10 cell groups, located in the midbrain in and near the substantia nigra, that modulate motor systems as well as forebrain mechanisms of reward and motivation. The A11 and A13 dopaminergic neurons, in the dorsal hypothalamus, provide input to sensory, motor, and autonomic systems in the brain stem and spinal cord. The A12, A14, and A15 neurons have a neuroendocrine role, including release of dopamine as a pituitary release-inhibiting hormone for prolactin secretion. The A16 cell group modulates olfactory inputs, and the A17 neurons in the retina modulate vision.

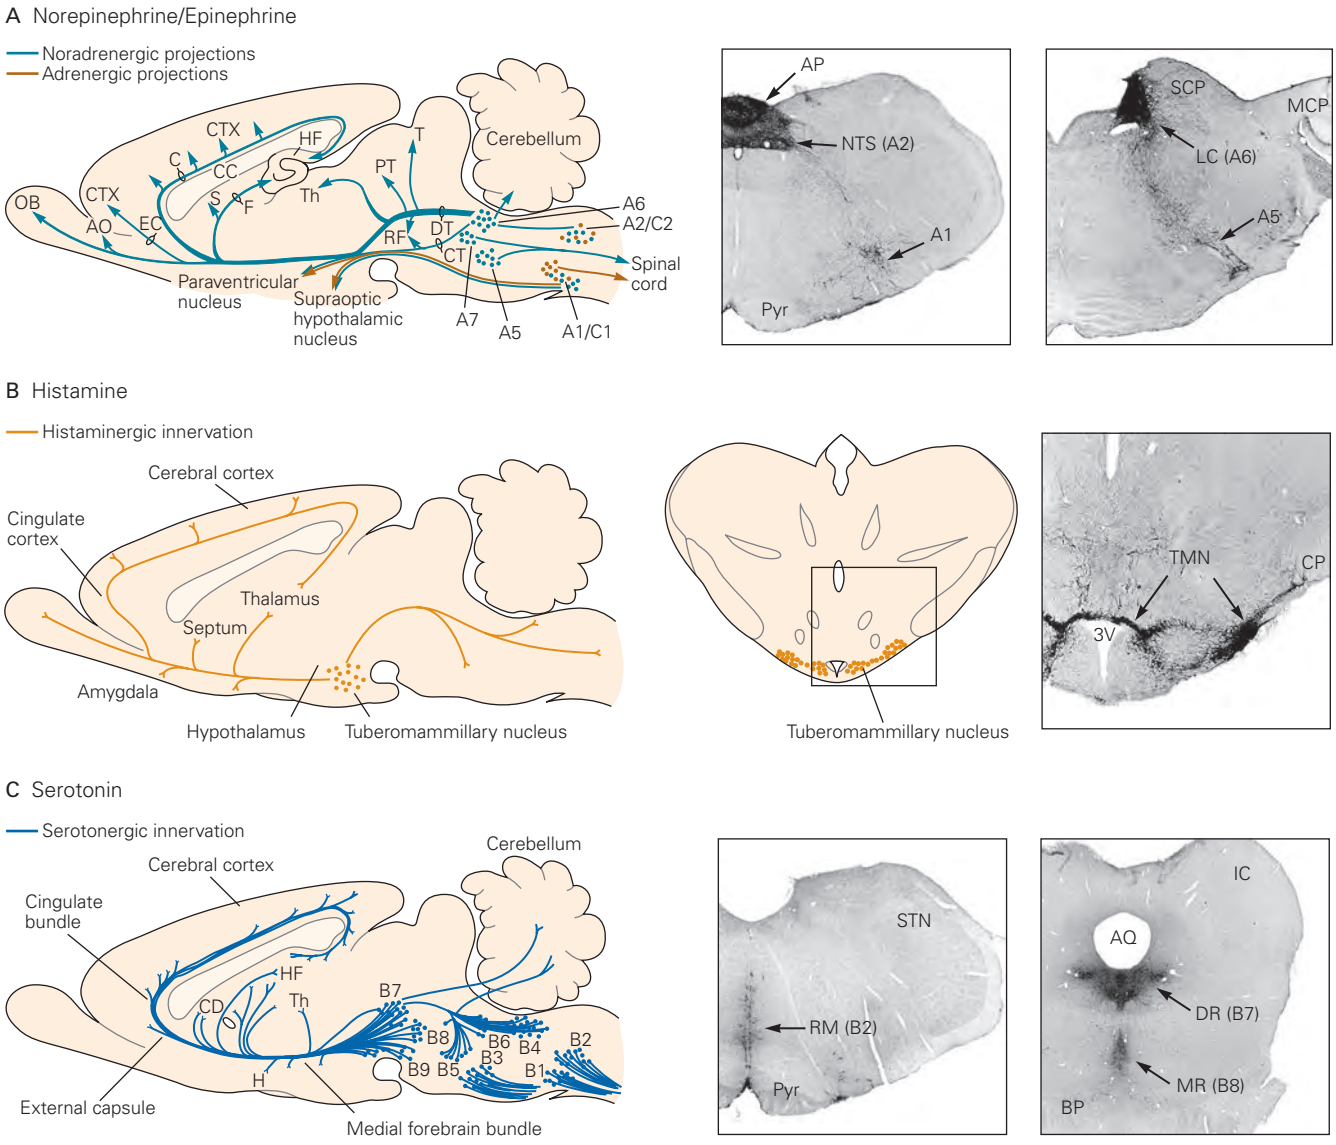

Figure 40–11 Locations and projections of monoaminergic and cholinergic neurons in the rat brain. (Abbreviations: **3V**, third ventricle; **AC**, anterior commissure; **AP**, area postrema; **AQ**, Sylvian aqueduct; **ARC**, arcuate nucleus; **BM**, nucleus basalis of Meynert; **BP**, brachium pontis; **CD**, caudate; **CP**, cerebral peduncle; **DBh**, horizontal limb of the diagonal band; **DR**, dorsal raphe; **FX**, fornix; **IC,** inferior colliculus; **LC**, locus ceruleus; **LDT**, laterodorsal tegmental nucleus; **MCP**, middle cerebellar peduncle; **MGN**, medial geniculate nucleus; **MR**, median raphe; **MS**, medial septum; **MTT**, mammillothalamic tract; **NTS**, nucleus tractus solitarius; **OC**, optic chiasm; **PPT**, pedunculopontine tegmental nucleus; **PUT**, putamen; **Pyr**, pyramidal tract; **RM**, raphe magnus; **SC**, superior colliculus; **SCP**, superior cerebellar peduncle; **SN**, substantia nigra; **STN**, spinal trigeminal nucleus; **TMN**, tuberomammillary nucleus; **VTA**, ventral tegmental area.)

A. Noradrenergic neurons (A groups) and adrenergic neurons (C groups) are located in the medulla and pons. The A2 and C2 groups in the dorsal medulla are part of the nucleus of the solitary tract. The A1 and C1 groups in the ventral medulla are located near the nucleus ambiguus. Both groups project to the hypothalamus; some C1 neurons project to sympathetic preganglionic neurons in the spinal cord and control cardiovascular and endocrine functions. The A5, A6 (locus ceruleus), and A7 cell groups in the pons project to the spinal cord and modulate autonomic reflexes and pain sensation. The locus ceruleus also projects rostrally to the forebrain and plays an important role in arousal and attention.

B. All histaminergic neurons are located in the posterior lateral hypothalamus, mostly within the tuberomammillary nucleus. These neurons project to virtually every part of the neuraxis and play a major role in arousal.

C. Serotonergic neurons (B groups) are found within the medulla, pons, and midbrain, mostly near the midline in the raphe nuclei. Those within the medulla (the B1–B4 groups corresponding to the raphe magnus, raphe obscurus, and raphe pallidus) project throughout the medulla and spinal cord and modulate afferent pain signals, thermoregulation, cardiovascular control, and breathing. Those within the pons and midbrain (the B5–B9 groups in the raphe pontis, median raphe, and dorsal raphe) project throughout the forebrain and contribute to arousal, mood, and cognition.

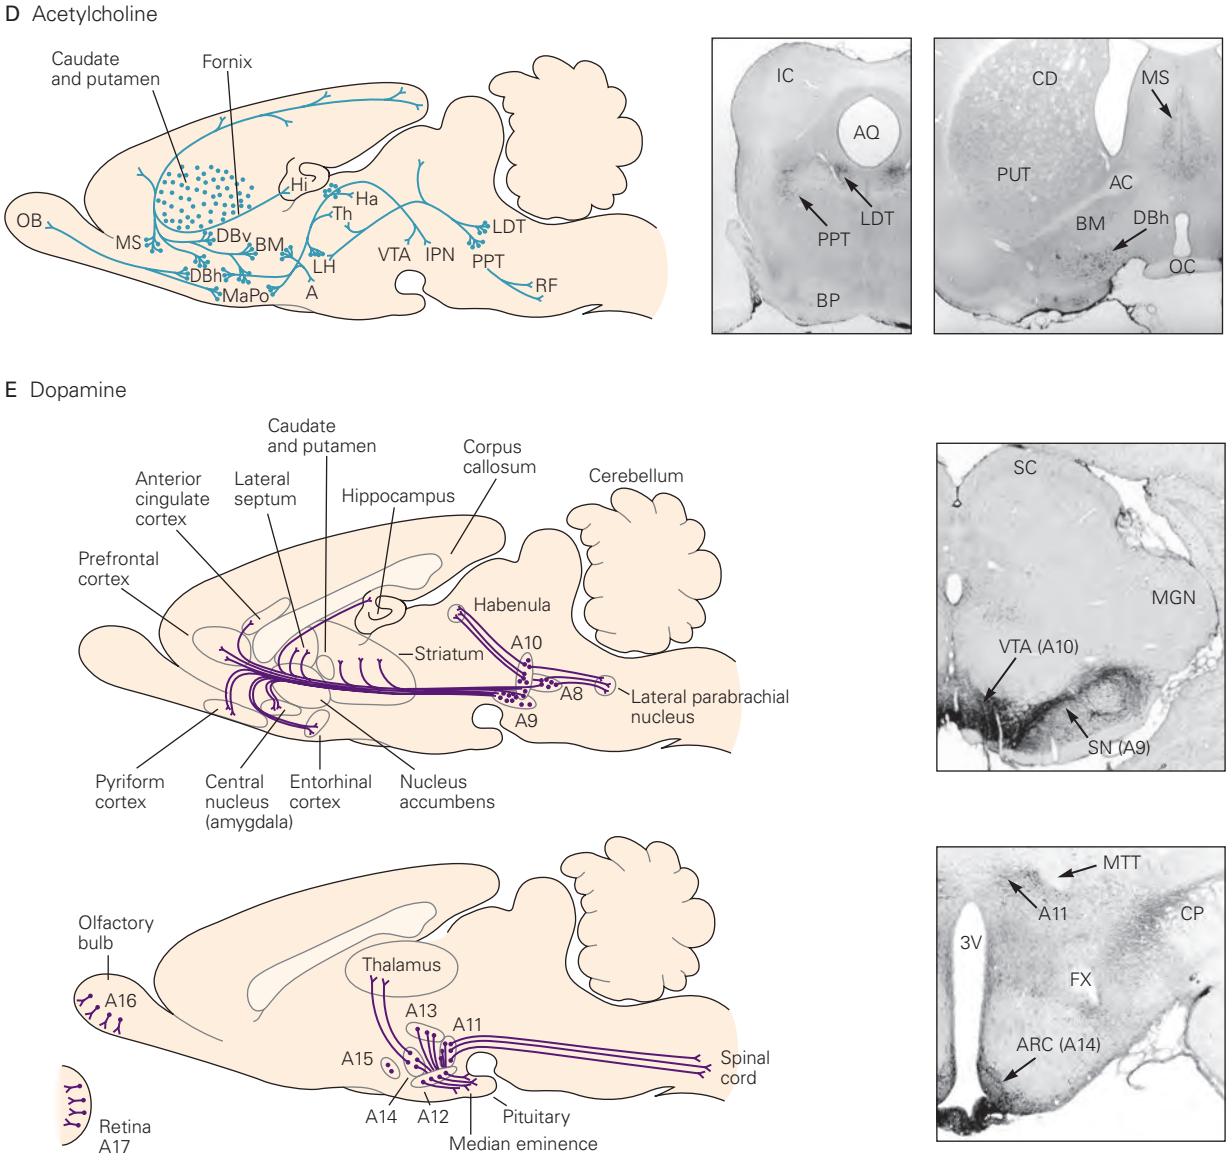

Figure 40–11 (*Continued*) **D.** Cholinergic neurons (sometimes called Ch groups) are located in the pons, midbrain, and basal forebrain. Those in the pons and midbrain (mesopontine groups) are divided into a ventrolateral cluster (pedunculopontine nucleus) and the dorsomedial cluster (laterodorsal tegmental nucleus). The mesopontine cholinergic neurons project to the brain stem reticular formation and the thalamus. Those in the basal forebrain are divided into the medial septum, the nuclei of the vertical and horizontal limbs of the diagonal band, and the nucleus basalis of Meynert. These neurons project throughout the cerebral cortex, hippocampus, and amygdala. Both groups play an important role in arousal, and the basal forebrain groups are also involved in more selective attention.

E. Dopaminergic neurons are located in the midbrain and hypothalamus. The dopaminergic cell groups were originally included with the noradrenergic cell groups and are still labeled as A groups (A8–A17). The A8 group is in the midbrain dorsally adjacent to the substantia nigra. The A9 cell group constitutes the substantia nigra pars compacta. These two groups of neurons project to the striatum and play an important role in initiation of movement. The A10 group is located in the ventral tegmental area just medial to the substantia nigra. These cells project to the frontal and temporal cortex and limbic structures of the basal forebrain and play a role in emotion and memory. The A11 and A13 cell groups in the zona incerta of the hypothalamus project to the lower brain stem and spinal cord and regulate sympathetic preganglionic neurons. The A12, A14, and A15 cell groups are components of the neuroendocrine system. Some of them inhibit release of prolactin into the hypophysial portal circulation, and others control gonadotrophin secretion. Dopaminergic neurons are also found in the olfactory bulb (A16) and the retina (A17).

The B cell groups, which had a slightly different color of fluorescence, were found to produce serotonin. They are associated with the midline raphe cell groups in the pons and medulla (Figure 40–11C). The B1–B4 cell groups in the medulla mainly provide descending modulation of sensory, motor, and autonomic neurons in the brain stem and spinal cord. The B5–B7 neurons in the pons mainly provide serotonergic innervation of the thalamus, hypothalamus, and cerebral cortex. The functions of serotonin in modulating these targets can be quite complex to decipher, mainly because there are at least 14 different serotonin receptors, and different ones can be expressed by different cell types in a target area.

A few years after the A and B cell groups were named, immunohistochemical studies demonstrated that some medullary neurons have the enzymes to make dopamine and norepinephrine but do not fluoresce. These neurons, named cell groups C1–C3, were found to process these other catecholamines to adrenalin, or epinephrine. They are closely related to the A1–A3 cell groups in the medulla (Figure 40–11A).

Histaminergic cell groups are mainly found in the tuberomammillary nucleus and adjacent areas of the posterior hypothalamus (near the mammillary body) and are named E1–E5 (Figure 40–11B). They are the sole source of histaminergic actions in the entire brain, from the cerebral cortex to the spinal cord, and are involved in a variety of arousal responses.

Although cholinergic neurons are not, strictly speaking, monoaminergic, some of them also participate in modulatory systems, and these have been numbered Ch1–Ch6 (Figure 40–11D). This classification system did not include the many other cholinergic neurons in the nervous system, such as motor neurons or striatal interneurons, and is not used much anymore. Rather, scientists refer to the cholinergic neurons by their location, eg, the pedunculopontine (Ch6) and laterodorsal tegmental (Ch5) neurons in the pons, which project widely from the cerebral cortex to the medulla, and the basal forebrain (Ch1–Ch4) groups, which project to the cerebral cortex, hippocampus, and amygdala.

Monoaminergic Neurons Share Many Cellular Properties

Neurons that use monoamines as neurotransmitters have many similar electrophysiological properties. For example, most continue to fire spontaneous action potentials in a highly regular pattern when isolated from their synaptic inputs in brain slice preparations. Their action potentials typically are followed by a slow membrane depolarization that leads to the next spike (Figure 40–12). The spontaneous regular firing pattern of monoaminergic neurons is regulated by intrinsic pacemaker currents (Chapter 10). Tonic firing in vivo may be important for ensuring continuous delivery of monoamines to targets. For example, the basal ganglia depend on continuous exposure to dopamine from the neurons of the substantia nigra to facilitate motor responses.

The properties of monoaminergic neurons are suited to their unique and widespread modulatory roles in brain function. Indeed, some axon terminals of monoaminergic cells do not even form conventional synaptic connections, instead releasing neurotransmitter diffusely to many targets at once. Most

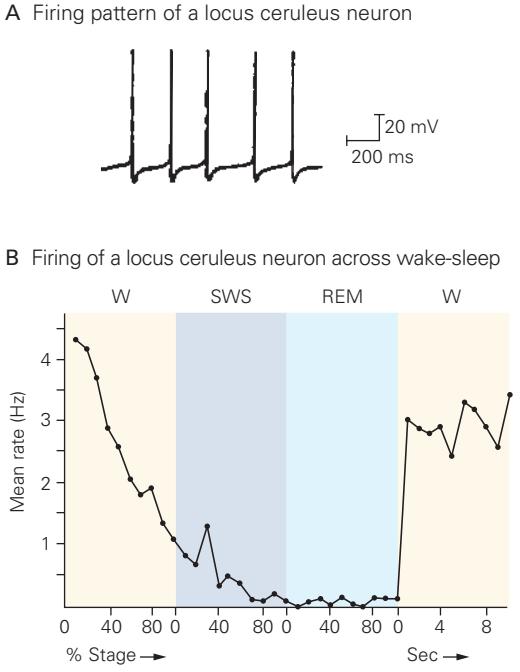

Figure 40–12 Monoaminergic neurons have similar firing patterns across the wake–sleep cycle.

A. When monoaminergic neurons are isolated from synaptic input, they fire spontaneously at a regular rate. This recording is from a noradrenergic neuron in the locus ceruleus. Action potentials are followed by a characteristic afterhyperpolarization followed by a slow depolarization to the next spike, producing a pacemaker-like activity (Chapter 10). Serotonergic and histaminergic neurons exhibit similar spontaneous activity.

B. All three monoaminergic cell types show similar patterns of firing across the wake–sleep cycle. The plot shows that a locus ceruleus neuron in a rat fires fastest when the animal is awake (**W**), slows down as wakefulness wanes and during slow-wave sleep (**SWS**), and almost completely ceases to fire during rapid eye movement (**REM**) sleep. (Adapted, with permission from Aston-Jones and Bloom 1981. © Society for Neuroscience.)

monoaminergic neurotransmission occurs by means of metabotropic synaptic actions through G protein–coupled receptors. Many monoaminergic neurons co-release neuropeptides, which have slow effects through other G protein–coupled receptors. Thus, although some monoaminergic synaptic actions involve fast synaptic mechanisms (Chapter 13), many involve slower metabotropic and neuromodulatory pathways as well (Chapter 14).

Autonomic Regulation and Breathing Are Modulated by Monoaminergic Pathways

Neurons in the adrenergic C1 group in the rostral ventrolateral medulla play a key role in maintaining resting vascular tone as well as adjusting vasomotor tone necessitated by various behaviors. For example, an upright posture disinhibits neurons in the rostral ventrolateral medulla that directly innervate the sympathetic preganglionic vasomotor neurons, thus increasing vasomotor tone to prevent a drop in blood pressure (the baroreceptor reflex). Neurons in the noradrenergic A5 group in the pons inhibit the sympathetic preganglionic neurons and play a role in depressor reflexes (eg, the fall in blood pressure in response to deep pain).

Serotonin regulates many different autonomic functions including gastrointestinal peristalsis, thermoregulation, cardiovascular control, and breathing. Electrical stimulation of serotonergic neurons within the medullary raphe nuclei increases heart rate and blood pressure. Serotonergic neurons in the medulla also project to neurons in the medulla and spinal cord that regulate breathing, as described earlier.

The role of serotonergic neurons as CO_2 receptors may explain why defects in the serotonergic system have been linked to sudden infant death syndrome (SIDS) (Figure 40–13A). SIDS is the leading cause of postneonatal mortality in the Western world, responsible for six infant deaths every day in the United States. A widely held theory holds that some SIDS cases are due to defective CO_2 chemoreception, breathing, and arousal. A relatively high number of serotonergic neurons are found in the raphe nuclei of infants who die of SIDS, but these have an immature morphology, and they are associated with relatively low serotonin levels and low serotonergic receptor densities.

A plausible neurobiological mechanism for SIDS is that a defect in development of serotonergic neurons leads to reduced ability to detect a rise in partial pressure of CO_2 when airflow is obstructed during sleep, thus blunting the normal protective response, which includes arousal and increased ventilation (Figure 40–13C). Infants sleeping face down would be unable to arouse sufficiently to change position when bedding blocks the airway. The Back to Sleep campaign, which encourages parents to place infants on their backs when put down to sleep, has reduced the incidence of SIDS by 50%.

Pain Perception Is Modulated by Monoamine Antinociceptive Pathways

Although pain is necessary for an animal to minimize injury, continued pain following an injury may be maladaptive (eg, if the pain prevents vigorous escape from

Figure 40–13 (Opposite) Serotonergic neurons have a role in the response to a rise in CO_2 levels as well as sudden infant death syndrome.

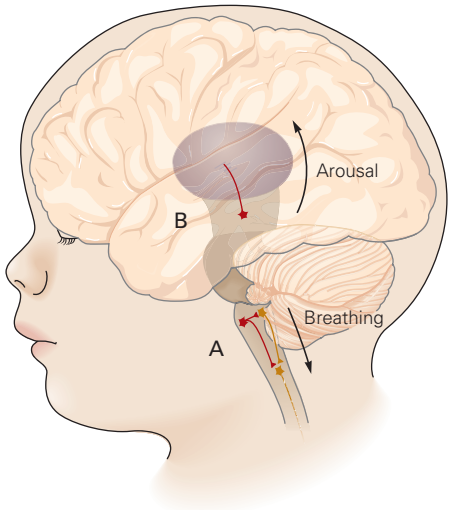
A. Serotonergic neurons in the medulla are central respiratory chemoreceptors that are thought to stimulate breathing in response to an increase in arterial blood PCO_2 (partial pressure of CO_2). The dendrites of these neurons wrap around large arteries and are stimulated by an increase in PCO_2 (see Figure 40–9C). They project to and excite motor neurons in the medulla and spinal cord that control breathing.

B. Serotonergic neurons in the midbrain are also PCO_2 sensors. Shown here is the increase in firing rate of a serotonergic neuron from the dorsal raphe nucleus in response to an increase in PCO_2 (monitored by the resultant decrease in external pH). This increase in firing rate may sensitize ascending arousal pathways from the parabrachial nucleus, which also receives input from other CO_2 sensory pathways. This important response prevents suffocation during sleep when the airway is obstructed. (Reproduced, with permission, from Richerson 2004. Copyright © 2004 Springer Nature.)

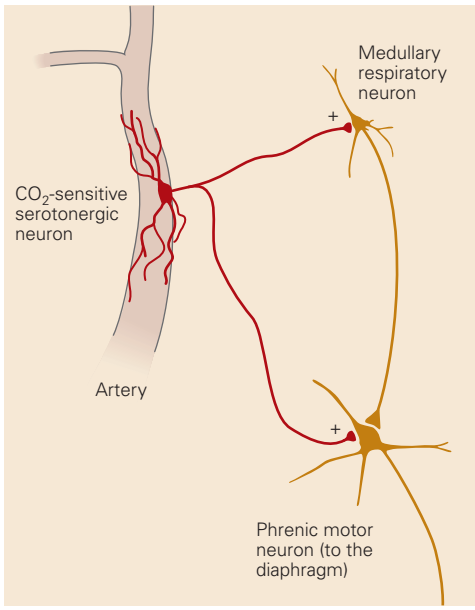
C. Sudden infant death syndrome (SIDS).

1. *Triple risk hypothesis of SIDS*. Infants are at risk to die from SIDS when three conditions coincide. First, the infant must be vulnerable because of an underlying abnormality of the brain stem, such as a genetic predisposition or an environmental insult (eg, exposure to cigarette smoke). Second, the baby must be in the stage of development (usually 2–6 months of age) when it may be difficult to change position to escape suffocation. Third, there also must be an exogenous stressor (eg, lying face down in a pillow). (Reproduced, with permission from, Filiano and Kinney 1994. © 1994 S. Karger AG.)

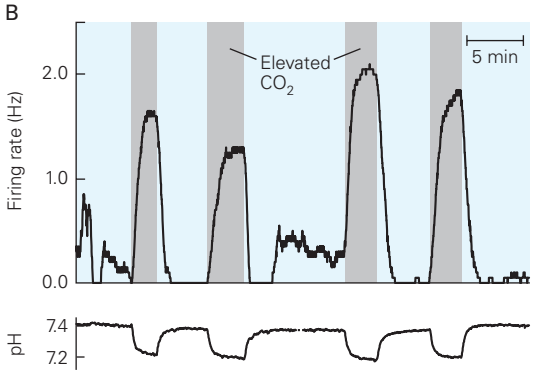
2. *Proposed mechanism of SIDS*. The combination of abnormal serotonergic neurons (eg, from exposure to cigarette smoke) and postnatal immaturity of neurons involved in respiratory control leads to the inability to respond effectively to airway obstruction (eg, from lying face down in a crib). The infant then does not wake up and turn its head or breathe faster, either of which would correct the problem. As a result, blood oxygenation decreases severely (hypoxia) while blood CO_2 rises (hypercapnia).



A Serotonergic neurons

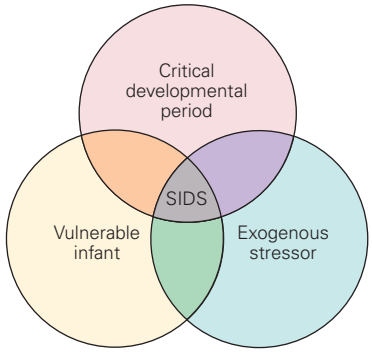


B

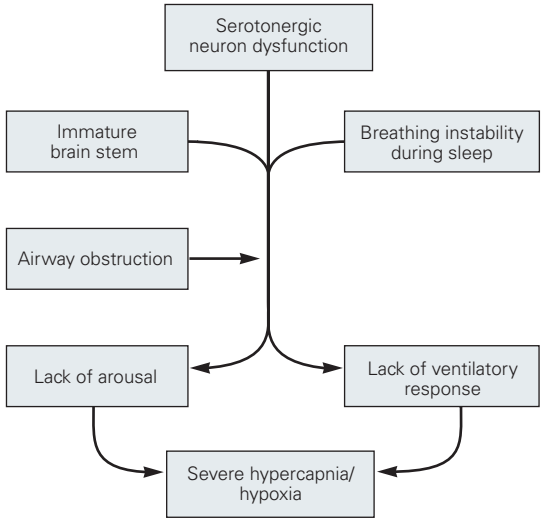


C Sudden Infant Death Syndrome

1 Triple risk hypothesis



2 Proposed mechanism



a predator). The monoaminergic systems include important descending projections to the dorsal horn of the spinal cord that modulate pain perception (Chapter 20).

The noradrenergic inputs to the spinal cord originate from the pontine cell groups A5–A7, with the locus ceruleus (A6) providing most of the input to the dorsal horn. Similarly, the serotonergic raphe nuclei in the medulla, particularly the nucleus raphe magnus, project to the dorsal horn where they modulate the processing of information about noxious stimuli. Direct application of serotonin to dorsal horn neurons inhibits their response to noxious stimuli, and intrathecal administration of serotonin attenuates the defensive withdrawal of the paw evoked by noxious stimuli. In addition, intrathecal administration of antagonists of serotonin receptors blocks the pain inhibition evoked by stimulation of the raphe nuclei.

Insight into the role of serotonin in pain processing has been used in treating migraine headaches. In particular, the triptan agonists of 5-HT_{1D} receptors have been found to be therapeutically effective. One of the possible mechanisms of action of this family of tryptamine-based drugs includes presynaptic inhibition of pain afferents from the meninges, preventing sensitization of central neurons. Drugs that block monoamine reuptake, including both traditional antidepressants and selective serotonin reuptake inhibitors, are effective in limiting pain in patients with chronic pain and migraine headaches.

Motor Activity Is Facilitated by Monoaminergic Pathways

The dopaminergic system is critical for normal motor performance. A massive projection ascends from the substantia nigra pars compacta to the striatum, where dopaminergic fibers act on striatal neuron receptors to release inhibition of motor responses (Chapter 38).

Patients with Parkinson disease in whom midbrain dopaminergic neurons have degenerated have trouble initiating movement and difficulty sustaining movements. Such patients speak softly, write with small letters, and take small steps. Conversely, drugs that facilitate dopaminergic transmission in the striatum can result in unintended behaviors, ranging from motor tics (small muscle twitches), to chorea (large-scale, jerky limb movements), to complex cognitive behaviors (such as compulsive gambling or sexual activity).

As first shown by Sten Grillner, serotonergic neurons play an important role in modulating motor programs. Drugs that activate serotonin receptors can induce hyperactivity, myoclonus, tremor, and rigidity, all of which are part of the "serotonin syndrome." Increases in the firing of raphe neurons have been observed in animals during repetitive motor activities such as feeding, grooming, locomotion, and deep breathing. Conversely, the firing of both serotonergic raphe and noradrenergic locus ceruleus neurons practically ceases during the atonia and lack of movement that occur during rapid eye movement (REM) sleep.

Noradrenergic cell groups in the pons also send extensive projections to motor cell groups. This modulatory input acts on presynaptic β- and α_1-adrenergic receptors to facilitate excitatory inputs to motor neurons (Chapter 31). The sum of these effects is to facilitate motor neuron responses in stereotypic and repetitive behaviors such as rhythmic chewing, swimming, or locomotion. Conversely, increased β-adrenergic activation during stress can exaggerate motor responses and produce tremor. Drugs that block β-adrenergic receptors are used clinically to reduce certain types of tremor and are often taken by musicians prior to performances to minimize tremulousness.

Ascending Monoaminergic Projections Modulate Forebrain Systems for Motivation and Reward

The forebrain is continuously bombarded with sensory information and must determine which stimuli deserve attention. It must also decide which of many available behaviors should receive priority, based in part on experience—which behaviors have achieved rewarding outcomes in the past. The ascending monoaminergic systems play key roles in modulating all of these choices.

As noted earlier, dopaminergic inputs to the striatum adjust the likelihood that a specific motor pattern or even a cognitive pattern will be expressed. Low dopamine levels reduce output from the direct pathway striatal neurons (which release behaviors) and increase activity of indirect pathway striatal neurons (which inhibit behavior). Dopamine also has been linked to reward-based learning. Rewards are objects or events for which an animal will work (Chapter 42) and are useful in positively reinforcing behavior. Activity of dopaminergic neurons increases when a reward (such as food or juice) is unexpectedly given. But after animals are trained to expect a reward following a conditioned stimulus, the activity of the neurons increases immediately after the conditioned stimulus rather than after the reward. This pattern of activity indicates that dopaminergic neurons provide a reward-prediction error signal, an important element in reinforcement learning. The importance of dopamine in learning is also supported by observations that lesions of dopaminergic systems prevent reward-based learning.

The same dopaminergic pathways that are important for reward and learning are involved in addiction to many drugs of abuse (Chapter 43)

Noradrenergic neurons of the locus ceruleus play an important role in attention. These neurons have a low baseline level of activity in drowsy monkeys. In alert, attentive monkeys the cells have two firing patterns. In the *phasic mode*, the baseline activity of the neurons is low to moderate, but there are bursts of firing just before the monkey responds to stimuli to which it has been attentive. This pattern of activity is thought to facilitate selective attention to a stimulus that is about to initiate a behavior. In contrast, in the *tonic mode*, the baseline level of activity is elevated and does not change in response to external stimuli. This mode of firing may promote the search for a new behavioral and attentional goal when the current task is no longer rewarding (Figure 40–14).

Many monoaminergic neurons also participate in regulating overall arousal (Figure 40–15). The noradrenergic locus ceruleus, serotonergic dorsal and median raphe nuclei, dopaminergic A10 neurons, and histaminergic tuberomammillary neurons innervate the thalamus, hypothalamus, basal forebrain, and cerebral cortex. All of these systems have the property of firing fastest during wakefulness, slowing down during slow wave (or non-REM) sleep, and grinding to a halt during REM sleep.

Stimulation of noradrenergic neurons in the locus ceruleus or histaminergic cells in the tuberomammillary nucleus increases electroencephalogram (EEG) arousal, indicating that these systems play an important role in cortical and behavioral arousal. However, lesions restricted to one or even a combination of monoaminergic cell groups do not cause profound loss of wakefulness, suggesting that the various cell groups

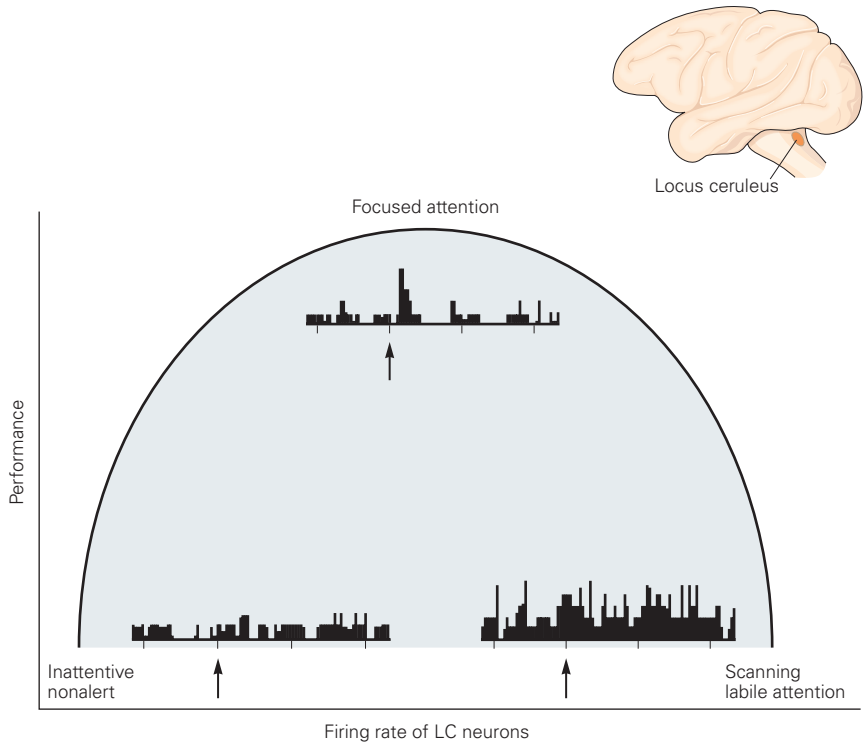


Figure 40–14 Locus ceruleus (LC) neurons exhibit different patterns of activity with different levels of attentiveness and task performance. The inverted U curve shows the relationship between a monkey's performance on a target detection task and the level of locus ceruleus activity. Histograms show the responses of LC neurons to presentation of the target during different levels of task performance. Performance is poor at low levels of LC activity because the animals are not alert. Performance is optimal when baseline activity is moderate and phasic activation follows presentation of the target. Performance is also poor when baseline activity is high because the higher baseline is incompatible with focusing on the assigned task. The tonic mode (with high baseline activity) might be optimal for tasks (or contexts) that require behavioral flexibility instead of focused attention. If so, the LC could regulate the balance between focused and flexible behavior. (Adapted, with permission, from Aston-Jones, Rajkowski, and Cohen 1999. Figure 40–15 Major cell groups in the ascending arousal system. Neurons using the neurotransmitters norepinephrine, serotonin, dopamine, histamine, and acetylcholine have widespread forebrain projections. Although they all contribute to arousal by modulating various brain functions, ablation of any one of these cell groups has little effect on the waking state, suggesting that none of them are essential for maintaining a waking state. On the other hand, extensive damage to glutamatergic neurons in the parabrachial and pedunculopontine nuclei or to the GABAergic, glutamatergic, and cholinergic neurons in the basal forebrain (**orange boxes**) can cause a profound and prolonged coma. Thus, the parabrachial–pedunculopontine–basal forebrain–cortical pathway appears to be the only one that is essential to maintaining a waking state. (Abbreviations: **GABA**, γ-aminobutyric acid; **ILT**, intralaminar thalamic nuclei; **LC**, locus ceruleus; **RT**, reticular nucleus of the thalamus.)

probably have overlapping and at least partly redundant roles in sleep/wake regulation. The monoaminergic pathways modulate specific cellular properties of postsynaptic neurons in the thalamus and cerebral cortex, enhancing alertness and interaction with environmental stimuli.

Monoaminergic and Cholinergic Neurons Maintain Arousal by Modulating Forebrain Neurons

The monoaminergic and cholinergic neurons induce arousal by activating cortical neurons both directly and indirectly. They do this in part by modulating the activity of neurons in the brain stem, hypothalamus, basal forebrain, and thalamus that activate the cerebral cortex.

Both noradrenergic and serotonergic neurons innervate the parabrachial complex, a glutamatergic cell group that is critical for maintaining a waking forebrain. Noradrenergic inputs also activate histaminergic and orexin neurons in the lateral hypothalamus as well as cholinergic and GABAergic neurons in the basal forebrain, all of which project directly to the cerebral cortex. The parabrachial, histaminergic, orexin, and cholinergic basal forebrain neurons all excite cortical pyramidal cells, whereas the GABAergic basal forebrain neurons inhibit cortical inhibitory interneurons, thus disinhibiting the cortical pyramidal cells. The net effect of these inputs is to make the cortical pyramidal neurons more responsive to incoming sensory and cognitive inputs.

Parabrachial, noradrenergic, serotonergic, histaminergic, and cholinergic inputs also innervate the thalamus and modulate its ability to transmit sensory information to the cerebral cortex. Thalamic relay neurons fire in rhythmic bursts during sleep (Chapter 44) but fire single spikes related to incoming sensory stimuli during wakefulness. The firing pattern of thalamic and cortical neurons changes from burst mode to single-spike mode when the cells are depolarized following application of acetylcholine, norepinephrine,

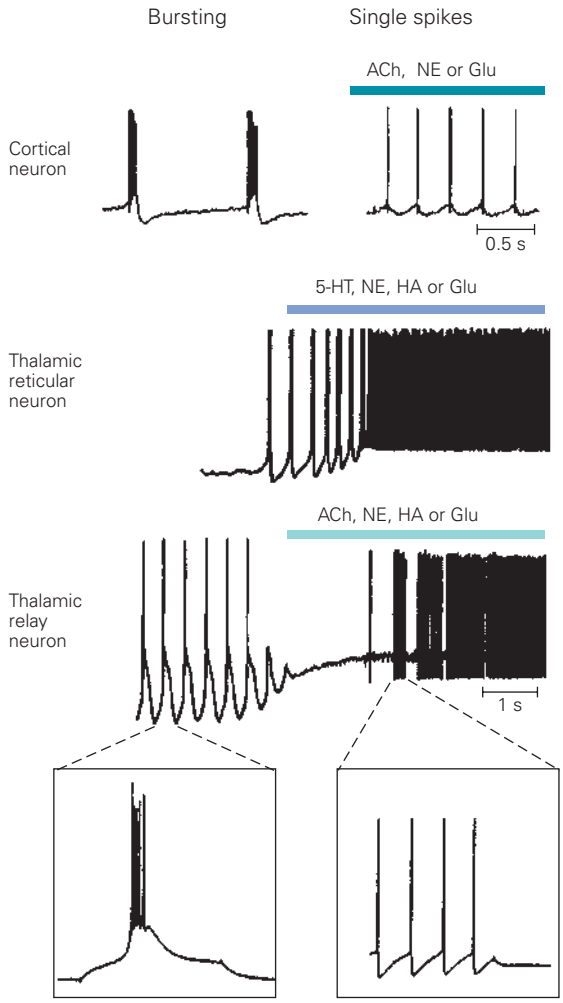

Figure 40–16 Monoaminergic and cholinergic systems modulate the activity of thalamic and cortical neurons to maintain arousal. The firing patterns of cortical and thalamic neurons are converted from burst mode to single-spike mode by the action of acetylcholine or monoamines. Recordings are from neurons in brain slices. Thalamic and cortical neurons have limited ability to convey information when firing in rhythmic bursts. However, when in single-spike mode, their firing activity reflects the inputs they receive. Therefore, the monoaminergic and cholinergic arousal systems keep open the lines of communication necessary for cortical information processing. (Reproduced, with permission, from Steriade, McCormick, and Sejnowski 1993. Copyright © 1993 AAAS.)

serotonin, or histamine (Figure 40–16). Thus, the monoaminergic neurons that participate in the ascending arousal system regulate cortical activity in part by altering the firing of thalamic neurons.

Many pharmacological agents that target monoaminergic and cholinergic systems influence arousal. For example, antihistamines cause drowsiness, serotonin reuptake blockers decrease the amount of REM sleep, and nicotine is a powerful stimulant. In addition, arousal is induced by amphetamines, cocaine, and other drugs that block dopamine reuptake; mice lacking the dopamine transporter are insensitive to such drugs.

Patients with Parkinson disease, who lose dopaminergic neurons in the substantia nigra, also lose noradrenergic neurons in the locus ceruleus and tend to be abnormally sleepy during the day. Some drugs used to treat Parkinson disease activate the D_2 dopamine receptor on presynaptic terminals of the remaining dopaminergic arousal neurons, which results in presynaptic inhibition, thus reducing dopamine release. As a result, although these drugs may make the movement disorder better (through their effects on postsynaptic D_2 receptors on neurons in the striatum), the inhibitory effect on remaining dopaminergic cells in the arousal system may exacerbate daytime sleepiness.

Highlights

1. The plan for the brain stem and the cranial nerves unfolds early in development, as neurons assemble into clusters that come, in time, to assume their functional organization. Building on the basic plan of the spinal cord, motor and sensory neurons concerned with the face, head, neck, and internal viscera form into discrete nuclei with specific functions and territories of innervation.
2. Neurons in the reticular formation surrounding these cranial nerve nuclei develop into ensembles of neurons that can generate patterns of autonomic and motor responses that subserve simple, stereotyped, coordinated functions, ranging from facial expression to feeding and breathing. These behavior patterns are sufficiently complex and flexible to represent the entire behavioral repertory of a newborn baby.
3. As the forebrain develops and exerts its control over these brain stem pattern generators, a variety of more complex responses and ultimately volitional control of behavior evolve.
4. Even a skilled actor, however, finds it difficult to produce the facial expressions associated with specific emotions unless he recreates the emotional states internally, thereby triggering the prepatterned facial expressions associated with those feeling states. Thus, some of the most complex human emotions and behaviors are played out unconsciously by means of stereotypic patterns of motor and autonomic responses in the brain stem.

5. The brain stem also contains a series of cell groups that have long-ranging and diffuse projections. Their targets range from the cognitive and behavioral systems in the cerebral cortex, to hypothalamic and brain stem autonomic control areas, to sensory and motor control systems in the spinal cord. Many of the neurons that participate in these modulatory systems, which set the tone for more specific sensory, motor, behavioral, and autonomic outputs, use monoamines as neuromodulators.
6. As a result of the diffuseness of these modulatory pathways and the multiplicity of receptors that they employ, a large portion of all central nervous system–active drugs act on these pathways. Unfortunately, many of the off-target effects of these drugs are due to the diffuseness of these pathways and their use of the same neurotransmitters and receptors at multiple locations. A challenge for the future of central nervous system pharmacology will be to develop drugs more highly selective for the targeted functions that require modulation.

The Hypothalamus: Autonomic, Hormonal, and Behavioral Control of Survival

THE SURVIVAL OF AN INDIVIDUAL requires tight control of body temperature, water balance, and blood pressure, together with sufficient food intake and appropriate regulation of sleep/wakefulness

cycles. Survival of a species requires that individuals be fertile, mate, and nurture their offspring, and that aggression toward others be appropriate and adaptive. Neurons in the hypothalamus control all of these key survival activities.

As we shall learn in this chapter, the hypothalamus together with interconnected areas of the brain responds to bodily and emotional challenges by recruiting appropriate behavioral and physiological responses. Coordination of these activities ensures constancy of the internal environment, a process known as homeostasis. The hypothalamus acts on three major systems: the autonomic motor system, the neuroendocrine system, and neural pathways that mediate motivated behavior.

The autonomic motor system is distinct from the somatic motor system, which controls skeletal muscle. Whereas somatic motor neurons regulate contractions of striated muscles (Chapter 31), autonomic motor neurons regulate blood vessels, the heart, the skin, and visceral organs through synapses upon smooth and cardiac muscle cells, upon glands cells that serve endocrine and exocrine functions, and upon metabolic targets such as adipocytes. The neuroendocrine system works differently, by secreting several peptide hormones from the pituitary, the "master gland," located just beneath the hypothalamus. These pituitary hormones control water retention by the kidney, parturition, lactation, somatic growth, gamete development, and also the release of nonpeptide hormones from three downstream glands—the gonads, adrenal cortex, and thyroid.

Although largely involuntary, autonomic and neuroendocrine responses are tightly integrated with voluntary behavior executed by the somatic motor system. Running, climbing, and lifting exemplify voluntary actions that have metabolic, cardiovascular, and thermoregulatory consequences. These needs are automatically met by the autonomic and neuroendocrine systems through changes in cardiorespiratory drive, cardiac output, regional blood flow, heat dissipation, and fuel mobilization. Such compensatory changes are implemented primarily by feedforward central commands, supplemented by reflexes activated by sensory feedback. Similarly, emotional states evoke autonomic and neuroendocrine responses. Feelings of fear, anger, happiness, and sadness have characteristic autonomic and hormonal manifestations.

In this chapter, we first explore the concept of homeostasis and the general means by which it is achieved. We then discuss the anatomical and functional organization of the hypothalamus and its two "involuntary" motor arms—the autonomic and neuroendocrine systems. After that, we focus in depth on three classic examples of hypothalamic homeostatic control—regulation of body temperature, of water balance and its related deficiency drive, thirst, and of energy balance and its drive, hunger. We conclude by examining sexually dimorphic regions of the hypothalamus and their role in regulating sexual behavior, aggression, and parenting. Additional discussion of sleep cycles and regulation of circadian rhythms can be found in Chapter 44.

Homeostasis Keeps Physiological Parameters Within a Narrow Range and Is Essential for Survival

In the mid-19th century, the French physiologist and founder of experimental medicine Claude Bernard drew attention to the stability of the body's internal environment over a broad range of behavioral states and external conditions. "The internal environment (*le milieu interior*)," he wrote, "is a necessary condition for a free life." Building on this idea, in the 1930s, the American physiologist Walter B. Cannon introduced the concept of homeostasis to describe the mechanisms that maintain the constancy of composition of the bodily fluids, body temperature, blood pressure, and other physiological variables—all of which are necessary for survival.

Homeostatic mechanisms are highly adaptive because they greatly extend the range of conditions that can be tolerated. For example, during exercise, many parameters can increase dramatically—cardiac output by 4- to 5-fold, oxygen and fuel consumption by 5- to 10-fold, and heat production to a similar degree. In the absence of compensatory responses, blood pressure would increase in proportion to cardiac output, rupturing blood vessels; circulating fuels would fall to critically low levels, starving cells of energy; and hyperthermia would denature cell proteins. Indeed, the capacity of homeostasis is remarkable, making it possible for animals to survive at high latitudes where seasonal temperatures can fluctuate by 70°C and for humans to run 251 km in the sands of the extremely hot Sahara Desert (Marathon des Sables). Homeostatic mechanisms greatly extend the range of habitats, activities, and traumas that can be survived.

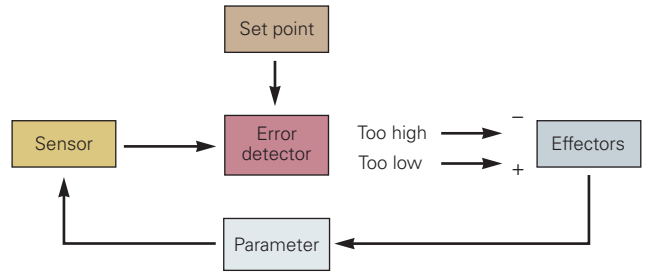
Homeostasis requires negative sensory feedback from the body. The concept of feedback loops evolved from the discovery of sensors that detect critical physiological variables and then couple them with behavioral, autonomic, and neuroendocrine motor outputs. Drawing upon the engineering principle of negative feedback control, this led to the concept that

physiological "set points" help control key parameters like body temperature, blood osmolarity, blood pressure, and body fat content.

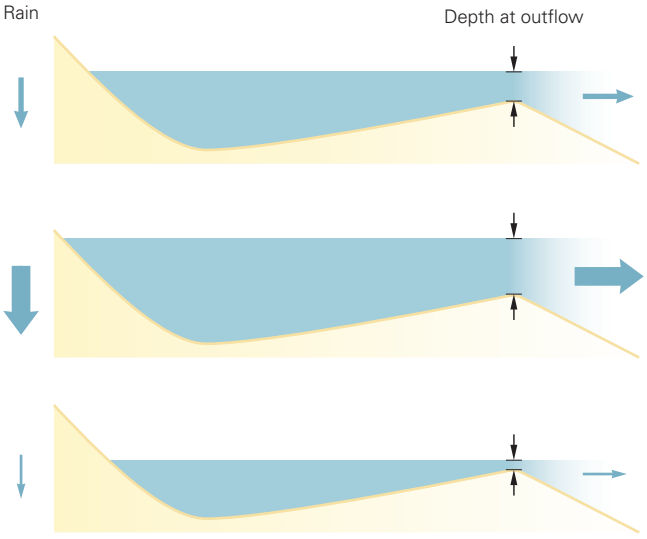
Set point models are appealing because thermostats are so effective in maintaining room temperature at a targeted set point and, by analogy, physiological variables like body temperature are likewise tightly controlled. In such models, a "set point" exists for a parameter, 37°C in the case of body temperature, and at any given moment, the real level of the parameter is assessed and compared with the targeted set point through feedback and error detection (Figure 41–1A). Any deviation above or below triggers counteracting corrective responses—if too hot, cutaneous vasodilatation, sweating, and a dip in the pool; if too cold, vasoconstriction, thermogenesis, shivering, and the donning of a sweater. For regulation of body temperature, the set point and detection of error were historically seen as emergent properties of neurons in the preoptic area of the hypothalamus (POA).

Over time, the set point model required revision because intensive investigation failed to uncover any molecular or neuronal bases for encoding set points and performing error detection. In addition, "set point–like" regulation can, in principle, be achieved without a set point, feedback, or error detection—the so-called "settling point" model (Figure 41–1B). Consider the changing level of a lake. When rainfall is excessive, its level rises; the rivers draining the lake rise and their flow increases. The converse is true when rainfall is low. The changing flow of the rivers draining the lake thus maintains its level near a settling point without requiring an idealized set point, feedback, or error detection. While aspects of the settling point model have appeal, it too is incomplete because homeostatic processes clearly receive important feedback

A Set point model



B Settling point model



C Combined model: settling point of multiple afferent/efferent loops

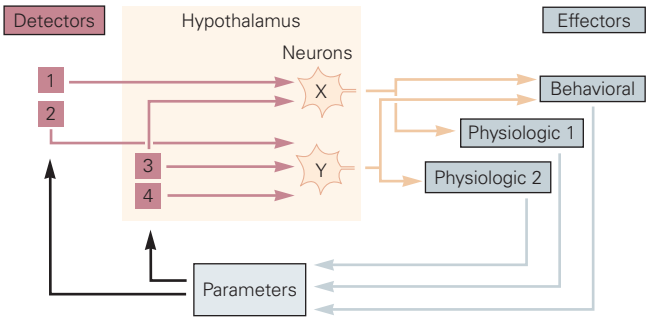


Figure 41–1 (Left) Set points, settling points, and homeostasis.

A. The set point view was inspired by engineering principles. As with a thermostat, constancy is achieved by providing feedback on the existing level of a parameter, determining how it compares to an idealized set point, and then instituting corrective measures to return the parameter to the set point. While popular for many years, it has fallen out of favor as years of research have failed to uncover molecular and neural bases for encoding set points and performing error detection.

B. The settling point model was inspired by observations that many systems achieve constancy in the absence of any feedback or error detection. In this example, the level of outflow of water from a lake is proportional to the depth of the lake. When it rains, the increase or decrease in the level of the lake causes more or less water to flow out of the lake. The level of the lake remains fairly constant without a set point or error detection. A related example is regulation of body weight. Increased food intake leads to increased body weight. As body weight increases, the energy cost of carrying and sustaining that increased weight goes up. Because of this, body weight too should have its settling point. (Reproduced, with permission, from Speakman et al. 2011.)

C. In this model the concepts of feedback in part **A** and settling point in part **B** are combined. The apparent set point is in fact the settling point, an emergent property of multiple feedback-informed afferent/efferent loops.

regarding disturbances, and this feedback produces vital responses that hasten recovery. As we shall see, temperature, osmolarity, and body fat are directly or indirectly "sensed," and this affects the activity of neurons in the hypothalamus that generate counteracting responses.

Most physiologists today have adopted a "distributed settling point" model that incorporates strong feedback control of multiple sensory/effector loops (Figure 41–1C). With body temperature, for example, there is no single specific set point and no location in the brain where a single set point is encoded and error detection takes place; in short, there is no thermostat. Instead, there are multiple temperature detectors located in different sites (skin, core, and brain), and each is coupled through neuronal pathways that traverse the preoptic area on their way to different body temperature effectors (cutaneous blood vessels, sweat glands, brown fat metabolism, shivering and behavioral pathways). When engaged, each of these effectors impact body temperature. The apparent set point for body temperature is in fact the emergent settling point that results from the combined activities of the multiple feedback-informed afferent/efferent loops. As we will see later, this nuanced model also applies to regulation of blood pressure, blood osmolarity, and body fat.

The Hypothalamus Coordinates Homeostatic Regulation

The hypothalamus integrates the status of physiological parameters with outputs to behavioral, autonomic, and neuroendocrine motor systems and thereby regulates six vital physiological functions (Table 41–1). The hypothalamus lies at the base of the brain immediately above the pituitary gland (Figure 41–2). It is bounded anteriorly (rostrally) by the diagonal band of Broca; dorsally by the anterior commissure, the bed nuclei of the stria terminalis, the zona incerta, and thalamus; and posteriorly (caudally) by the ventral tegmental area and interpeduncular nucleus.

The Hypothalamus Is Commonly Divided Into Three Rostrocaudal Regions

Regions of the hypothalamus are named according to their location and appearance in Nissl-stained sections. The hypothalamus is divided, rostral to caudal, into three regions. (1) The *preoptic hypothalamus* lies above the optic chiasm and contains neurons that control water balance and thirst, temperature, sleep, sexual behavior, and circadian rhythms. (2) The *tuberal hypothalamus* lies above the pituitary and contains neurons controlling pituitary hormone secretion, autonomic outflow, and various behaviors including hunger, sexual behavior, and aggression. (3) The *posterior hypothalamus* includes the posterior and mammillary nuclei, as well as histaminergic neurons in the tuberomammillary nucleus that affect arousal. The functions of other neurons in the posterior hypothalamus areas are less well defined.

The *lateral hypothalamic area* (LHA) spans from the middle to the caudal hypothalamus. It is linked more closely to reward pathways and arousal than to maintenance of homeostasis and specific survival behaviors. Indeed, it is heavily connected with the nucleus accumbens and ventral tegmental area, two areas involved in reward (Chapter 43), and contains neurons that project extensively throughout the cortex. Lastly, LHA neurons expressing the neuropeptide orexin (hypocretin) play a critical role in stabilizing wakefulness (Chapter 44).

Table 41–1 The Hypothalamus Integrates Behavioral (Somatomotor), Autonomic, and Neuroendocrine Responses Involved in Six Vital Functions

1. *Blood pressure and electrolyte composition*. The hypothalamus regulates thirst, salt appetite, and drinking behavior; autonomic control of vasomotor tone; and the release of hormones such as vasopressin (via the paraventricular nucleus).
2. *Energy metabolism*. The hypothalamus regulates hunger and feeding behavior, the autonomic control of digestion, and the release of hormones such as glucocorticoids, growth hormone, and thyroid-stimulating hormone (via the arcuate and paraventricular nuclei).
3. *Reproductive (sexual and parental) behaviors*. The hypothalamus controls autonomic modulation of the reproductive organs and endocrine regulation of the gonads (via the medial preoptic, ventromedial, and ventral premammillary nuclei).
4. *Body temperature*. The hypothalamus influences thermoregulatory behavior (seeking a warmer or cooler environment), controls autonomic body heat conservation/loss mechanisms, and controls secretion of hormones that influence metabolic rate (via the preoptic region).
5. *Defensive behavior*. The hypothalamus regulates the stress response and fight-or-flight response to threats in the environment such as predators (via the paraventricular, anterior hypothalamic, and dorsal premammillary nuclei, and the lateral hypothalamic area).
6. *Sleep–wake cycle*. The hypothalamus regulates the sleep–wake cycle (via a circadian clock in the suprachiasmatic nucleus) and levels of arousal when awake (via the lateral hypothalamic area and tuberomammillary nucleus).

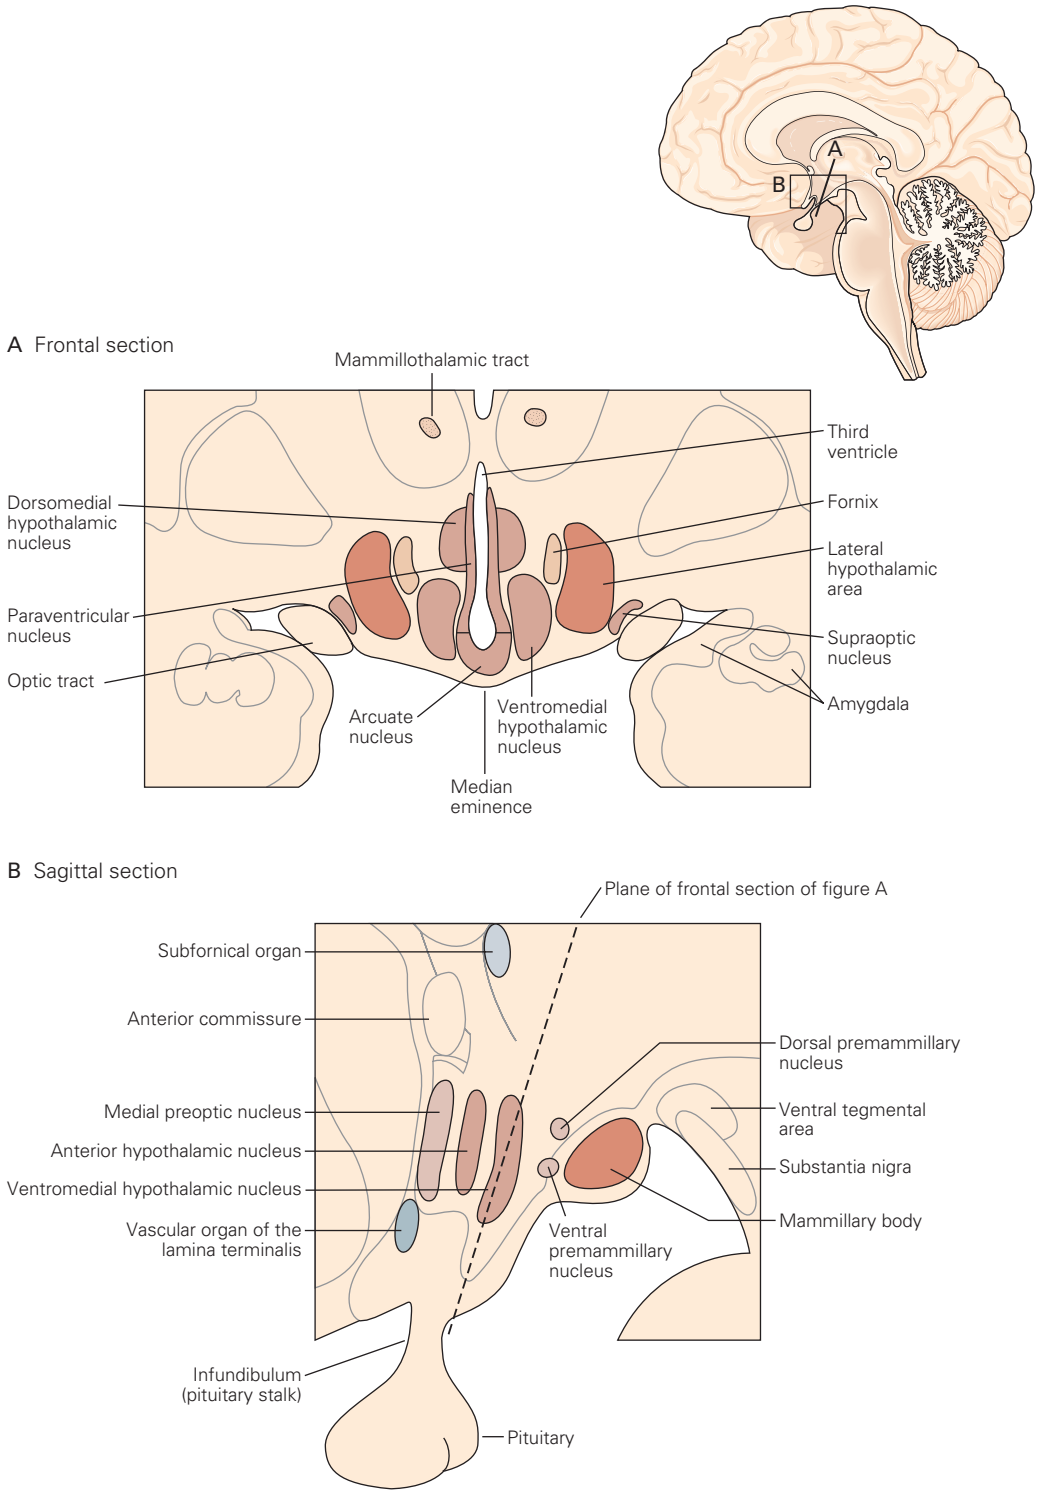

Figure 41–2 The structure of the hypothalamus.

A. Frontal view of the hypothalamus (section along plane A shown in the sagittal view of the brain, upper right). The third ventricle is in the midline; the paraventricular, dorsomedial, and arcuate nuclei adjacent to the ventricle form the neuroendocrine motor zone and periventricular region at this level. The ventromedial nucleus is part of the medial column of hypothalamic nuclei, and the lateral hypothalamic area is the lateral zone component represented in the part of the hypothalamus shown here.

B. Sagittal (rostrocaudal) view of the medial column of hypothalamic nuclei, showing the adjacent (caudal) substantia nigra and ventral tegmental area of the midbrain. The functional significance of key hypothalamic nuclei is summarized in Table 41–1.

Modality-Specific Hypothalamic Neurons Link Interoceptive Sensory Feedback With Outputs That Control Adaptive Behaviors and Physiological Responses

General principles of hypothalamic function have emerged over several decades. Neurons in the periphery and brain respond when parameters under homeostatic control are disturbed. Such neurons can respond directly to the stimulus or indirectly to changes in hormones and other factors that track the regulated parameter. This sensory information is then relayed to functionally appropriate regulatory neurons in a particular site (or sites) within the hypothalamus. Once the information is integrated by hypothalamic neurons, the results are then conveyed downstream to motor circuits that control specific behaviors and physiological responses. The result is a coordinated corrective response (eg, warmth-seeking plus heat production and retention, thirst plus water retention by the kidney, or hunger plus decreased energy expenditure).

Our understanding of the functions of hypothalamic neurons has been refined recently using optogenetic and chemogenetic techniques in active animals. By selectively activating subsets of hypothalamic neurons, one can evoke specific behaviors and physiological responses, even when the need is totally absent. Key regulatory neurons for body temperature are located in the median preoptic nucleus (MnPO). Water balance is regulated by neurons in three sites—the MnPO, the vascular organ of the lamina terminalis (OVLT), and the subfornical organ (SFO)—and energy balance by neurons in the arcuate nucleus (Figure 41–2A).

Modality-Specific Hypothalamic Neurons Also Receive Descending Feedforward Input Regarding Anticipated Homeostatic Challenges

In addition to input from sensory signals that provide important feedback regarding the status of the body, key regulatory neurons in the hypothalamus receive "top-down" feedforward inputs from neurons that anticipate future homeostatic challenges. For example, when food-deprived animals detect cues that predict the availability of food, there is a rapid drop in the firing of hunger-promoting neurons in the arcuate nucleus even before food is ingested. Such top-down feedforward control prepares the body for anticipated homeostatic challenges. In addition, such rapid regulation, by countering an aversive state represented by high activity in deficiency-driven neurons, could be important for motivating deficiency-based behaviors such as thirst and hunger (discussed below).

Next, we examine two effectors arms of the hypothalamus—the autonomic motor system and the neuroendocrine system.

The Autonomic System Links the Brain to Physiological Responses

Although the autonomic motor system implements many of the physiological responses initiated by the hypothalamus, the autonomic system is also regulated by circuits in the brain stem and spinal cord (Chapter 40). As a consequence, autonomic functions vary in their dependence on the hypothalamus. For example, micturition is largely independent of the hypothalamus, while blood pressure regulation depends heavily on circuits in the brain stem but can also be modulated by the hypothalamus. In contrast, thermogenesis by brown adipose tissue is largely subservient to the hypothalamus.

Visceral Motor Neurons in the Autonomic System Are Organized Into Ganglia

Unlike the somatic motor system, in which motor neurons are located in the ventral spinal cord and brain stem, the cell bodies of autonomic motor neurons are found in enlargements of peripheral nerves called ganglia.[1] The autonomic motor neurons innervate secretory epithelial cells in glands, smooth and cardiac muscle, and adipose tissue.

Efforts to understand the principles of organization of autonomic ganglia began in 1880 in England with the work of Walter Gaskell and were later continued by John N. Langley. They stimulated autonomic nerves and observed the responses of end organs (eg, vasoconstriction, piloerection, sweating, pupillary constriction). They used nicotine to block signals from individual ganglia to test interactions between ganglia. Langley proposed that specific chemical substances must be released by preganglionic neurons of the autonomic ganglia and that these substances act by binding to receptors on the postganglionic neurons, which target the end organs. These ideas set the stage for the later investigations of chemical synaptic transmission.

[1]The peripheral nerves also have sensory ganglia, located on the dorsal roots of the spinal cord and on five of the cranial nerves: trigeminal (V), facial (VII), vestibulocochlear (VIII), glossopharyngeal (IX), and vagus (X) (Chapter 40).

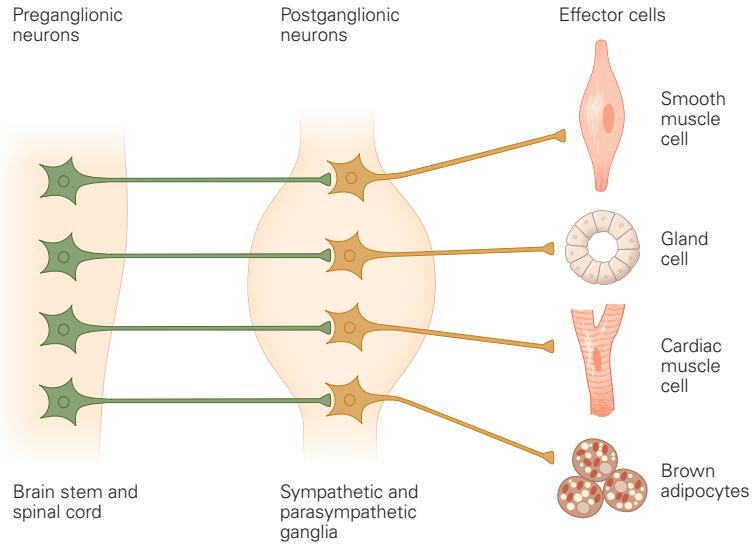

Figure 41–3 Distinct cell types in peripheral autonomic pathways selectively control target cells with different phenotypes. Autonomic motor neurons lie outside the central nervous system in ganglia controlled by preganglionic neurons in the spinal cord and brain stem. These downstream neurons within parasympathetic and sympathetic ganglia regulate three types of effector cells: smooth muscle, gland cells, and cardiac muscle. Additionally, downstream neurons found only in sympathetic ganglia selectively control brown adipocytes and immune cells in lymphoid tissue. This figure illustrates the three basic cell types—preganglionic neurons, downstream ganglionic neurons, and different target effector cells—that control function.

Langley also distinguished the autonomic and somatic motor systems and in so doing, created much of our current nomenclature.

The autonomic system is divided into three divisions: sympathetic, parasympathetic, and enteric. All neurons in sympathetic and parasympathetic ganglia are controlled by *preganglionic neurons* whose cell bodies are located in the spinal cord and brain stem. The preganglionic neurons synthesize and release the neurotransmitter acetylcholine (ACh), which acts on nicotinic ACh receptors on *postganglionic neurons*, producing fast excitatory postsynaptic potentials and initiating action potentials that propagate to synapses with effector cells in *end organs* (Figure 41–3). The sympathetic and parasympathetic systems are differentiated by five criteria:

1. The segmental organization of their preganglionic neurons in the spinal cord and brain stem
2. The peripheral locations of their ganglia
3. The types and locations of end organs they innervate

5. The neurotransmitters employed by their postganglionic neurons

Preganglionic Neurons Are Localized in Three Regions Along the Brain Stem and Spinal Cord

The parasympathetic pathways arise from a cranial nerve zone in the brain stem and a second zone in sacral segments of the spinal cord (Figure 41–4). These parasympathetic zones surround a sympathetic zone that extends continuously in thoracic and lumbar segments of the cord.

The cranial parasympathetic pathways arise from preganglionic neurons in the general visceral motor nuclei of four cranial nerves: the oculomotor (N. III) in the midbrain and the facial (N. VII), glossopharyngeal (N. IX), and vagus (N. X) in the medulla. The cranial parasympathetic nuclei are described in Chapter 40 together with the mixed cranial nerves (eg, the facial, glossopharyngeal, and vagus). The spinal parasympathetic pathway originates in preganglionic neurons in sacral segments S2–S4. Their cell bodies are located in intermediate regions of the gray matter, and their axons project in peripheral nerves through the ventral roots.

The sympathetic preganglionic cell column extends between the cervical and lumbosacral enlargements of the spinal cord, corresponding to the first thoracic segment and third lumbar segment (Figure 41–4). Most of the cell bodies of sympathetic preganglionic neurons are located in the intermediolateral cell column; others are found in the central autonomic area surrounding the central canal and in a band connecting the central area with the intermediolateral cell column. The axons of preganglionic sympathetic neurons project from the spinal cord through the nearest ventral root and then run with small connecting nerves known as rami communicantes before terminating on postganglionic cells in the paravertebral sympathetic chain (Figure 41–5).

Sympathetic Ganglia Project to Many Targets Throughout the Body

The sympathetic motor system regulates systemic physiological parameters such as blood pressure and body temperature by influencing target cells within virtually every tissue throughout the body (Figure 41–4).

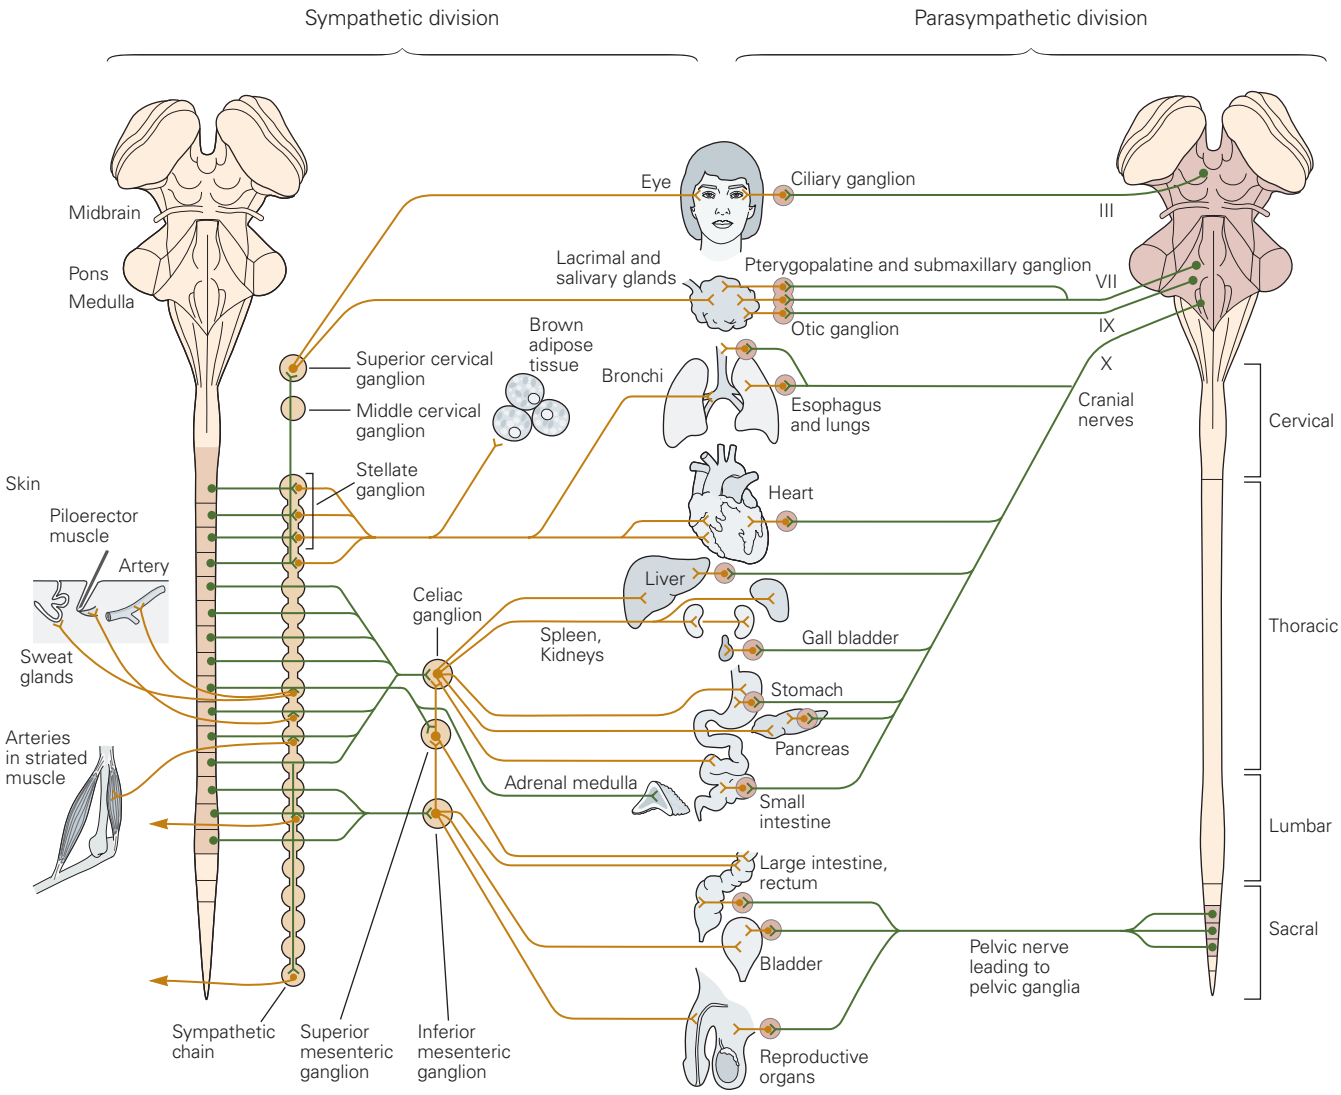

Figure 41–4 Sympathetic and parasympathetic divisions of the autonomic motor system. The sympathetic ganglia lie close to the spinal column and supply virtually every tissue in the body. Some tissues, such as skeletal muscle, are regulated only indirectly through their arterial blood supply. The parasympathetic ganglia are located near their targets, which do not include the skin or skeletal muscle.

This regulation depends on synaptic input from the spinal cord and from supraspinal structures that control the activity of the preganglionic neurons.

Important groups of supraspinal neurons that excite preganglionic sympathetic activity are located in the rostral ventrolateral medulla, the raphe pallidus in the brain stem, and the paraventricular nucleus in the hypothalamus. Preganglionic neurons integrate these descending inputs along with local segmental sensory inputs and form synapses with neurons in paravertebral and prevertebral sympathetic ganglia (Figure 41–5).

Ganglionic neurons in turn form synapses with a variety of end organs, including blood vessels, heart, bronchial airways, piloerector muscles, brown fat, and salivary and sweat glands. Sympathetic neurons also regulate immune function through projections to primary lymphoid tissue in the bone marrow and thymus and to secondary lymphoid cells in the spleen. A subset of preganglionic neurons synapse on chromaffin cells in the medulla of the adrenal gland (Figure 41–5), which secrete epinephrine (adrenaline) and norepinephrine (noradrenaline) into the circulation as hormones to act on distant targets.

The paravertebral and prevertebral sympathetic ganglia differ in both location and organization. Paravertebral ganglia are distributed segmentally,

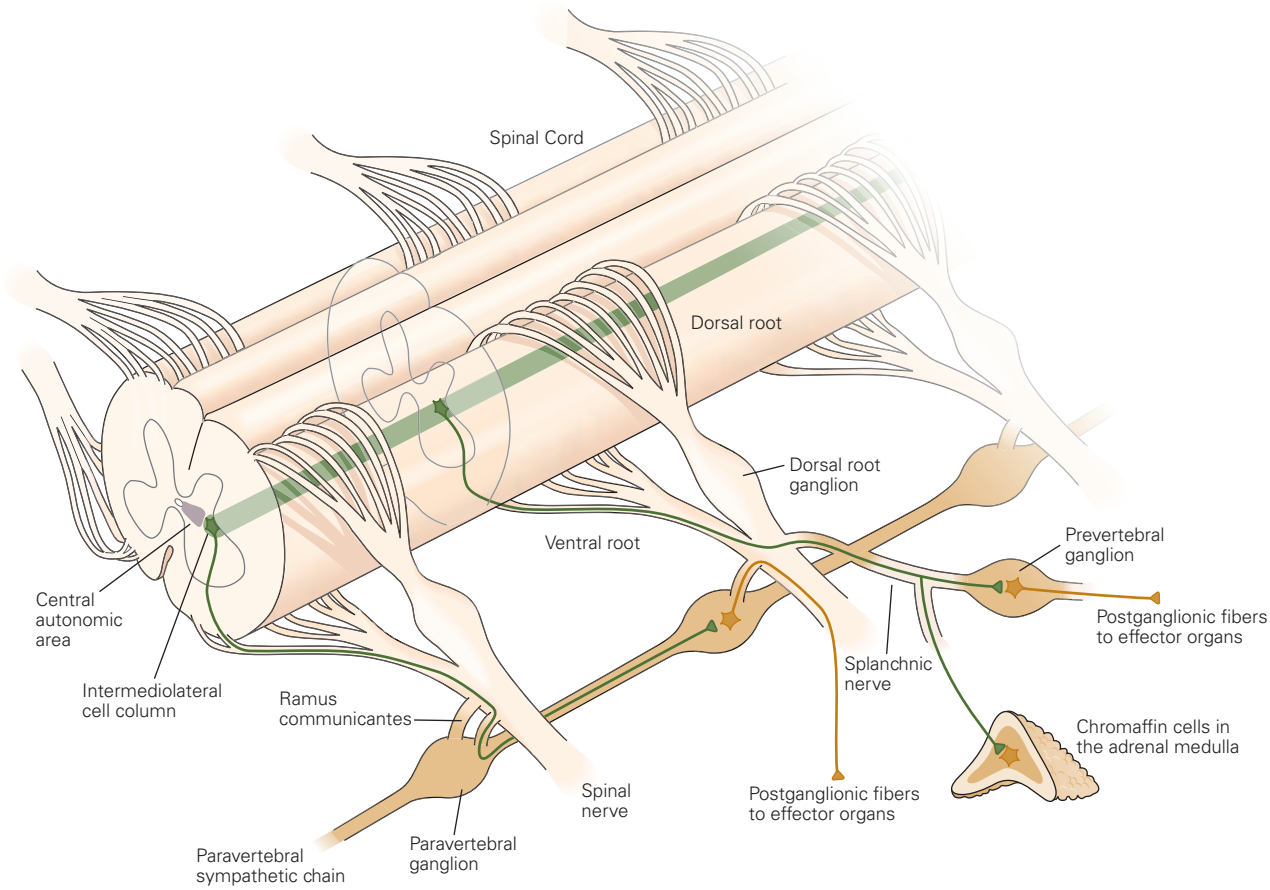

Figure 41–5 The sympathetic outflow is organized into groups of paravertebral and prevertebral ganglia. The axons of preganglionic cells in the spinal cord reach postganglionic neurons by way of ventral roots and the paravertebral sympathetic chain. The axons either form synapses on postganglionic neurons in paravertebral ganglia or project out of the chain into splanchnic nerves. Preganglionic axons in the splanchnic nerves form synapses with postganglionic neurons in prevertebral ganglia and with chromaffin cells in the adrenal medulla.

extending bilaterally as two chains from the first cervical segment to the last sacral segment. The chains lie lateral to the vertebral column at its ventral margin and generally contain one ganglion per segment (Figures 41–4 and 41–5). Two important exceptions are the superior cervical and stellate ganglia. The superior cervical ganglion is a coalescence of several cervical ganglia and supplies sympathetic innervation to the entire head, including the cerebral vasculature. The stellate ganglion, which innervates the heart and lungs, is a coalescence of ganglia from lower cervical segments and the first thoracic segment. These sympathetic pathways have an orderly somatotopic relation to one another from their segmental origin in preganglionic neurons to their terminus in peripheral targets.

The prevertebral ganglia are midline structures that lie close to the arteries for which they are named (Figures 41–4 and 41–5). In addition to sending sympathetic signals to visceral organs in the abdomen and pelvis, these ganglia also receive sensory feedback from their end organs.

Parasympathetic Ganglia Innervate Single Organs

In contrast to sympathetic ganglia, which regulate many targets and lie some distance from their targets close to the spinal cord, parasympathetic ganglia generally innervate single end organs and lie near to or within the end organs they regulate (Figure 41–4). In addition, the parasympathetic system does not influence lymphoid tissue, skin, or skeletal muscle except in the head, where it regulates vascular beds in the jaw, lip, and tongue.

The cranial and sacral parasympathetic ganglia innervate different targets. The cranial outflow includes four ganglia in the head (Chapter 40). The oculomotor

(III) nerve projects to the ciliary ganglion, which controls pupillary size and focus by innervating the iris and ciliary muscles. The facial (VII) nerve and a small component of the glossopharyngeal (IX) nerve project to the pterygopalatine (or sphenopalatine) ganglion, which promotes production of tears by the lacrimal glands and mucus by the nasal and palatine glands. Cranial nerve IX and a small component of nerve VII project to the otic ganglion. Its postganglionic neurons innervate the parotid, the largest salivary gland. Nerve VII also projects to the submandibular ganglion, which controls secretion of saliva by the submaxillary and sublingual glands.

The vagus (X) nerve projects broadly to parasympathetic ganglia in the heart, lungs, liver, gallbladder, and pancreas. It also projects to the stomach, small intestine, and more rostral segments of the gastrointestinal tract. The caudal parasympathetic outflow supplies the large intestine, rectum, bladder, and reproductive organs.

The Enteric Ganglia Regulate the Gastrointestinal Tract

The entire gastrointestinal tract, from the esophagus to the rectum—and including the pancreas and gallbladder—is controlled by the system of enteric ganglia. This system, by far the largest and most complex division of the autonomic nervous system, contains as many as 100 million neurons.

The enteric system has been studied most extensively in the small intestine of the guinea pig. Its activity is coordinated by two interconnected plexuses, small islands of interconnected neurons. The myenteric plexus controls smooth muscle movements of the gastrointestinal tract; the submucous plexus controls mucosal function (Figure 41–6). Working together, this distributed network of ganglia coordinates the orderly peristaltic propulsion of gastrointestinal contents and controls the secretions of the stomach and intestines and other components of digestion. In addition, the enteric system regulates local blood flow and also immune function in Peyer's patches. The enteric system is modulated by external inputs from sympathetic prevertebral ganglia and from parasympathetic components of the vagus nerve.

Unlike the sympathetic and parasympathetic divisions of the autonomic system, the enteric plexus contains interneurons and sensory neurons in addition to motor neurons. This intrinsic neural circuitry can maintain the basic functions of the gut even after the splanchnic sympathetic and vagal parasympathetic pathways are cut. Through splanchnic nerves and the afferent portion of the vagus nerve, the gastrointestinal tract also sends sensory information about the physiological status of the tract to the spinal cord and brain stem.

Acetylcholine and Norepinephrine Are the Principal Transmitters of Autonomic Motor Neurons

All preganglionic neurons in the sympathetic and parasympathetic systems use ACh as their excitatory neurotransmitter, activating ionotropic nicotinic ACh receptors on ganglionic neurons. These receptors resemble those at the neuromuscular junction in having nonselective cation pores, but they are encoded by different genes.

Activation of the ganglionic neurons triggers action potentials that propagate to postganglionic synapses with end organs in the periphery. At these end organ synapses, parasympathetic neurons release ACh, which activates muscarinic G protein–coupled receptors; sympathetic neurons release norepinephrine, which activates α- and β-adrenergic G protein–coupled receptors. The postsynaptic action can be either excitatory or inhibitory, depending on the type of target cell and its receptors (Table 41–2). Notable exceptions to this organization are the sympathetic postganglionic neurons that control sweat glands. They assume a cholinergic phenotype after birth.

In addition to acting on different receptors in different postsynaptic cells, one transmitter can activate different receptor types in the same postsynaptic cell. This principle was first discovered in sympathetic ganglia where ACh activates both nicotinic and muscarinic postsynaptic receptors to produce both a fast and slow excitatory postsynaptic potential (Figure 41–7A and Chapter 14). In some cases, one transmitter can activate both a postsynaptic receptor as well as a receptor on the presynaptic terminals from which the transmitter was released. Such presynaptic responses can cause either presynaptic inhibition or presynaptic facilitation (Figure 41–7B and Chapter 15). This specialization of synaptic transmission in sympathetic and parasympathetic neurons leads to functional diversity in the regulation of end organ function.

Cholinergic and adrenergic synaptic transmission in the peripheral autonomic motor system is often modulated by the co-release of various neuropeptides, nitric oxide, or adenosine triphosphate, which by activating multiple receptor types further contribute to functional diversity (Table 41–2 and Figure 41–7C). The motor responses elicited in end organs depend on the identity of the postganglionic neurotransmitters and the pre- and postsynaptic receptors

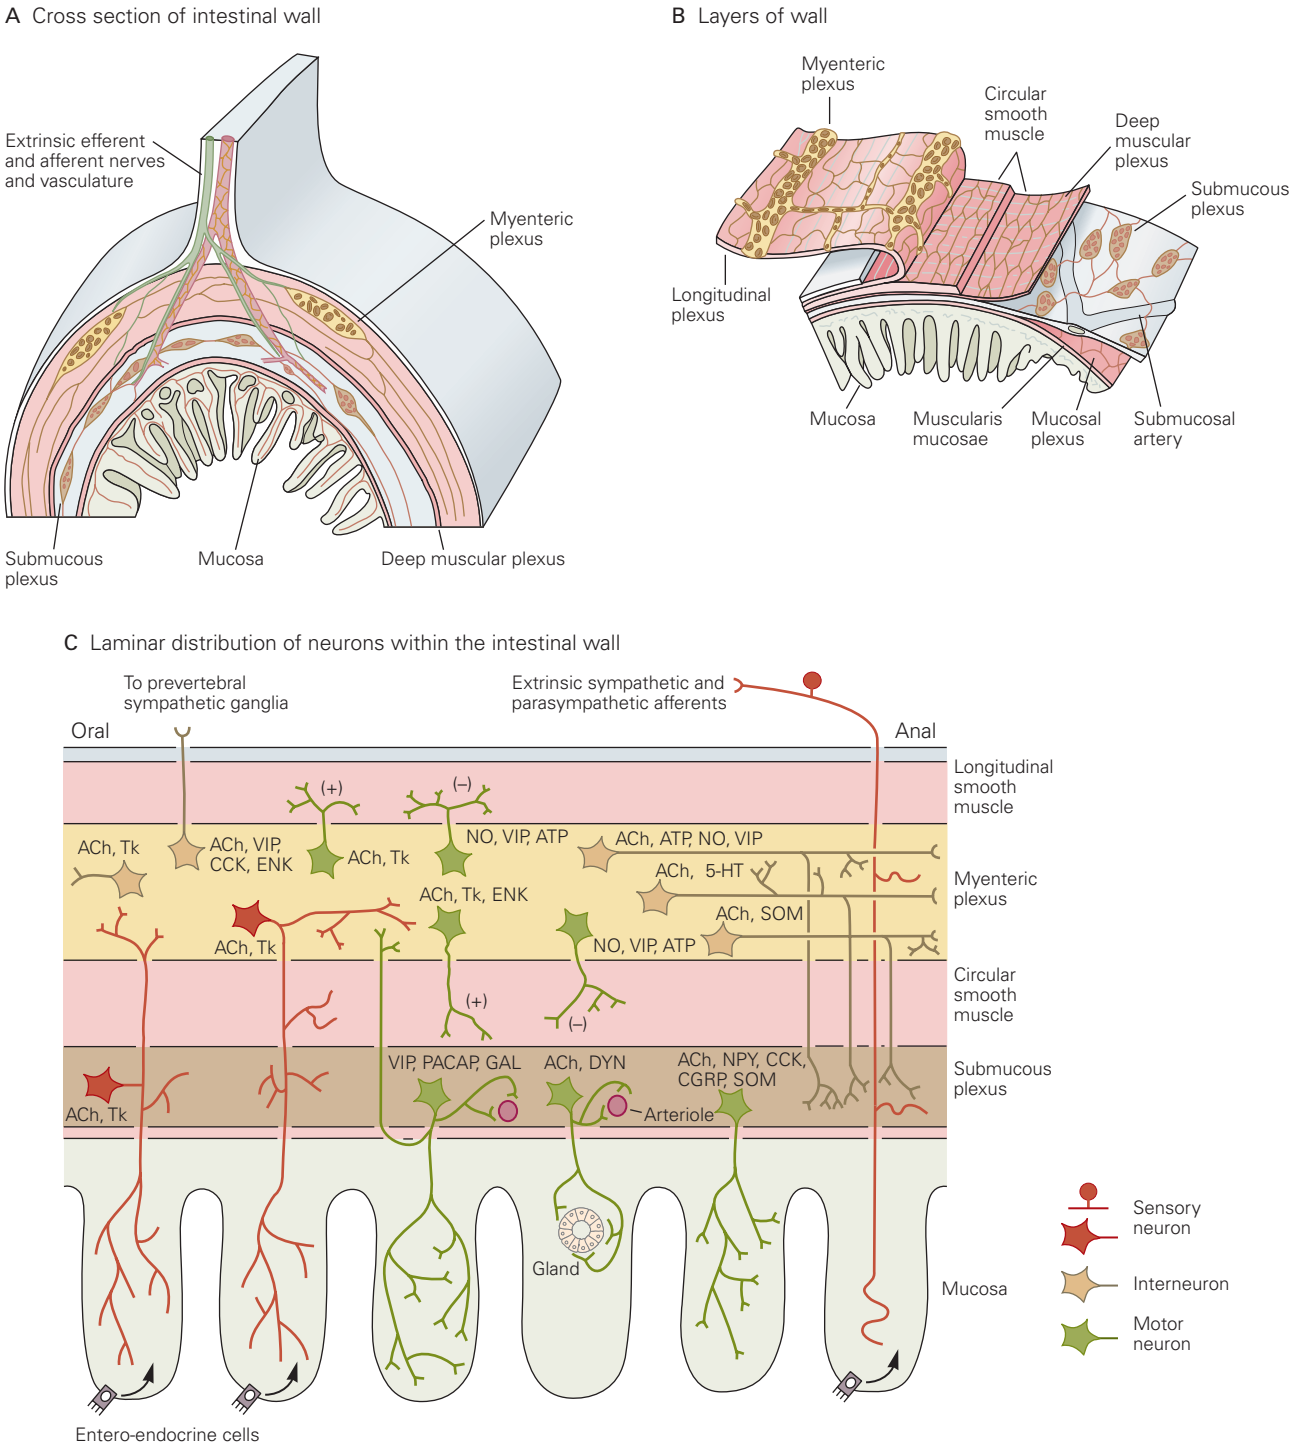

Figure 41–6 Organization of the enteric plexuses in the guinea pig. The myenteric plexus and submucous plexus lie between the layers of intestinal wall (**A** and **B**). At least 14 types of neurons have been identified within the enteric system based on morphology, chemical coding, and functional properties (**C**). Four sets of motor neurons provide excitatory (+) and inhibitory (–) inputs to two smooth muscle layers. Three additional groups of motor neurons control secretions from the mucosa and produce vasodilation. The network also includes two major classes of intrinsic sensory neurons. (Abbreviations: **ACh**, acetylcholine; **ATP**, adenosine triphosphate; **CCK**, cholecystokinin; **CGRP**, calcitonin gene-related polypeptide; **DYN**, dynorphin; **ENK**, enkephalin; **GAL**, galanin; **NO**, nitric oxide; **NPY**, neuropeptide Y; **PACAP**, pituitary adenylate cyclase-activating peptide; **SOM**, somatostatin; **Tk**, tachykinin; **VIP**, vasoactive intestinal peptide; **5-HT**, serotonin.) Table 41–2 Autonomic Neurotransmitters and Their Receptors

Transmitter	Receptor	Responses
Norepinephrine	α_1	Stimulates smooth muscle contraction in arteries, urethra, gastrointestinal tract, iris (pupillary dilation), uterine contractions during pregnancy, ejaculation; glycogenolysis in liver; glandular secretion (salivary glands, lacrimal glands).
	α_2	Presynaptic inhibition of transmitter release from sympathetic and parasympathetic nerve terminals; stimulates contraction in some arterial smooth muscle.
	β_1	Increases heart rate and strength of contraction.
	β_2	Relaxes smooth muscle in airways and gastrointestinal tract; stimulates glycogenolysis in liver.
	β_3	Stimulates lipolysis in white adipocytes and thermogenesis in brown adipocytes; inhibits bladder contraction.
Acetylcholine	Nicotinic	Fast EPSP in autonomic ganglion cells.
	Muscarinic: M_1, M_2, M_3	Glandular secretion; ocular circular muscle (pupillary constriction); ciliary muscles (focus of lens); stimulates endothelial production of NO and vasodilation; slows EPSPs in sympathetic neurons; slows heart rate; presynaptic inhibition at cholinergic nerve terminals; bladder contraction; salivary gland secretion.
Neuropeptide Y	Y_1, Y_2	Stimulates arterial contraction and potentiates responses mediated by α_1-adrenergic receptors; presynaptic inhibition of transmitter release from some postganglionic sympathetic nerve terminals.
NO	Diffuses through membranes; often acts to stimulate intracellular soluble guanylate cyclase	Vasodilation, penile erection, urethral relaxation.
Vasoactive intestinal peptide	VIPAC1, VIPAC2	Glandular secretion and dilation of blood vessels supplying glands.
ATP	P_{2X}, P_{2Y}	Fast and slow excitation of smooth muscle in bladder, vas deferens, and arteries.

ATP, adenosine triphosphate; EPSP, excitatory postsynaptic potential; NO, nitric oxide.

at the postganglionic synapse. For example, ACh and vasoactive intestinal peptide (VIP) are frequently co-released from neurons that control glandular secretion (Figure 41–7C). In salivary glands, the two transmitters act directly to evoke secretion. In addition, VIP causes dilation of the blood vessels supplying the gland. Because cotransmitters can be released in varying proportions that depend on the frequency of presynaptic firing, different patterns of activity can regulate the volume of secretions, their protein and water content, and their viscosity. This regulation operates both through a direct effect on the gland cells and through indirect effects on the glandular blood flow that provides the water contained in secretions.

Understanding the pharmacology of these receptors and the second-messenger signaling pathways they control is important in the treatment of numerous medical conditions, including hypertension, heart failure, asthma, emphysema, allergies, sexual dysfunction, and incontinence.

Autonomic Responses Involve Cooperation Between the Autonomic Divisions

To survive, animals and humans must have "fight-or-flight" responses in order to stand and fight a predator or run away and live to see another day. Walter Cannon, in addition to introducing the concept of

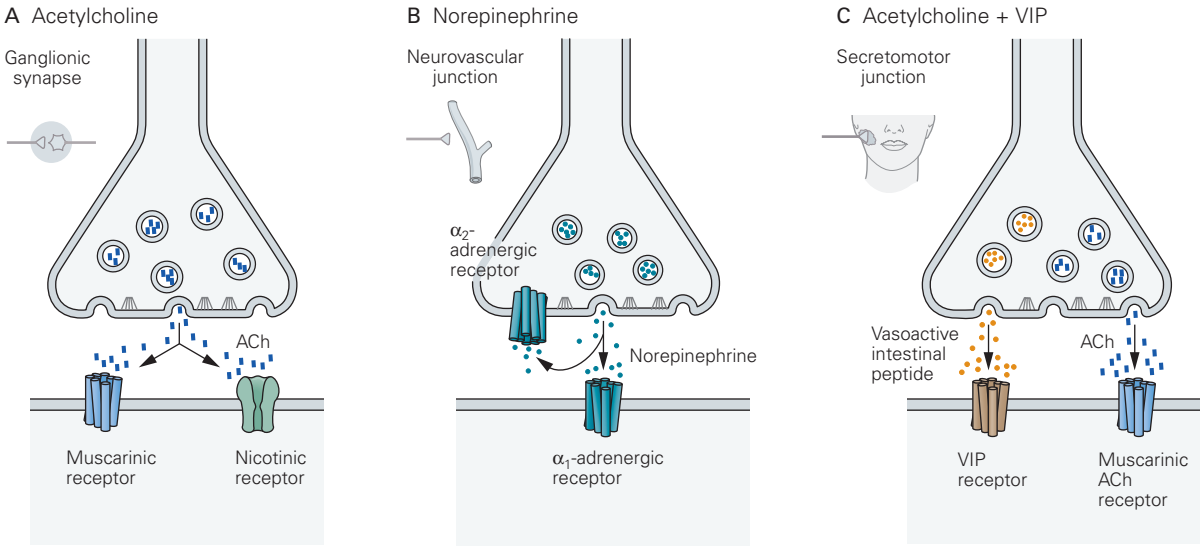

Figure 41–7 Synaptic transmission in the peripheral autonomic system.

A. In sympathetic ganglia, acetylcholine (**ACh**) can activate both nicotinic and muscarinic receptors to produce fast and slow postsynaptic potentials, respectively.

B. At neurovascular junctions, norepinephrine can simultaneously activate postsynaptic α_1-adrenergic receptors to produce vasoconstriction and presynaptic α_2-adrenergic receptors to inhibit further transmitter release.

C. Cotransmission involves the co-activation of more than one type of receptor by more than one transmitter. Parasympathetic postganglionic nerve terminals in the salivary glands release both ACh and vasoactive intestinal peptide (**VIP**) to control secretion. At some autonomic synapses with end organs, three or more receptor types are activated.

homeostasis, also appreciated that this fight-or-flight response is a critical sympathetic function.

Two important ideas underlie this insight. First, the sympathetic and parasympathetic systems play complementary, even antagonistic, roles; the sympathetic system promotes arousal, defense, and escape, whereas the parasympathetic system promotes eating and procreation. Second, actions of the sympathetic system are relatively diffuse; they influence all parts of the body and once turned on can persist for some time. These ideas are behind the popular notion of the "adrenaline rush" produced by excitement, as by a roller coaster ride.

We now know that extreme sympathetic responses such as "fight-or-flight" can have long-term pathological consequences resulting in the syndrome known as post-traumatic stress disorder (Chapter 61). This disorder was first recognized in soldiers during World War I, when it was referred to as "shell shock." A variety of life-threatening experiences, ranging from sexual abuse and domestic violence to aircraft disasters, can also induce post-traumatic stress disorder, which affects millions of people in the United States alone.

Because the fight-or-flight model assumes antagonistic roles for the sympathetic and parasympathetic systems, Cannon's model led to an overemphasis on the extremes of autonomic behavior. Actually, during everyday life, the different divisions of the autonomic system are tightly integrated. In addition, we now know that the sympathetic system is less diffusely organized than first envisioned by Cannon. Even within the sympathetic division, subsets of neurons control specific targets, and these pathways can be activated independently.

As in the somatic motor system, reflexes in the autonomic motor system are elicited through sensory pathways and are hierarchically organized. An important feature of this organization is that it allows for coordination between the different divisions of the autonomic system. The interplay between different systems in simple autonomic behaviors is analogous to the role of antagonist muscles in locomotion. To walk, one must alternately contract antagonist muscles that flex and extend a joint. Similarly, the sympathetic and parasympathetic systems are often partners in the regulation of end organs. In most cases, ranging from the simplest reflexes to more complex behaviors, all three peripheral divisions of the autonomic system work together. We illustrate this organization with two examples: control of the bladder (micturition reflex) and regulation of blood pressure.

Bladder Control

The micturition reflex is an example of a physiological cycle resulting from coordination between sympathetic and parasympathetic systems. In this cycle, the bladder is emptied by the parasympathetic pathway, which contracts the bladder and relaxes the urethra. The sympathetic system allows the bladder to fill by stimulating the urethra and inhibiting the parasympathetic pathway, thus inhibiting the reflex for bladder emptying. The sensory feedback required for this behavior is integrated with the motor outflow at both spinal and supraspinal levels (Figure 41–8).

Spinal components of the reflex are most influential during the storage phase of the micturition cycle, when sympathetic and somatic motor effects predominate. When the bladder is full, its distension triggers a sensory signal sufficient to activate the pontine micturition center (PMC). Descending signals from the PMC then increase parasympathetic outflow. Somatic control of the external urinary sphincter, which consists of striated muscle, contributes to both phases of the micturition cycle and is a voluntary behavior that originates through forebrain mechanisms (Figure 41–8). Patients with spinal cord injuries at the cervical or thoracic levels retain the reflex but not voluntary control of urination, because the connections between the bladder and the pons are severed.

Blood Pressure Regulation

The baroreceptor reflex is one of the simplest mechanisms for regulating blood pressure and further illustrates coordinated homeostatic control by antagonist sympathetic and parasympathetic pathways. It prevents orthostatic hypotension and fainting by compensating for rapid hydrostatic effects produced by changes in posture. When a recumbent person stands up, the sudden elevation of the head above the heart causes a transient decrease of cerebral blood pressure that is rapidly sensed by baroreceptors in the carotid sinus in the neck (Figure 41–9). Other important pressure sensors are located in the aortic arch and in the pulmonary circulation.

When neurons in the ventrolateral medulla detect the decrease in afferent baroreceptor activity produced by low blood pressure, they produce a reflexive suppression of parasympathetic activity to the heart and stimulation of sympathetic activity to the heart and vascular system. These changes in autonomic tone restore blood pressure by increasing heart rate, the strength of cardiac contractions, and the overall vascular resistance to blood flow through arterial vasoconstriction.

Under the converse condition of elevated arterial pressure, the increase in baroreceptor activity enhances parasympathetic inhibition of the heart and decreases sympathetic stimulation of cardiac function and vascular resistance. In general, the parasympathetic component of the baroreceptor reflex has a more rapid onset and is briefer than the sympathetic component. Consequently, parasympathetic activity is critical for the rapid response of baroreceptor reflexes but less important than sympathetic activity for long-term blood pressure regulation.

Visceral Sensory Information Is Relayed to the Brain Stem and Higher Brain Structures

Visceral sensory information reaches the brain mainly through two cranial nerves (IX and X), which end in caudal segments of the nucleus of the solitary tract (NTS), and through the abdominal splanchnic nerves, which end in the spinal cord (Chapter 40). The splanchnic information is transmitted to the brain through the spinothalamic tract (Chapter 4), which branches out along the way and also sends afferents to the NTS and lateral parabrachial nucleus.

The NTS relays sensory information in two different directions. First, it projects to networks in the brain stem and spinal cord that control and coordinate autonomic reflexes (as we saw for the baroreceptor reflex). In this way, visceral sensory signals relayed through the NTS regulate vagal motor control of the heart and gastrointestinal tract directly. Some neurons in the NTS project to neurons in the ventrolateral medullary reticular formation that control blood pressure by differentially regulating blood flow in particular vascular beds (Figure 41–9). Second, the NTS sends ascending projections to the forebrain, relaying visceral information to higher structures (Figure 41–10A). These higher structures, including the hypothalamus, use this information to coordinate autonomic, neuroendocrine, and behavioral responses.

Visceral sensory information is relayed from the NTS to the forebrain via direct and indirect projections (Figure 41–10A). The major indirect pathway involves the lateral parabrachial nucleus, which receives afferents from the NTS and sends efferents to higher structures, including the amygdala, hypothalamus, bed nucleus of the stria terminalis, insular cortex, and infralimbic/prelimbic cortex. The direct projections from the NTS target many of these same forebrain sites. The rostral NTS is an important part of the afferent taste pathway (Chapter 29). Information

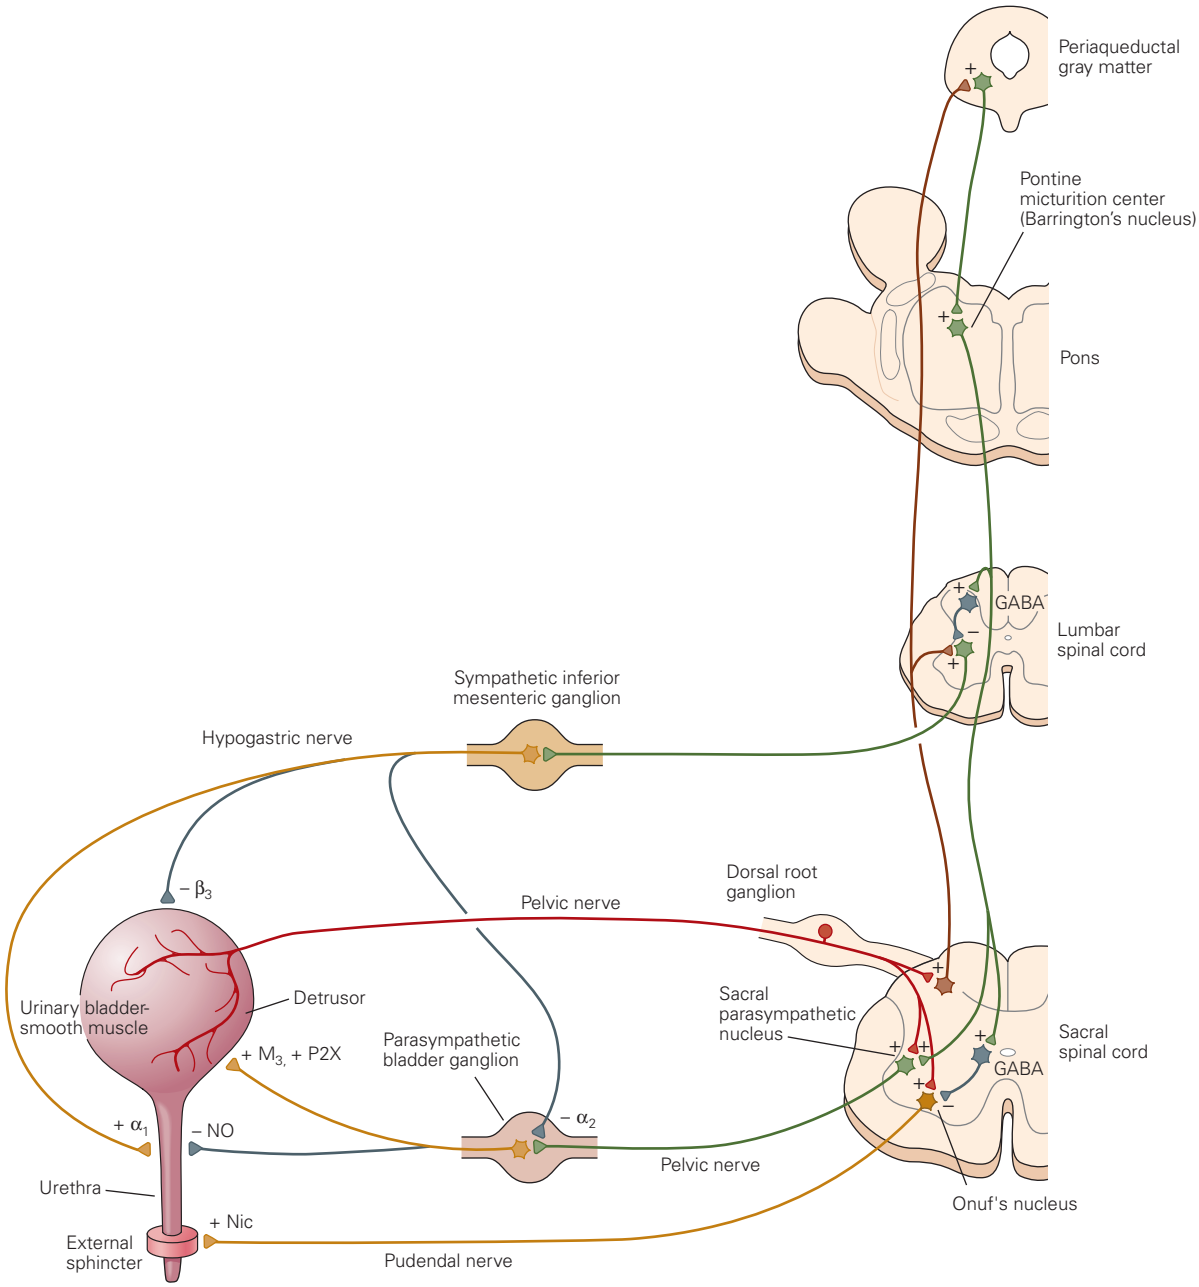

Figure 41–8 **The micturition reflex requires interplay between the parasympathetic and sympathetic divisions of the autonomic system.** (Adapted from DeGroat, Booth, and Yoshimura 1993.)

When bladder volume is low, urinary outflow is inhibited because activity in the sympathetic pathway is greater than activity in the parasympathetic pathway. Mild distension of the detrusor (storage portion of the bladder) initiates a low level of sensory activity, which reflexively activates spinal preganglionic neurons. The resulting low level of preganglionic activity is effectively transmitted and amplified by the sympathetic inferior mesenteric ganglion but filtered out by the parasympathetic bladder ganglion because of differences in patterns of synaptic convergence in the two ganglia. The resulting predominance of sympathetic tone keeps the detrusor relaxed and the urethra constricted. Sympathetic postganglionic fibers also reduce parasympathetic activity by inhibiting preganglionic release of acetylcholine. In addition to their effects on the autonomic outflow, the sensory signals are sufficient to keep the external urinary sphincter closed.

When filling causes the bladder to reach a critical volume, the associated increase in sensory activity reaches a threshold that allows impulses to pass through the pontine micturition center (Barrington's nucleus). Descending activity from this nucleus then further excites the parasympathetic outflow. The resulting increase in parasympathetic preganglionic firing promotes summation of fast excitatory postsynaptic potentials and initiation of postsynaptic action potentials in the bladder ganglion as it switches to its "on" state. During the emptying process, descending pathways also inhibit the sympathetic and somatic outflows through inhibitory spinal interneurons. Inhibition of somatic motor neurons in Onuf's nucleus causes relaxation and opening of the external sphincter. In this figure, the sacral spinal cord is enlarged relative to the other slices.

(Abbreviations: α_1, alpha-1 adrenergic receptor, α_2, alpha-2 adrenergic receptor, β_3, beta-3 adrenergic receptor, **GABA**, γ-aminobutyric acid; M_3, muscarinic ACh receptor 3; **nic**, nicotinic receptor; **NO**, nitric oxide; **P2X**, purinergic receptor.)

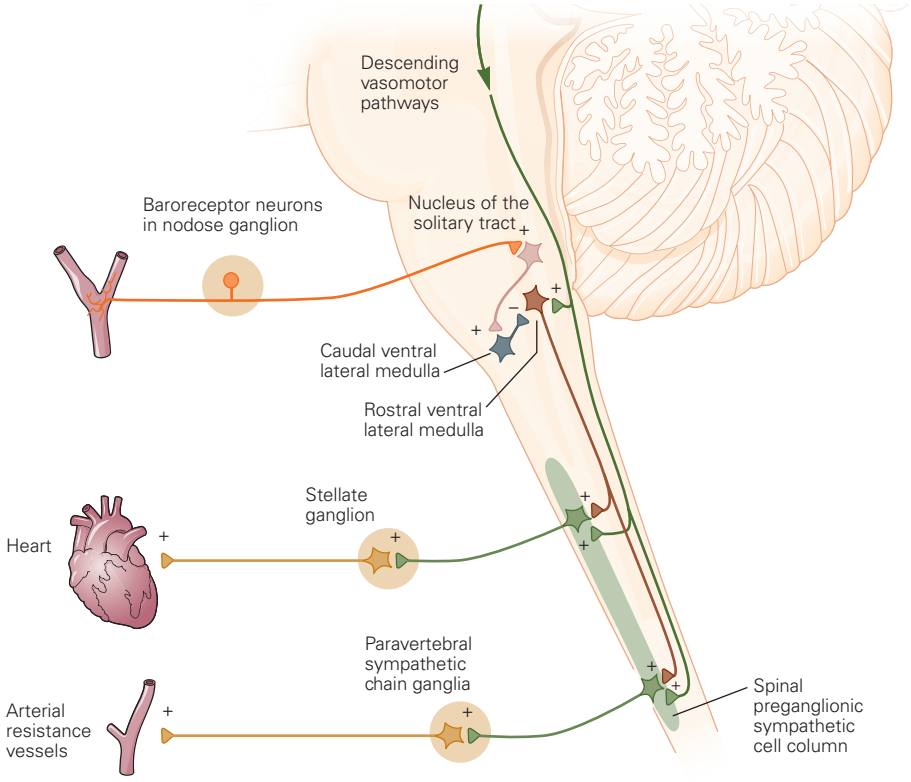

Figure 41–9 The baroreceptor reflex behaves as a negative feedback loop with gain. Arterial blood pressure is sensed by baroreceptors, a type of stretch receptor neuron, in the carotid sinus near the base of the brain. After integration in the medulla, this information provides negative feedback control of the cardiovascular system. The sympathetic component of the circuit includes outputs that stimulate the heart's pumping capacity (cardiac output) by increasing heart rate and the strength of contractions. In addition, sympathetic stimulation causes arteries to contract, which raises the hydraulic resistance to blood flow. Together, the effects of increased cardiac output and increased vascular resistance raise mean arterial blood pressure. Inhibitory projections from the caudal to the rostral ventral lateral medulla create negative feedback so that an increase in blood pressure inhibits sympathetic activity, whereas a decrease raises sympathetic activity. Although omitted for simplicity, parasympathetic neurons in the cardiac ganglion also contribute to the reflex by creating an inhibitory cardiac input that is functionally antagonistic to the sympathetic pathway (Figure 41–10). During baroreceptor reflexes, parasympathetic activity within the heart is therefore increased by hypertension and reduced by hypotension.

in this pathway is relayed via the medial parabrachial nucleus to the taste area of insular cortex.

Central Control of Autonomic Function Can Involve the Periaqueductal Gray, Medial Prefrontal Cortex, and Amygdala

The periaqueductal gray, which surrounds the cerebral aqueduct in the midbrain, receives inputs from most parts of the central autonomic network and projects to the medullary reticular formation to initiate integrated behavioral and autonomic responses. For example, in the defensive "fight-or-flight" response, the periaqueductal gray helps redirect blood flow from the digestive system to the hind limbs, thus enhancing running (Figure 41–10B).

The medial prefrontal cerebral cortex is a visceral sensory-motor region. It includes two functional areas that interact with each other: the rostral insular cortex and the rostromedial tip of the cingulate gyrus (also referred to as the infralimbic and prelimbic areas). Stimulation here can produce a variety of autonomic effects including contractions of the stomach and changes in blood pressure. These visceral sensory and motor areas of cortex send descending projections to the parts of the central autonomic network in the brain stem discussed above.

Finally, visceral regions of cortex, along with many subcortical parts of the central autonomic

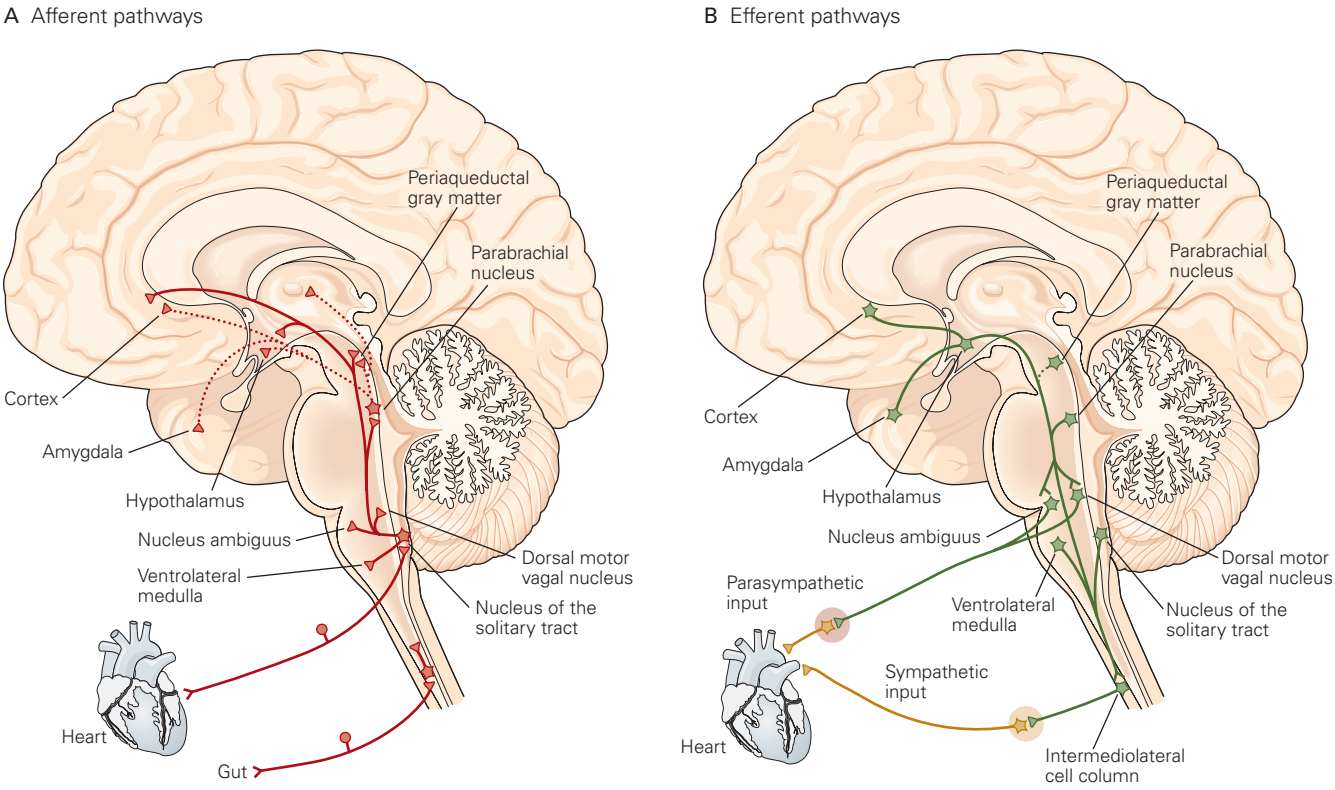

Figure 41–10 **The central autonomic network.** Nearly all of the cell groups illustrated here are interconnected with one another, forming the central autonomic network.

A. Visceral information (**solid lines**) is distributed to the brain from the nucleus of the solitary tract and from ascending spinal pathways activated by the splanchnic nerves (from the gut, for example). The nucleus of the solitary tract distributes this information to preganglionic parasympathetic neurons (the dorsal motor vagal nucleus and nucleus ambiguus), to regions of the ventrolateral medulla that coordinate autonomic and respiratory reflexes, and to more rostral parts of the central autonomic network in the pons (parabrachial nucleus), midbrain (periaqueductal gray), and forebrain. The parabrachial nucleus also projects to many of the more rostral components of the central autonomic network, including visceral and gustatory nuclei of the thalamus (**dotted lines**). Other pathways from the spinal cord (not shown) also transmit visceral information to many parts of the central autonomic network, including the nucleus of the solitary tract, parabrachial nucleus, periaqueductal gray, hypothalamus, amygdala, and cortex. The spinal cord also projects to the main somatosensory nucleus of the thalamus (ventral posterolateral nucleus).

B. All of the efferent pathways shown here (except perhaps for the periaqueductal gray) project directly to autonomic preganglionic neurons. In the hypothalamus, the descending division of the paraventricular nucleus and three cell clusters in the lateral zone project heavily to both parasympathetic and sympathetic preganglionic neurons. Other pathways (not shown) arise from certain monoaminergic cell groups in the brain stem, including noradrenergic neurons in the A5 region and serotonergic neurons in the raphe nuclei.

network, interact with the amygdala. Complex pathways between certain amygdalar cell groups underlie certain conditioned emotional responses—learned associations between specific stimuli and behaviors with accompanying autonomic responses. When a rat learns that a mild electric shock follows an auditory cue, the auditory cue alone comes to produce the elevated heart rate and freezing that was originally elicited by the shock alone (Chapters 42 and 53). Such learned responses are prevented by selective lesions of the amygdalar region, which projects to the hypothalamus and lower brain stem parts of the central autonomic network.

The Neuroendocrine System Links the Brain to Physiological Responses Through Hormones

Another effector arm of the hypothalamus is the neuroendocrine system, which controls secretion of hormones by the pituitary gland. The pituitary has two functionally and anatomically distinct subdivisions,

the anterior and posterior pituitary. The posterior pituitary is an extension of the brain and contains hormone-secreting axon terminals of hypothalamic neurons. These terminals secrete vasopressin or oxytocin directly into the systemic circulation. The anterior pituitary, on the other hand, is entirely nonneuronal and is composed of five types of endocrine cells. Hormone secretion from these cells is controlled by stimulatory and inhibitory factors released by hypothalamic neurons into a specialized circulatory system that carries blood from the base of the brain (median eminence) to the anterior pituitary.

Hypothalamic Axon Terminals in the Posterior Pituitary Release Oxytocin and Vasopressin Directly Into the Blood

Large neurons in the paraventricular and supraoptic nuclei form the magnocellular component of the neuroendocrine motor system of the hypothalamus (Figure 41–11). The magnocellular neurons send their axons through the hypothalamo-hypophysial tract to the posterior pituitary, or *neurohypophysis* (Figure 41–12). Approximately one-half of these neurons synthesize and secrete vasopressin (the antidiuretic hormone) into the general circulation; the other half synthesize and secrete oxytocin, a structurally similar hormone. Both hormones circulate to organs, where vasopressin controls blood pressure and water reabsorption by the kidney and oxytocin controls uterine smooth muscle and milk release.

Vasopressin and oxytocin are nine-amino acid peptide hormones. Like other peptide hormones, they are synthesized in the cell body as larger prohormones (Chapter 16) and then cleaved within Golgi transport vesicles before traveling down the axon to release sites in the posterior pituitary. The genes for these peptides have similar sequences and probably arose by duplication.

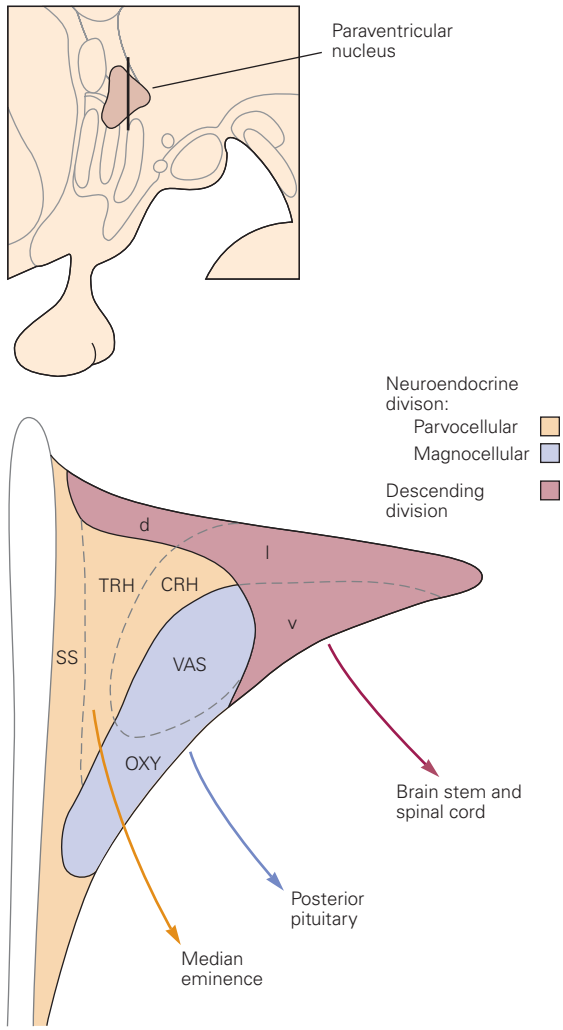

Figure 41–11 **The paraventricular nucleus in the hypothalamus is a microcosm of neuroendocrine, autonomic, and sensory-motor integration.** The three structural-functional divisions of the paraventricular nucleus are shown. The *magnocellular neuroendocrine division* comprises two distinct although partly interdigitated pools of neurons that normally release vasopressin (**VAS**) or oxytocin (**OXY**). Their axons course through the internal zone of the median eminence and terminate in the posterior pituitary. Two other populations of magnocellular vasopressin and oxytocin neurons lie in the supraoptic nucleus along the base of the brain.

The *parvocellular neuroendocrine division* includes three major, separate (although partly interdigitated) pools of neurons that control anterior pituitary hormone secretion. Their axons end in the external zone of the median eminence, where they release their peptide neurotransmitters—somatostatin (**SS**), growth hormone-inhibiting hormone (GIH), thyrotropin-releasing hormone (**TRH**), or corticotropin-releasing hormone (**CRH**)—into the hypophysial portal veins.

The *descending division* has three parts—dorsal (**d**), lateral (**l**), and ventral (**v**)—each comprising topographically organized conventional neurons that project to the brain stem and spinal cord. Their axons terminate in many parts of the central autonomic network in the brain stem (Figure 41–10), the marginal zone (lamina I) of the dorsal horn of the spinal cord and spinal trigeminal nucleus, and a number of regions in the brain stem reticular formation and periaqueductal gray matter. The descending division modulates autonomic outflow (and inflow), the inflow of nociceptive information, and eating and drinking behaviors. Appropriate integration of magnocellular neuroendocrine, parvocellular neuroendocrine, autonomic, and behavioral responses is mediated primarily by external inputs rather than by interneurons or extensive recurrent axon collaterals of projection neurons. Circulating steroid and thyroid hormones also produce selective effects on particular types of neurons in the paraventricular nucleus.

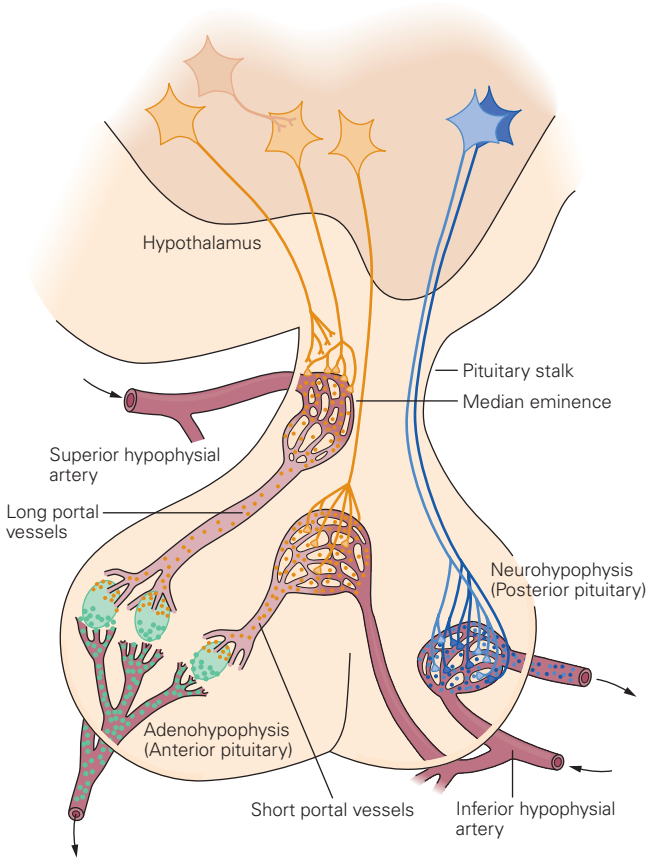

Figure 41–12 The hypothalamus controls the pituitary gland both directly and indirectly through neuroendocrine neurons. Neurons in the magnocellular neuroendocrine system (**blue**) send their axons directly to the posterior pituitary (neurohypophysis) where they release the peptides vasopressin and oxytocin into the general circulation. Neurons in the parvocellular neuroendocrine system (**yellow**) send their axons to the hypophysial portal system in the median eminence and pituitary stalk. Portal veins transport hypothalamic hormones (peptides and dopamine) to the anterior pituitary (adenohypophysis) where they increase the release of hormones from five classic types of endocrine cells (Figure 41–11). The output of neuroendocrine neurons is regulated in large part by inputs from other regions of the brain. (Adapted from Reichlin 1978, and Gay 1972.)

Endocrine Cells in the Anterior Pituitary Secrete Hormones in Response to Specific Factors Released by Hypothalamic Neurons

In the 1950s, Geoffrey Harris proposed that the anterior pituitary, or *adenohypophysis*, is regulated indirectly by the hypothalamus. He showed that the hypophysial portal veins, which carry blood from the hypothalamic median eminence to the anterior pituitary, transport factors released from hypothalamic neurons that control anterior pituitary hormone secretion (Figure 41–12). In the 1970s, Andrew Schally, Roger Guillemin, and Wylie Vale determined the structure of a group of hypothalamic peptide hormones that control pituitary hormone secretion from the five classic endocrine cell types in the anterior pituitary. These hormones, which are released into the median eminence by hypothalamic neurons, fall into two classes: releasing hormones and release-inhibiting hormones. Only one anterior pituitary hormone, prolactin, is under predominantly inhibitory control (mediated by dopamine).

The *parvocellular neuroendocrine motor zone* of the hypothalamus is centered along the wall of the third ventricle (Figure 41–2A) and contains neurons that project to and release their hormones into the median eminence. The parvocellular neurons releasing *gonadotropin-releasing hormone* (GnRH) are atypical in that they are scattered in a continuum extending from the medial septum through to the mediobasal hypothalamus. They are controlled by upstream neurons that release *kisspeptin*. The remaining parvocellular neuroendocrine neurons lie within the paraventricular and arcuate nuclei and the short periventricular region between them (Figures 41–2 and 41–11).

Distinct pools of neurons in and around the paraventricular nucleus release *corticotropin-releasing hormone* (CRH), *thyrotropin-releasing hormone* (TRH), or *somatostatin* (or growth hormone release-inhibiting hormone) (Figure 41–11). The CRH neurons control the release of anterior pituitary adrenocorticotropic hormone (ACTH), which in turn controls the release of cortisol (glucocorticoids) from the adrenal cortex. Thus, this pool of CRH neurons is the "final common pathway" for all centrally mediated glucocorticoid stress hormonal responses. The arcuate nucleus contains two pools of parvocellular neuroendocrine neurons. One group releases *growth hormone–releasing hormone* (GHRH) and the other dopamine, which inhibits prolactin secretion. Some of the dopaminergic neurons are distributed dorsally as far as the paraventricular nucleus.

The axons of all these parvocellular neuroendocrine neurons travel in the hypothalamo-hypophysial tract and end in the specialized proximal end of the pituitary stalk, the median eminence (Figure 41–12). There, in a region of capillary loops in the external zone of the median eminence, the axon terminals release the various hypophysiotropic factors. While the median eminence is within the brain, it is considered outside the blood–brain barrier. This is due to the fenestrated nature of the median eminence

Table 41–3 Hypothalamic Substances That Release or Inhibit the Release of Anterior Pituitary Hormones

Hypothalamic substance	Anterior pituitary hormone
Releasing:	
Thyrotropin-releasing hormone (TRH)	Thyrotropin (TSH), prolactin (PRL)
Corticotropin-releasing hormone (CRH)	Adrenocorticotropin (ACTH), β-lipotropin
Gonadotropin-releasing hormone (GnRH)	Luteinizing hormone (LH), follicle-stimulating hormone (FSH)
Growth hormone–releasing hormone (GHRH or GRH)	Growth hormone (GH)
Inhibiting:	
Prolactin release-inhibiting hormone (PIH), dopamine	Prolactin
Growth hormone release-inhibiting hormone (GIH or GHRIH; somatostatin)	Growth hormone, thyrotropin

capillaries, which allow diffusion of the hypophysiotropic factors into the portal circulation. The median eminence capillary loops are the proximal end of the hypophysial portal system of veins that carry the factors to the anterior pituitary, where they act on cognate receptors on the five types of endocrine cells (Figure 41–12 and Table 41–3).

Dedicated Hypothalamic Systems Control Specific Homeostatic Parameters

Body Temperature Is Controlled by Neurons in the Median Preoptic Nucleus

Body Temperature Reflects the Balance Between Heat Production and Loss

The body generates heat through all of its exothermic biochemical reactions and ion fluxes. These processes can be greatly increased above a baseline level, the resting metabolic rate, by exercise and shivering (both of which increase skeletal muscle heat production), by the digestion and assimilation of food (the so-called thermic effect of food), and by sympathetic stimulation of thermogenic activity in brown adipose tissue (Box 41–1).

The body loses heat by radiation, convection, conduction (if immersed in cool water), and endothermic evaporation of either sweat from the skin or moisture from the respiratory tract (a process augmented in some species by panting). The defensive reaction to cold, in addition to producing heat, involves sympathetically mediated cutaneous vasoconstriction and piloerection (goose bumps). By sending less blood to the skin, vasoconstriction conserves core temperature. Piloerection helps insulate the skin by creating a layer of motionless air near the skin's surface. Conversely, defenses against overheating include inhibition of sympathetic pathways that activate cutaneous vasodilation and brown adipose tissue. Voluntary behavioral responses like taking a swim or putting on a sweater play a particularly important role in thermoregulation.

Box 41–1 Brown Adipose Tissue, Bioenergetics, and Sympathetically Driven Thermogenesis

Brown adipose tissue is a remarkably specialized heat-producing tissue that is especially abundant in newborns and small mammals, but is also found in adult humans. It has a rich blood supply for delivery of fuel and oxygen and for removal of heat and is densely innervated by postganglionic sympathetic nerves. Brown adipocytes, the producers of heat, are found in concentrated deposits in and around the core and also as isolated cells within larger white adipose tissue depots.

Sympathetic stimulation of β-adrenergic receptors activates uncoupling protein-1 (UCP1), a mitochondrial proton transport protein that is unique to brown adipocytes. When activated, UCP1 "leaks" protons across the mitochondrial inner membrane into the mitochondrial matrix, down the proton electrochemical gradient. This uncouples mitochondrial respiration from adenosine triphosphate (ADP) availability, greatly increasing fuel oxidation and, importantly, the production of heat.

Exercise and shivering, on the other hand, increase heat production by using adenosine triphosphate (ATP) to perform work. The resulting increase in ADP activates proton transport into mitochondria via ATP synthase, which then increases coupled mitochondrial respiration, fuel oxidation, and ultimately the production of heat.

They usually begin before the onset of physiologic responses. Like thirst/drinking and hunger/eating, activities generated in response to cold or hot challenges are motivated behaviors.

Body Temperature Is Detected at Multiple Sites

Core temperature is held relatively constant. At the shell, on the other hand, temperature fluctuates extensively because the shell is adjacent to the external environment, it has a high surface-to-mass ratio (in the case of limbs favoring heat loss over heat production), and thermal challenges dramatically affect its supply of warm blood (decreased when heat needs to be conserved; increased when heat needs to be lost).

Most primary afferents that detect temperature have their cell bodies in the spinal dorsal root ganglia. Neurons that detect noxious temperatures are part of the pain pathway (Chapter 20). Their function is to limit local tissue damage by promoting withdrawal as opposed to regulating body temperature. Neurons that respond to innocuous temperatures are often called thermoreceptors. Some thermoreceptor neurons have their endings in the skin, just below the epidermis, and these respond to shell temperature. They are predominantly, but not entirely, cold-responsive. Other thermoreceptor neurons have their endings in and around the large organs and respond to core temperature. They are also largely, but not entirely, cold-responsive. The fibers for the deep-tissue thermoreceptor neurons travel in the splanchnic nerves and, like the thermoreceptor neurons in the shell, have their cell bodies in the dorsal root ganglia. In addition, some also travel in the vagal afferent nerve. Finally, there are warm-sensing neurons in the hypothalamic medial preoptic area.

The molecular sensors utilized by thermoreceptor neurons for detecting changes in temperature are a subset of excitatory transient receptor potential (TRP) channels. Different TRP channels respond to different ranges of temperatures (Chapter 20). Recent studies have implicated specific TRP channel types in various forms of sensing innocuous temperature in the three sites mentioned above: TRMP8 channels mediate cold-sensing by shell thermoreceptor neurons, and TRPM2 channels mediate warm-sensing both by somatosensory thermoreceptor neurons and by neurons in the hypothalamic preoptic area.

Multiple Thermoreceptor/Thermoeffector Loops Control Temperature

Involuntary thermal regulation is controlled by a multisensor, multieffector thermoregulatory system. Thermal information from the shell and the viscera ascends via primary afferents whose cell bodies are in the dorsal root ganglia. They project to second-order neurons in the dorsal horn of the spinal cord. These neurons project via the spinothalamic tract to the lateral parabrachial nucleus where neurons relay cold-sensing and warm-sensing information to neurons in the hypothalamic MnPO. Activation of the cold-sensing or warm-sensing afferent pathways induces appropriate physiological responses aimed at increasing or decreasing body temperature.

The neurons in the MnPO that indirectly respond to cold and warmth send efferent signals via relays through the medial preoptic area, dorsomedial hypothalamus, and raphe pallidus in the ventral medulla, and from there on to the sympathetic preganglionic neurons in the intermediolateral nucleus of the spinal cord. These latter neurons excite postganglionic sympathetic neurons that project to blood vessels, sweat glands, and arrector muscles of hair follicles to control cutaneous blood flow, sweating, and piloerection, respectively, as well as to brown adipose tissue to control thermogenesis. In addition, cold causes shivering when gamma motor neurons in the ventral horn of the spinal cord are activated by excitatory neurons in the raphe pallidus (Chapter 32). The resultant contraction of intrafusal muscle fibers within muscle spindles activates IA afferents from the spindles to alpha motor neurons. This proprioceptive feedback increases activity of alpha motor neurons, as well as their propensity to undergo rhythmic bursts of activity, causing increased muscle tone and frank shivering.

The neural pathways controlling voluntary thermoregulatory behaviors involve the same thermoreceptor pathways. Stimulation of warm-sensitive neurons in and around the MnPO evokes dramatic cold-seeking behavior, decreases heat production, and increases heat loss. The conscious perception of body temperature relies upon the same first-order thermoreceptor neurons, but the afferent pathway diverges to activate second-order neurons in the dorsal horn, which project directly or indirectly to neurons in the ventromedial nucleus of the thalamus. These thalamic neurons project to the insular cortex.

From the above discussion, it is clear that there is neither a set point for body temperature nor a "thermostat" that maintains it at 37°C. Instead, as mentioned earlier, an apparent set point for body temperature emerges as a settling point controlled by multiple sensorymotor feedback loops containing thermoreceptors and thermoeffectors. It is a major achievement of evolution that this multicomponent afferent/efferent system is

so effective in keeping the temperature of the body core remarkably constant.

Dysregulation of Circuits Controlling Temperature Causes Fever

In the past, when the set point view of thermoregulation was dominant, fever was thought to be caused by raising the body temperature set point—a view that still persists in major medical textbooks. Based on the advances described above, fever is now thought to arise through modulation of the afferent/efferent loops, particularly as they traverse the hypothalamic preoptic area. Prostaglandin E2, generated by the action of inflammatory cytokines on endothelial cells in the preoptic area, inhibits warm-activated GABAergic neurons in the MnPO, thus disinhibiting the effector pathways that promote cutaneous vasoconstriction, brown adipose tissue thermogenesis, and shivering. Nonsteroidal anti-inflammatory drugs, such as aspirin, ibuprofen, and acetaminophen, reduce fever by inhibiting hypothalamic generation of prostaglandin E2.

Water Balance and the Related Thirst Drive Are Controlled by Neurons in the Vascular Organ of the Lamina Terminalis, Median Preoptic Nucleus, and Subfornical Organ

Changes in Blood Osmolarity Cause Cells to Shrink or Swell

Driven by osmosis, water moves freely across cell membranes. This has a number of important consequences. First, because of its large size, the intracellular compartment contains two-thirds of the body's water. Second, if blood osmolarity changes from its normal value (~290 mOsm/kg)—because water is gained by drinking or lost by renal excretion and by sweating, or because solutes have been added by eating (or by drinking, eg, sea water—1000 mOsm/kg)—water will move and the osmolarity of all compartments will equilibrate, including the intracellular one.

Because the intracellular content of osmotically active molecules is relatively fixed over the short term, increases in blood osmolarity cause cells to shrink, and conversely, decreases cause cells to swell. This is particularly dangerous for the brain because it is encased by the rigid skull. With extreme hyperosmolarity (too little water), the brain shrinks, pulling away from the skull and tearing blood vessels. With hypo-osmolarity (too much water), the brain swells, causing cerebral edema, seizures, and coma. To prevent such incidents, the brain acts to maintain normal osmolarity. It does this by detecting changes in osmolarity and then regulating the motivation to drink (thirst) and the kidney's capacity to excrete water.

Osmolarity Is Affected When Water Is Lost or Gained and When Food Is Ingested

Water is gained by drinking and, to a small degree, by the oxidation of fuel (fuel + $O_2 \rightarrow CO_2 + H_2O$). It is lost in a number of ways—by breathing (dry air in, humidified air out), via the gastrointestinal tract (especially when diarrhea is present), by sweating, and by urination. Eating also increases blood osmolarity by moving water from the blood to the gut to aid digestion and by adding solutes to the bloodstream as food is broken down and absorbed.

Because of these effects, there are significant interactions between neural systems that control hunger and thirst. For example, eating is such a significant osmotic challenge that dehydration and its associated hyperosmolarity strongly suppress hunger (dehydration-induced anorexia). Conversely, the act of eating itself, even in an individual with normal water content, rapidly stimulates thirst so as to mitigate the anticipated, eating-induced increase in osmolarity.

Vasopressin Released From the Posterior Pituitary Regulates Renal Water Excretion

The ability of the kidney to excrete water is tightly controlled by vasopressin. When it is absent, humans can excrete up to approximately 900 mL/h of urine, and when it is at maximal levels, humans excrete as little as approximately 15 mL/h. Vasopressin decreases water excretion by increasing its reabsorption from urine by the kidney.

Osmolarity Is Detected by Osmoreceptor Neurons

The brain maintains water balance by monitoring sensory input from osmoreceptors—sensory neurons that respond to osmolarity—which reflects the body's state of hydration. Osmoreceptor neurons are found in the periphery and on neurons in and around the hypothalamus. The central osmoreceptors monitor systemic osmolarity, while the peripheral osmoreceptors monitor osmolarity in and around the gut and related structures.

Peripheral Osmoreceptors Allow Changes in Systemic Osmolarity to Be Anticipated

Sensory information about peripheral osmolarity enables the brain to make preemptive changes in thirst

and vasopressin secretion that anticipate and mitigate future shifts in systemic osmolarity, such as the decrease that occurs with drinking or the increase that occurs with eating. Such regulation serves to prevent overshooting normal osmolarity, which would otherwise occur when previously ingested water, which has not yet affected systemic osmolarity, is slowly absorbed from the gut. Indeed, when a dehydrated, hyperosmolar individual ingests water, thirst and vasopressin secretion rapidly decrease, well before systemic osmolarity falls. The identity of peripheral osmoreceptors is unknown.

Central Osmoreceptors and the Afferent/Efferent Circuits Control Water Balance

Three nuclei in the lamina terminalis, which forms the anterior wall of the third ventricle, play a key role in detecting and in responding to disturbances in systemic osmolarity (Figure 41–13). From ventral to dorsal, they are the OVLT, the MnPO, and the SFO. The OVLT and SFO are circumventricular organs, and like the previously discussed median eminence, they lie outside the blood–brain barrier. Because of this, neurons in these two nuclei can rapidly detect changes in blood osmolarity as well as blood-borne circulating factors that are unable to cross the blood–brain barrier (an important example being angiotensin II).

Consistent with this arrangement, osmoreceptor neurons in the OVLT and SFO make extensive connections to neurons in the MnPO. While MnPO neurons themselves do not directly sense osmolarity, they are indirectly responsive to osmolarity via relays from the OVLT and SFO. While all neurons in the OVLT and SFO appear to be dedicated to the regulation of water balance, some neurons in the MnPO are involved in regulation of body temperature (as noted earlier), cardiovascular function, and sleep. Regulation of water balance or body temperature is carried out by subsets of modality-specific neurons in the MnPO.

Neurons from all three lamina terminalis nuclei send dense excitatory projections to secretory vasopressin neurons in the paraventricular hypothalamic nucleus (PVH) and supraoptic nucleus. As described below, these three lamina terminalis nuclei are also able to cause thirst.

Central osmoreceptors, and probably also peripheral osmoreceptors, detect changes in osmolarity by

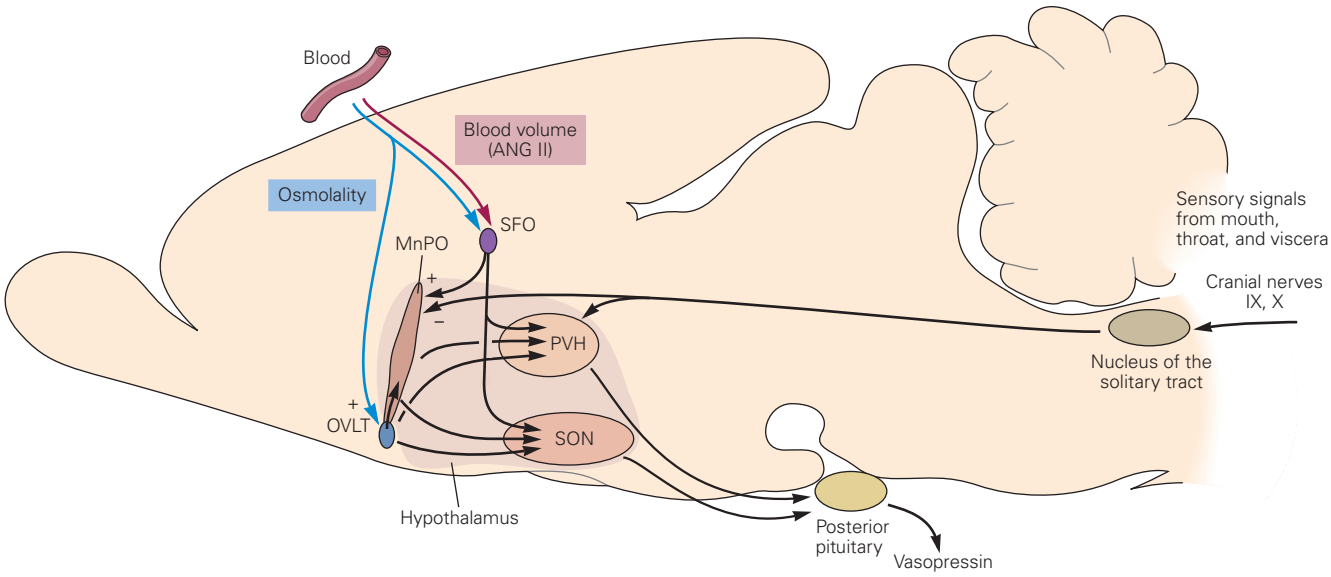

Figure 41–13 Neural and endocrine components combine to regulate fluid balance. The circuitry is shown in a sagittal section through the rat brain. Information from baroreceptors in the circulatory system and from sensory receptors in the mouth, throat, and viscera is conveyed to the nucleus of the solitary tract and neighboring structures in the caudal brain stem through the glossopharyngeal (**IX**) and vagal (**X**) nerves. The hormone angiotensin II (**ANG II**) provides the brain with an additional signal concerning low blood volume. Circulating angiotensin II is sensed by receptors in the subfornical organ (**SFO**); SFO neurons project to the median preoptic area (**MnPO**), paraventricular nucleus of the hypothalamus (**PVH**), supraoptic nucleus (**SON**), and the vascular organ of the lamina terminalis (**OVLT**). The osmolality of the blood is sensed by receptors in and near the OVLT that project to the MnPO, PVH, and SON. Neurosecretory cells in the PVH and SON nuclei trigger release of vasopressin from the posterior pituitary, thus decreasing water excretion by the kidney. (Adapted, with permission, from Swanson 2000.)

responding to changes in cell volume. Shrinking or swelling, which increases or decreases, respectively, their cation permeability, causes increases or decreases in firing rate.

Decreased intravascular volume—for example, that due to acute blood loss—also potently stimulates thirst and vasopressin secretion. Low blood volume is detected by the kidney, which increases its secretion of renin. Renin is a protease that converts circulating angiotensinogen to *angiotensin I* (ANG I). ANG I is then further cleaved by angiotensin-converting enzyme in the lung, generating *angiotensin II* (ANG II). ANG II excites SFO neurons that directly, and also via a relay in the MnPO, drive vasopressin neurons and presumptive thirst neurons.

Thirst Is Controlled by Neurons in the OVLT, MnPO, and SFO

As with vasopressin secretion, all three lamina terminalis structures participate in generating the motivational state of thirst, the desire to seek and ingest water. Lesion of all three structures completely blocks dehydration- and ANG II–induced thirst, as well as secretion of vasopressin. Electrical stimulation of these structures, on the other hand, elicits drinking. Activation of excitatory glutamatergic neurons in the SFO and MnPO induces intense drinking in an otherwise water-satiated mouse within seconds.

Thus, excitatory neurons in the SFO and MnPO, and likely also in the OVLT, have a remarkable capacity to induce thirst. Importantly, the behavior induced is specific—only water drinking occurs. Notably, the excitatory SFO neurons driving this behavior are the same subset of SFO neurons that are activated by dehydration and that express ANG II receptors. The downstream pathway by which these neurons stimulate thirst is presently unknown.

The activity of both the thirst neurons in the SFO and vasopressin neurons in the SON and PVH decreases or increases rapidly in response to sensory cues, such as drinking or eating, respectively, that anticipate future homeostatic disturbances. This rapid regulation occurs independent of any changes in systemic osmolarity and is therefore independent of feedback; hence, it is an example of feedforward control. The likely function of this feedforward regulation is to anticipate disturbances, institute preemptive corrective actions, and thus greatly reduce or eliminate their impact.

In summary, years of research have led to a clear model. Dehydration (water deficiency) increases the activity of neurons in the SFO and OVLT, and in the MnPO via relays from the SFO and OVLT, and this increase in activity enhances thirst and vasopressin secretion. As we shall see, a similar general system, but with different neural structures, controls caloric deficiency–based regulation of hunger and energy metabolism.

Energy Balance and the Related Hunger Drive Are Controlled by Neurons in the Arcuate Nucleus

As with temperature and water balance, energy balance is regulated by feedback signals from the body that modulate activity of key hypothalamic neurons, which then initiate adaptive changes in both physiology and behavior. Regulation of energy balance differs, however, in important ways.

First, the feedback signals monitored are numerous and, in many cases, only very indirectly related to the key parameter, energy balance. Examples of this feedback include neural and hormonal signals from the gut, leptin from adipocytes, insulin from pancreatic beta cells, and metabolite levels in the blood. This is in striking contrast to the single, directly sensed signals monitored for thermoregulation and water balance. Second, energy can be stored as fat. The amount of energy that can be accumulated is remarkably high, so high that the energy needs of a starving person can be met for more than a month. Heat and water, in contrast, are not stored. Thus, organisms have an "energy buffer" that allows survival during prolonged deficiency.

Third, since storage has benefits, regulation of energy balance, as opposed to temperature and water balance, is asymmetric in that low energy stores are defended against very aggressively, while high stores are defended against only very weakly—hence the high prevalence of obesity in societies with calorically dense, palatable food. Fourth, energy storage can be a liability—when excessive, it promotes diseases such as obesity, diabetes, heart disease, and cancer. Finally, in circuits regulating energy balance, neuropeptides play a remarkably important role.

Fat Is Stored When Intake of Energy Exceeds Expenditure

Consistent with the first law of thermodynamics, the calories that are stored as fat equal the number of calories ingested minus calories expended. While there is only one way to gain energy—by eating—there are many ways to expend energy.

Most energy is expended by biochemical reactions that are required for basic life functions. As these processes are constantly in operation, such "obligatory energy expenditure" is fixed and not regulated. Two other types of energy expenditure, however,

are dramatically different; one is voluntary physical activity, while the other is involuntary, resulting from sympathetic stimulation of brown adipose tissue and shivering. Sympathetically controlled energy expenditure, often referred to as adaptive thermogenesis, is controlled by the brain. Its function is to respond to perturbations in temperature and in energy stores.

The Intake and Expenditure of Energy Are Usually Matched

For most individuals, body fat stores are relatively constant over time. Thus, calories ingested roughly equal calories expended. A simple calculation demonstrates this point. An average middle-aged person expends 3,392 kcal per day (kcal corresponds to the common term "calorie"). Over the course of a year, this typical person gains 350 g of fat (which equates to 9 kcal of fat per day). Thus, on average, 9 kcal extra must have been consumed per day to account for this gain. This is the amount of energy found in 4% of a typical candy bar or expended by walking about 150 meters. Thus, the mismatch between intake and expenditure (9 kcal) is tiny—only 0.27% of total energy expenditure.

Such close matching is the result of powerful homeostatic mechanisms that use feedback from the body to regulate intake and expenditure. As is true for regulation of temperature and osmolarity, the constancy of body weight, and the close matching between intake and expenditure, is unrelated to any specific "set point." Instead, this remarkable control is the emergent settling point of multiple afferent/efferent feedback loops.

Obesity Is Caused by Genes and Recent Lifestyle Changes

Dysregulation of the above-mentioned afferent/efferent feedback loops results in obesity. While some cases of obesity are due to known mutations in genes required for homeostatic regulation, most are of undetermined cause. Of these, many are likely due to multiple mutations, many of which are uncharacterized. Because the incidence of obesity in Western societies has increased greatly in recent years, too fast to be due to new mutations, changes in diet and physical activity must also play an important role. Homeostatic systems that evolved to achieve energy balance in hunter-gatherers are likely overwhelmed by abundant, palatable, calorically dense food.

But even in our modern obesogenic environment, there are still large variations in fat stores: Only 41% to 70% of interindividual variation in fat stores can be attributed to genetic factors. Thus, genetic predisposition and environment together cause obesity. Of interest, many of the predisposing genetic loci identified to date involve genes that affect brain function.

Multiple Afferent Signals Control Appetite

The major afferent signals affecting energy balance can be divided into two major categories. (1) Short-term signals from cells that line the gastrointestinal tract report the status of food in the gut. All but one of these signals increase with eating and function to terminate meals; the exception is ghrelin, which increases with fasting and stimulates hunger. (2) Longer-term signals report the status of energy reserves (ie, fat stores). These include the pancreatic hormone insulin and the adipocyte hormone leptin, both of which are released in proportion to fat stores. Their levels, especially that of leptin, inform the brain whether fat stores are adequate (Figure 41–14A).

Signals From the Gut Trigger Meal Termination. During eating, as food enters the stomach and intestine, physical distention increases firing of stretch-sensitive vagal afferents. In addition, chemodetection of food by intestinal endocrine cells stimulates secretion of hormones such as cholecystokinin (CCK), glucagon-like peptide-1 (GLP-1), and peptide YY (PYY). These responses have three primary functions.

First, they cause contraction of the pyloric sphincter, a valve between the stomach and intestine. This limits further passage of food, preventing the small intestine from being overloaded. Second, the intestinal hormones stimulate secretion of bile and enzymes into the intestinal lumen to aid digestion. Third, the vagal afferents and the intestinal hormones decrease subsequent food intake, bringing about meal termination (satiation). The intestinal hormones accomplish this primarily by stimulating local vagal afferent terminals, which in turn excite neurons in the caudal region of the NTS.

Two of these hormones, GLP-1 and PYY, may also directly stimulate neurons in the brain. The activated neurons in the NTS project directly, or via a relay in the lateral parabrachial nucleus, to neurons in the forebrain, including the amygdala and hypothalamus. Neurons in the lateral parabrachial nucleus that express calcitonin gene-related polypeptide (CGRP) are one such important relay involved in satiation. These circuits then bring about meal termination.

When food is absorbed, the increase in blood glucose stimulates β-cells to release insulin and the hormone amylin. Amylin then excites neurons in the area postrema (a circumventricular organ outside the blood–brain barrier, located just above the NTS).

Circulating amylin increases within minutes following a meal, decreasing subsequent food intake.

Ghrelin is released by endocrine cells in the stomach. Unlike the factors described above, its secretion is high before eating and falls during the meal. It may play a role in meal initiation. Indeed, ghrelin is the only known systemic factor that increases hunger and thus eating. It excites neurons in a number of sites, including agouti-related peptide neurons in the arcuate nucleus (see below). The physiological significance of ghrelin is unclear because deletion of its gene does not appear to affect hunger.

Blood Glucose and Insulin Affect Appetite. Glucose is sensed by neurons in the periphery, hindbrain, and hypothalamus. Although glucose sensing does not appear to play a role in the day-to-day regulation of energy balance, the detection of and response to dangerously low blood glucose levels (*glucopenia*) is an important function of the brain. Two adaptive responses are initiated: (1) intense glucoprivic hunger, due at least in part to indirect activation of agouti-related peptide neurons, and (2) secretion of glucagon, epinephrine, and corticosteroids, which stimulate hepatic glucose production. The hormonal responses are caused by increases in sympathetic outflow as well as activation of the CRH pathway associated with stress (Chapter 61). Amino acids also can be sensed and, consequently, regulate energy balance and dietary choice—the latter to ensure ingestion of sufficient quantity and quality of protein.

Insulin, on the other hand, is thought to signal an increase in fat stores. Insulin's primary function is to control blood glucose, the stimulus for its secretion. Insulin lowers blood glucose by driving it into muscle and fat cells and by decreasing its production by the liver. As fat stores increase, its ability to do this is decreased (a phenomenon called insulin resistance). Thus, higher fat stores increase basal and meal-stimulated insulin secretion in an effort to overcome resistance and normalize glucose. The fat store–mediated increase in insulin levels inhibits neurons in the hypothalamus, especially the arcuate nucleus, which is thought to decrease hunger.

The Fat Cell Hormone Leptin Signals the Brain About Fat Stores and Affects Hunger and Energy Expenditure. In 1949, scientists at the Jackson Laboratory in Maine noted the appearance of "some very plump young mice." This obesity was due to a genetic mutation, which they named *obese* (*ob*). Sixteen years later, they identified another obesity mutation, *diabetes* (*db*). The extreme obesity of *ob/ob* and *db/db* mice results from intense hyperphagia and reduced brown fat thermogenesis. Based on a series of parabiosis experiments, Douglas Coleman proposed that *ob/ob* mice lack a circulating satiety factor and that *db/db* mice lack its receptor.

In a tour-de-force positional cloning effort led by Jeffrey Friedman and Rudolph Leibel, the *ob* gene was localized on a small region on chromosome 6. Friedman and his lab then homed in on and identified the *ob* gene. Renamed the *leptin* gene, it encodes leptin, a 167-amino acid protein secreted by adipocytes in proportion to the size of fat stores. Treating *ob/ob* mice with leptin cures their obesity. The *db* gene was identified a few years later, and as predicted by Coleman, it turned out to encode leptin's receptor and was found to be expressed by neurons in the hypothalamus. It is an interleukin-6–type class I cytokine receptor that produces its antiobesity effects by activating the JAK2/STAT3 signaling pathway.

Much has been learned subsequently about leptin. First, humans with a genetic deficiency of leptin or its receptor, like the mutant mice, are massively obese; hence, leptin's function is highly conserved, and such mutations are extremely rare. Second, humans with common forms of obesity have very high circulating levels of leptin, a by-product of their increased fat stores. This finding initially led to the view, later questioned, that "garden variety" obesity is caused by resistance to leptin action. Third, starvation, which reduces fat stores, drastically decreases leptin levels. This reduction is of interest because fasting causes many adaptive responses that are also seen in mice and humans that lack leptin: hunger, low energy expenditure, decreased fertility, and other altered neuroendocrine responses. Indeed, restoration of normal leptin levels in fasted individuals reverses or ameliorates many of fasting's effects. Thus, leptin's primary function is to signal, when its levels are low, that fat stores are inadequate.

These low leptin levels then bring about key adaptive responses such as increased hunger, decreased sympathetically mediated thermogenesis (to conserve limited fuel stores), decreased fertility (to prevent pregnancy when its demands cannot be met), and others. According to this view, leptin's dynamic range for signaling extends from the very low levels seen with fasting, signaling that fat stores are too low, to the levels found in well-fed, nonobese individuals, signaling that fat stores are sufficient. Levels above this may produce some effect to restrain obesity, but this effect, if present, is remarkably weak. Thus, the defense of energy balance is asymmetric—strong against low stores, weak against high stores. A corollary of this is that obese individuals do not have leptin resistance;

POMC, AgRP, and MC4R Neurons Are Key Nodes in the Afferent/Efferent Loop

Neuron-specific manipulation technologies have revealed two antagonistic populations of neurons in the arcuate nucleus that control energy balance: one expresses agouti-related peptide (AgRP) and the other the precursor polypeptide proopiomelanocortin (POMC) (Figure 41–14B). POMC neurons decrease hunger and stimulate sympathetically driven energy expenditure; AgRP neurons do the opposite. POMC neurons release the processed peptide α-melanocyte-stimulating hormone (αMSH), which activates the melanocortin-4 receptor (MC4R), a G protein–coupled receptor.

The downstream MC4R-expressing neurons that control hunger lie within the PVH. When these MC4R neurons are excited by αMSH released from POMC afferents, hunger is decreased. The PVH-MC4R "satiety neurons" are glutamatergic; they decrease hunger via their excitatory projections to the lateral parabrachial nucleus.

The MC4R-expressing neurons that control energy expenditure are sympathetic preganglionic neurons in the spinal cord. POMC neurons project to these sites, in addition to the PVH, increasing sympathetically driven energy expenditure.

The AgRP neurons increase hunger in part by opposing the actions of POMC neurons (Figure 41–14B). They release three factors: AgRP, an inverse agonist of MC4R, and neuropeptide Y and γ-aminobutyric acid (GABA), two inhibitory transmitters. The AgRP neurons project to and inhibit the PVH-MC4R satiety neurons and directly inhibit POMC neurons. In addition, different subsets of arcuate AgRP neurons project to other sites, including the lateral hypothalamus and the bed nucleus of the stria terminalis. These sites, when inhibited by AgRP inputs, can also stimulate hunger.

A third group of neurons in the arcuate nucleus express VGLUT2, release glutamate, and act in parallel with POMC neurons to induce satiety (Figure 41–14B). Like POMC neurons, and opposite to AgRP neurons, they excite the PVH-MC4R satiety neurons. αMSH/MC4R signaling in PVH-MC4R neurons causes satiety by two mechanisms: by directly activating the PVH-MC4R satiety neurons and by upregulating excitatory transmission from the VGLUT2 neurons to the PVH-MC4R neurons via postsynaptic facilitation.

The importance of the POMC, AgRP, and PVH-MC4R satiety neurons in regulating food intake is supported by a number of compelling findings. First, fasting activates AgRP neurons and inhibits POMC neurons, while feeding or leptin treatment does the opposite. The downstream PVH-MC4R satiety neurons are inhibited by fasting and excited by feeding. Second, genetic deficiency of the POMC protein or MC4R causes massive obesity. Third, genetic ablation of AgRP neurons in mice causes starvation, while stimulation of AgRP neurons rapidly brings about extreme hyperphagia, even in mice that are calorically replete and otherwise sated. Finally, several findings implicate the PVH-MC4R satiety neurons as an important

Figure 41–14 (Opposite) Neural and endocrine components combine to regulate energy balance.

A. *Short-term signals*. During meals, cholecystokinin (**CCK**) from the intestinal tract stimulates sensory fibers of the vagus nerve, thus promoting satiation (meal termination). Glucagon-like peptide-1 (**GLP-1**) and peptide YY (**PYY**), also released by the intestinal tract, appear to work on both sensory fibers of the vagus and neurons in the brain. The vagal sensory fibers, along with sympathetic fibers from the gut and orosensory information, converge in the nucleus of the solitary tract (NTS). Prior to mealtime, release of ghrelin from the stomach peaks, providing a blood-borne signal to neurons in the brain. Whereas CCK promotes satiety, ghrelin promotes eating.

Long-term signals. Leptin and insulin are among the humoral signals that inform the brain about the status of the fat stores. Leptin is produced in fat-storing cells, whereas insulin is produced in the pancreas. Both hormones are sensed by receptors in the arcuate nucleus of the hypothalamus as well as by receptors in the NTS. Leptin and insulin reduce food intake and increase energy expenditure. (Abbreviation: **SNS**, sympathetic nervous system.)

B. Neurons in the arcuate nucleus that synthesize agouti-related peptide (**AgRP**), proopiomelanocortin (**POMC**), and vesicular glutamate transporter 2 (**VGLUT2**) project to the paraventricular nucleus of the hypothalamus (**PVH**) where they control hunger and satiety. Satiety-promoting POMC neurons release the processed POMC peptide, α-melanocyte stimulating hormone (**αMSH**), which binds to melanocortin-4 receptors (**MC4R**) on neurons in the PVH. Activation of these neurons causes satiety. In contrast, the hunger-promoting AgRP neurons release two inhibitory transmitters, γ-aminobutyric acid (**GABA**) and neuropeptide Y (**NPY**), and the MC4R antagonist AgRP. Their combined effect is to inhibit the MC4R-expressing neurons, causing hunger. The MC4R-expressing neurons also receive direct excitatory input from another population of arcuate neurons, VGLUT2 neurons, which also promote satiety. The binding of αMSH to MC4R causes satiety by two mechanisms: by directly activating the PVH-MC4R neurons and by upregulating excitatory transmission from the arcuate VGLUT2 neurons to the PVH-MC4R neurons (**blue arrows**). Finally, PVH-MC4R neurons project to the lateral parabrachial nucleus where they promote satiety.

downstream target of AgRP and POMC neurons. Most notable are the development of marked hyperphagia and obesity in mice genetically engineered to lack MC4R neurons in the PVH and the induction of intense feeding following optogenetic stimulation of AgRP terminals in the PVH, which inhibits the satiety neurons.

Surprisingly, environmental cues that predict future ingestion of food induce inhibition of AgRP neurons. Indeed, in fasted mice, which have high AgRP neuron activity, presentation of food alone without ingestion decreases AgRP neuron firing. This is roughly analogous to rapid, feedforward inhibition of vasopressin secretion and thirst neuron activity (mentioned previously). Thus, in addition to receiving strong bottom-up feedback signals from the body, the hunger-promoting AgRP neurons also receive top-down feedforward information from the environment. The function of this input is not yet clear, but it could serve as an anticipatory signal to limit future ingestion of excessive calories, or as discussed below, it could serve as a reward-related signal to motivate feeding.

Finally, the complete pathway accounting for regulation of hunger by the AgRP and POMC neuron → PVH pathway is presently unknown. It is likely that, via relays through a number of synapses, it affects neuronal activity in pathways controlling reward as well as perception. This is the case because, in the fasted state, food and cues predictive of food are both more rewarding and much more likely to become the focus of attention. How specificity for a given goal—in this case food—is retained as neural information flows from the highly specific deficiency-regulated homeostatic neurons in the hypothalamus to the "nonspecific" reward and perception pathways in the accumbens and cortex is one of the great mysteries of motivated behaviors such as hunger and thirst. The solution could provide clues for disorders of motivated behavior like drug addiction.

Psychological Concepts Are Used to Explain Motivational Drives Such as Hunger

In a simplified stimulus–response view of behavior, one might assume that neural detection of water or energy deficiency (the stimulus) is hardwired to motor pathways for drinking or eating (the response), and thus analogous to the knee-jerk stretch reflex (Chapter 3). However, this cannot be the case because the responses that can be employed to obtain food, all motivated by the deficiency stimulus, are remarkably varied and complex—to such a degree that they could not be hardwired. Indeed, animals can complete an infinite number of complex operant learning tasks to obtain water or food rewards.

The challenge to understanding motivational drive is to devise a model that accounts for the ability of deprivation states to induce behavior that is remarkably varied and complex, while remaining completely specific for one goal. Two compelling theories are relevant. According to *incentive motivation theory*, deficiency increases the reward value of food and water. *Drive reduction theory* posits that deficiency generates an aversive state, the resolution of which is thought to motivate behavior. Notably, these two views are not mutually exclusive and may in some ways be two sides of the same coin.

Incentive Motivation: Fasting Increases the Reward Value of Food. The incentive motivation theory is the work of theorists over many years, most recently refined by Frederick Toates and Kent Berridge. Consider eating and the hunger drive. Briefly, food is viewed as inherently rewarding. Through learned associations, cues and tasks related to obtaining food also become rewarding; in this way, varied and complex behavioral responses are learned (Figure 41–15A).

The theory posits that the deprivation state increases the reward value of food and of the related cues and tasks (ie, their incentive salience). Thus, during fasting, the reward value is increased, and all food and cues and tasks related to food are extremely rewarding. After a meal, the reward value is decreased, and only the most inherently palatable foods, for example, ice cream, are still sufficiently rewarding to be eaten. The task of neuroscientists is to determine how deprivation increases reward value. Experimental activation of AgRP neurons in an otherwise sated mouse dramatically increases the reward value of food—remarkably, the reward value of food is increased to the same extremely high level seen with fasting.

Drive Reduction: Activity of AgRP Hunger Neurons Can Be Aversive. As we know from personal experience, the behavioral states created by dehydration and caloric deficiency, namely thirst and hunger, are unpleasant. It was originally proposed many years ago that reduction of these states, which relieves this discomfort, is rewarding and hence motivates drinking and feeding. Recently, Scott Sternson's group has provided compelling new support for a modified version of this model (Figure 41–15B). Using a behavioral conditioning paradigm such as the place preference test, they discovered that optogenetic activation of AgRP neurons in sated mice was aversive. When the same mice were then studied in a food-deprived state (which is associated with

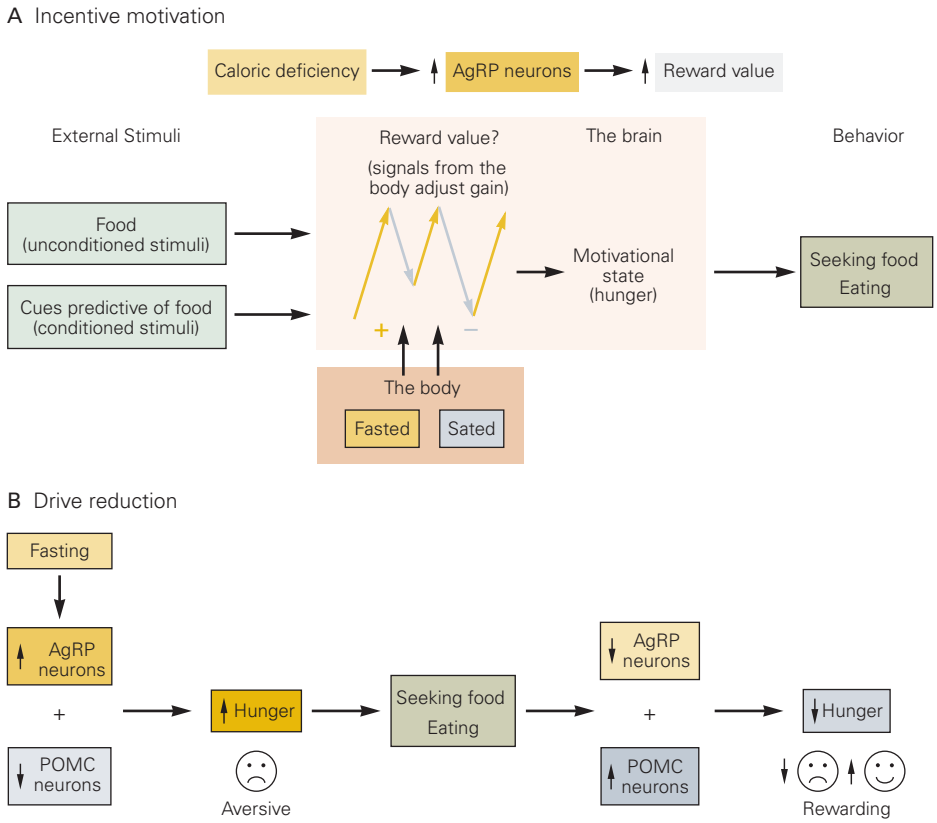

Figure 41–15 Two theories of how fasting promotes eating.

A. *Incentive motivation.* Food is inherently rewarding, and different foods have different reward values (lettuce–low, ice cream–high). Through learned associations, cues that predict food become rewarding. The fed (sated) versus fasted state sets the gain determining how rewarding food and food cues are. Fasting greatly increases while the sated state decreases reward value.

B. *Drive reduction.* The feeling of hunger is aversive. Eating reduces this aversive state. Consistent with this theory, experimental stimulation of hunger-promoting agouti-related peptide (**AgRP**) neurons is aversive, while stimulation of satiety-promoting paraventricular nucleus of the hypothalamus melanocortin-4 receptors (**MC4R**) neurons (which are downstream of the AgRP and proopiomelanocortin [**POMC**] neurons) in an otherwise hungry mouse creates a pleasant feeling.

increased AgRP neuron activity), they engaged in behaviors that in the earlier conditioning had lowered AgRP neuron activity—in short, they acted as if motivated to turn off the AgRP neuron–induced aversive state. Similar results were obtained with thirst neurons in the SFO.

In further support of this view, optogenetic activation of downstream PVH-MC4R satiety neurons in calorically deprived mice, but not in sated mice, is emotionally positive (ie, the mice like it). Thus, causing satiety when otherwise hungry is pleasant. In total, these findings provide strong evidence for the view that homeostatic deficiency is unpleasant, that the aversive state is caused by activation of deficiency-responsive homeostatic neurons, and that when afflicted by the deficiency-induced aversive state animals engage in behaviors that they associate with relief.

This model provides an explanation for why dieting is so difficult. It generates an aversive, unpleasant state that can only be relieved by eating. Finally, the rapid reduction in AgRP neuron activity in response to sensory cues that predict food, and the alleviation of the aversive state that this should cause, could function as a rewarding "teaching signal" that motivates pursuit of the goal (food).

Sexually Dimorphic Regions in the Hypothalamus Control Sex, Aggression, and Parenting

Now we turn to behaviors that are not homeostatic, but are controlled by the hypothalamus, involve integration between sensory cues and signals from the body (ie, gonadal steroids), and are critical for survival of the species.

Males and females differ in their sexual, aggressive, and parenting behaviors. These differences are especially notable in animals, for example in mice, where they are clearly hardwired (ie, require no prior training). These differences include mounting and lordosis by males and females, respectively; territorial-related behaviors such as marking and aggression by males; and the tendency toward nurturing in females versus aggressive behavior in males when dealing with the young. The latent capacity for these sexually dimorphic behaviors is the product of sex steroid action on the brain during embryogenesis (Chapter 51). Full actualization of adult sex-specific behaviors also requires adult levels of gonadal steroids. Sex chromosome–specific genes, other than *Sry*, which causes male sex determination, as well as genes that are imprinted in a sexually dimorphic way, also subtly modulate sex-specific behaviors independent of gonadal steroids. Ultimately, the behaviors themselves are triggered by cues from the environment, such as pheromones.

Two regions of the hypothalamus are critically involved in the control of these behaviors, the POA and the ventral lateral aspect of the ventromedial hypothalamic nucleus (vlVMH). Both sites are sexually dimorphic: The POA contains more neurons in males, and the vlVMH contains more progesterone-expressing neurons in females. These sites are heavily interconnected, and they receive strong input from two other sexually dimorphic areas outside the hypothalamus: the medial division of the posteromedial bed nucleus of the stria terminalis (BNSTmpm) and medial amygdala (MeA).

Sexual Behavior and Aggression Are Controlled by the Preoptic Hypothalamic Area and a Subarea of the Ventromedial Hypothalamic Nucleus

Brain lesion studies have demonstrated that the sexually dimorphic brain regions—the accessory olfactory bulb, BNSTmpm, MeA, and particularly POA and vlVMH—play important roles in sex-specific behaviors. Neurons in these regions are highly interconnected, are downstream of pathways involved in detecting and responding to pheromones (BNSTmpm and MeA), express sex hormone receptors, and, with the exception of neurons in the vlVMH, also express aromatase (Figure 41–16). Neurons in both the POA and vlVMH send strong projections to the lateral periaqueductal gray area, which is thought to mediate and coordinate the motor and autonomic aspects of sexual and aggressive behavior.

The vlVMH plays a critical role in controlling sexually dimorphic behaviors. Firing rates of vlVMH neurons in male mice increase during mating or periods of aggression toward a male intruder. Stimulation of these neurons triggers intense attack behavior toward intruder males and toward atypical targets for male aggression such as castrated males, females, or even rubber gloves! Silencing these neurons eliminates aggressive behavior toward male intruders.

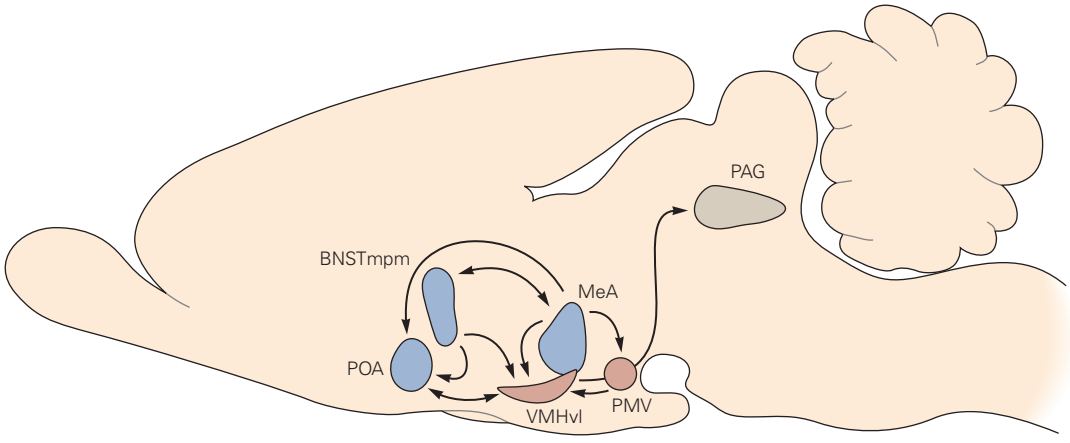

Figure 41–16 Sexually dimorphic neural structures comprise highly interconnected behavioral circuits. Hypothalamic and amygdalar nuclei that regulate sexually dimorphic behaviors are extensively interconnected. These areas process pheromonal information, and subsets of adult neurons within each of these regions express sex hormone receptors; neurons within some of these regions (**blue**) also express aromatase. (Abbreviations: **BNSTmpm**, medial division of the posteromedial bed nucleus of the stria terminalis; **MeA**, medial amygdala; **PAG**, periaqueductal gray; **PMV**, ventral premammillary nucleus; **POA**, preoptic hypothalamus; **VMHvl**, ventrolateral component of the ventromedial hypothalamus.) (Reproduced, with permission, from Yang and Shah 2014. Copyright © 2014 Elsevier Inc.)

Furthermore, stimulation of a subset of vlVMH neurons that express estrogen receptor evokes either sexual behavior (mounting) or aggression, depending on the number of neurons activated and their degree of activation: Lower levels of activation induce mounting, whereas higher levels induce aggression. Consistent with these results, genetic ablation of related progesterone receptor–expressing vlVMH neurons causes loss of both sexual behavior and aggression in males and loss of sexual behavior in females. Thus, it is clear that sex neurons in the vlVMH-expressing steroid receptors play a critical role in driving sexual behavior in males and females and aggression in males.

Parental Behavior Is Controlled by the Preoptic Hypothalamic Area

Nurturing parental behavior is key to the survival of one's offspring. Male rodents demonstrate strikingly different patterns of behavior. Males can be nurturing or hostile to offspring, even to the point of infanticide, depending on whether they view the offspring as their own or those of another male. Female mice, on the other hand, are generally nurturing.

Social interaction between mouse pups and appropriately receptive adult female and male mice, but not hostile adult male mice, induces activity in subsets of galanin-expressing neurons in the POA. These offspring-activated neurons are largely distinct from POA neurons activated by mating. Genetic ablation of galanin-expressing POA neurons prevents nurturing parental behavior, even to the point of inducing uncharacteristic aggression in females toward their offspring. On the other hand, stimulation of these galanin-positive neurons in males, which are normally extremely hostile to unrelated pups, decreases aggression and induces nurturing pup grooming. Thus, neurons in the POA, in addition to controlling sexual behavior itself, also play a role in ensuring survival of the fruit of sexual behavior.

Highlights

1. The hypothalamus and the autonomic and neuroendocrine motor systems coordinate and control body homeostasis by inducing adaptive behaviors; by controlling glands, smooth muscle, cardiac muscle, and adipocytes; and by releasing hormones from the pituitary gland.
2. Homeostatic control of body temperature, fluid and electrolyte balance, and blood pressure allows organisms to function under harsh environmental conditions.
3. Feedback loops that sense temperature, osmolarity, blood pressure, and body fat are essential for homeostatic control. The combined action of multiple feedback-informed sensory-afferent/efferent-effector control loops results in emergent settling points.
4. Modality-specific hypothalamic neurons link specific interoceptive sensory feedback with outputs that control adaptive behaviors and physiologic responses. In addition to feedback, these modality-specific neurons also receive feedforward information regarding future anticipated homeostatic challenges.
5. The autonomic motor system contains neurons located in sympathetic, parasympathetic, and enteric ganglia located near the spinal column or embedded within peripheral targets. Functional subsets of autonomic neurons selectively innervate effector tissues comprised of smooth muscle, cardiac muscle, glandular epithelia, and adipocytes.
6. Sympathetic neurons are activated in response to exercise and stress. Parasympathetic and sympathetic neurons generally have antagonistic functions, but often act in concert. The enteric system coordinates peristaltic contractions of the gastrointestinal tract with mucosal function and local blood flow.
7. Preganglionic neurons that control the sympathetic and parasympathetic outflows are located in the spinal cord and brain stem.
8. Acetylcholine, norepinephrine, and neuropeptide cotransmitters act as synaptic signaling molecules in the autonomic motor system. Excitatory fast synaptic transmission in autonomic ganglia is mediated by acetylcholine acting on nicotinic receptors. G protein–coupled receptors in ganglia mediate additional pre- and postsynaptic excitatory and inhibitory effects. G protein–coupled receptors mediate transmitter actions at autonomic neuroeffector junctions.
9. The neuroendocrine system links the hypothalamus, via the pituitary gland, to various physiologic responses in the body. The posterior pituitary contains hypothalamic axon terminals that release two neurohormones into the blood: Vasopressin stimulates water reabsorption by the kidney, while oxytocin controls uterine contraction and milk release. The anterior pituitary contains endocrine cells that secrete hormones in response to factors released by hypothalamic neurons. These anterior pituitary hormones control the thyroid gland, glucocorticoid secretion

by the adrenal cortex, sex steroid secretion by the gonads, lactation, and linear growth.

10. Body temperature is detected in multiple sites including the periphery, in and around major organs, and in the brain. Constancy of body temperature is maintained by multiple thermoreceptor-afferent/thermoeffector-efferent control loops.
11. Some neurons in the lamina terminalis are activated by both dehydration and loss of intravascular volume. Key parameters sensed in these deficiency states include osmolarity and angiotensin II levels, respectively. When these neurons are activated, they cause thirst and release of vasopressin from the posterior pituitary. Vasopressin release is also rapidly regulated in a feedforward fashion by cues that anticipate future disturbances in osmolarity.
12. Energy balance involves short-term and long-term feedback signals. Short-term signals from the gut mediate satiation, which terminates meals. CCK, released by intestinal endocrine cells, plays a key role in satiation. A key long-term signal is leptin, which is secreted by adipocytes in proportion to the amount of fat stores. When fat stores are low, the consequent low levels of leptin signal the brain to induce a hunger state and to decrease energy expenditure, resulting in replenished fat stores.
13. Leptin is more effective in defending against low fat stores than in resisting obesity.
14. POMC-, AgRP-, and MC4R-expressing neurons in the hypothalamus are key nodes in the afferent/efferent loop controlling energy balance. Neurons that signal satiety are activated by satiety-promoting POMC neurons and inhibited by hunger-promoting AgRP neurons.
15. How specificity for a given goal (eg, food) is retained as neural information flows from the highly specific deficiency-regulated homeostatic neurons in the hypothalamus to the "nonspecific" reward and perception pathways in the accumbens and cortex is one of the great mysteries of motivated behaviors such as hunger and thirst. Solving this could provide clues for disorders of motivated behavior like drug addiction.
16. Leptin regulates hunger and energy expenditure in part by activating POMC neurons and inhibiting AgRP neurons. Hunger-promoting AgRP neurons are also rapidly regulated in a feedforward fashion by cues that anticipate future changes in energy balance.
17. Motivational drives such as hunger have been explained by two mechanisms: The deficiency state (starvation) increases the reward value of food, or deficiency generates an aversive state, the resolution of which motivates behavior.
18. Sexually dimorphic regions in the hypothalamus control sexual behavior and aggression. Neural activity in the sexually dimorphic preoptic area controls parental behavior. Full actualization of adult sex-specific behaviors also requires adult levels of gonadal steroids.

Emotion

Elation, compassion, sadness, fear, and anger are commonly considered examples of emotions. These states have an enormous impact on our behavior and well-being. But what exactly is an emotion? Distinguishing different emotion states is difficult and requires an account of the environmentally or internally generated challenge an organism faces as well as its physiological responses. For example, before we can conclude that a rat is in a state of fear, we need to know that the rat is evaluating a specific threatening stimulus (a predator in its environment) and is mounting an adaptive response, such as high arousal and freezing.

Emotions are often represented along two dimensions: valence (ie, pleasantness to unpleasantness) and intensity (ie, low to high arousal), called "core affect" in many psychological theories. However, emotions can also be grouped into categories, such as categories of basic emotions (happiness, fear, anger, disgust, sadness) and categories of more complex emotions that help regulate social or moral behaviors (eg, shame, guilt, embarrassment, pride, jealousy). There is considerable debate about whether all the categories that are in common usage (like the ones just mentioned) will correspond to scientifically useful categories in a future neuroscience of emotion.

Within experimental contexts, the term *emotion* is used in several different ways, often related to the ways in which emotion is measured (Box 42–1). In everyday conversation, most people use the term "emotion" synonymously with "conscious experience of emotion" or "feeling," and most psychological studies in humans have focused on this sense of "emotion" as well. Most research in animals has focused instead on specific behavioral or physiological responses, in good part because it is impossible to obtain verbal reports in animal studies. Yet emotions have been conserved throughout the evolution of species, as Charles Darwin first observed in his seminal book, *The Expression of the Emotions in Man and Animals.* The empirical approach we describe in this chapter thus considers emotions as central brain states that can be studied in humans as well as many other animals, provided that we distinguish between emotions and feelings.

Emotion states typically cause a broad range of physiological responses that occur when the brain

Box 42–1 Ways of Measuring Emotion

Measures Commonly Used in Humans

Psychophysiology. Psychophysiology uses several measures to assay the physiological parameters associated with emotional states. These measures include autonomic responses (Chapter 41) as well as some somatic responses. The most commonly used measure is the galvanic skin response (also known as the skin conductance response), a measure of sympathetic autonomic arousal derived from the sweatiness of the palms of the hands. Other measures include heart rate, heart rate variability, blood pressure, respiration, pupil dilation, facial electromyography (EMG), and the startle response (see below). Some of these measures mostly correlate with basic dimensions of emotion, such as valence (eg, the

Table 42–1 Common Questionnaires Used to Assess Fear in Human Emotion Studies

Questionnaire	Type of fear questions
Fear Survey Schedule II	Probes an individual's level of fear across a range of different objects and situations that commonly evoke fear
Fear of Negative Evaluation Scale	Measures fear of being evaluated negatively by others
Social Avoidance and Distress Scale	Measures fear of social situations
Anxiety Sensitivity Index	Measures fear of experiencing different bodily sensations and feelings
Beck Anxiety Inventory	Measures fear and panic-related symptoms experienced over the prior week
Albany Panic and Phobia Questionnaire	Has the subject estimate the amount of fear they would experience in different situations
Fear Questionnaire	Measures the degree of avoidance due to fear
PANAS-X Fear (general)	Measures how much, in general, a person feels fear-related affective states
PANAS-X Fear (moment)	Measures how much, during the present moment, a person feels fear-related affective states

PANAS, Positive and Negative Affect Schedule.

detects certain environmental situations. These physiological responses are relatively automatic, yet depend on context, and occur within the brain as well as throughout the body. In the brain, they involve changes in arousal levels and in cognitive functions such as attention, memory processing, and decision making. Somatic responses involve endocrine, autonomic, and musculoskeletal systems (Chapter 41). In sum, emotions are neurobiological states that cause coordinated behavioral and cognitive responses triggered by the brain. This can occur when an individual detects a significant stimulus (positively or negatively charged) or has a specific thought or memory that leads to an endogenously generated emotion state.

Some stimuli—objects, animals, or situations—trigger emotions without the organism having to learn anything about those stimuli. Such stimuli have innately reinforcing qualities and are called unconditioned stimuli; examples are a painful shock or a disgusting taste. However, the vast majority of stimuli acquire their emotional significance through associative learning.

When an individual detects an emotionally significant stimulus, three physiological systems are engaged: the endocrine glands, the autonomic motor system, and the musculoskeletal system (Figure 42–1). The endocrine system is responsible for the secretion and regulation of hormones into the bloodstream that affect bodily tissues and the brain. The autonomic system mediates changes in the various physiological control systems of the body: the cardiovascular system, the visceral organs, and the tissues in the body cavity (Chapter 41). The skeletal motor system mediates

magnitude of the startle response) or arousal (eg, the galvanic skin response), whereas others (eg, facial EMG) can provide more fine-grained information about emotions. Facial expression has been used extensively but has no simple relationship to specific emotions.

Subjective ratings. Subjective ratings are often used in human studies and include categorical and continuous ratings (Table 42–1). These ratings can range along emotion dimensions, such as valence (pleasantness/unpleasantness), or the intensity of specific emotions. Subjective ratings necessarily depend on culture-specific words and concepts for emotions.

Experience sampling. Psychologists use experience sampling to quantify the emotions that people actually experience in everyday life. Participants might have their cell phone sound an alarm every few hours, and they then have to stop whatever activity they are doing and fill out a brief questionnaire about what they are feeling at the moment. In this way, a plot of the data can characterize how people's emotions change throughout the day or over longer periods. It turns out that we are actually fairly good at predicting what emotion people will feel next, from knowing how they currently feel.

Hormonal measures. Hormonal responses to emotional states are typically slower than psychophysiological measures. Emotion researchers measure a variety of hormones to assay emotional states over these lengthy periods. Relatively undifferentiated arousal responses are used to evaluate stress. The stress hormone cortisol (Chapter 61) is easily measured from people's saliva.

Specific experimental probes. Several specific behavioral and physiological assays are used to probe emotions with specific stimuli. These assays generally fall within the field of psychophysiology. A common measure is the amplitude of a subject's eyeblink (or other startle reflexes) when a loud sound is presented. This is potentiated when the subject is in a negatively valenced emotional state. Potentiation of the startle reflex is often used to assay the level of anxiety in people, and the same measure has also been validated in animals.

Measures Commonly Used in Nonhuman Animals

Innate behavioral responses. Animals often exhibit stereotyped behaviors as a consequence of certain emotional states. Observing and scoring the behavior is one method of measuring emotional behaviors. Such behaviors can include approaching a stimulus that is rewarding or that promises reward in the future (a positively valenced emotional state), as well as avoiding or defending against threatening stimuli (a negatively valenced emotional state). In addition, analysis of facial expressions can be utilized in many animal model systems, and has even been used for mice.

Psychophysiology and specific experimental probes. As in the case of humans, animal studies can use several psychophysiological measures (eg, heart rate, respiratory rate, galvanic skin response, pupil diameter, startle). In addition, specific behavioral assays have been developed in animals, often derived from initial observations of their innate behavioral responses. Behaviors such as freezing, attacking, exploring, approaching, and hiding can be measured in response to well-controlled experimental stimuli that are designed to induce certain emotional states. The correspondence between human and animal behaviors, which Charles Darwin originally noted in his 1872 book *The Expression of the Emotions in Man and Animals*, provides powerful animal models for investigating human emotions and their pathology.

overt behaviors such as freezing, fight-or-flight, and particular facial expressions. Together, these three systems control the physiological expression of emotion states in the body.

We begin this chapter with a discussion of the historical antecedents of modern research on the neuroscience of emotion. We then describe the neural circuits and cellular mechanisms that underlie the most thoroughly studied emotion, fear, and in so doing, we will focus on the amygdala. However, it is important to note that there does not appear to be any single brain structure that participates in only one emotion. For instance, the amygdala, which has been known to participate in negatively valenced emotions, also plays a central role in positively valenced emotions: Distinct populations of neurons within the amygdala process positively valenced versus negatively valenced stimuli. We briefly review how emotion states can be changed through extinction and regulation and how emotion interacts with other cognitive processes. We conclude with a survey on the relevance of emotion research to understanding psychiatric disorders.

The Modern Search for the Neural Circuitry of Emotion Began in the Late 19th Century

The modern attempt to understand emotions began in 1890 when William James, the founder of American psychology, asked: What is the nature of fear? Do we run from the bear because we are afraid, or are we afraid because we run? James proposed that the conscious

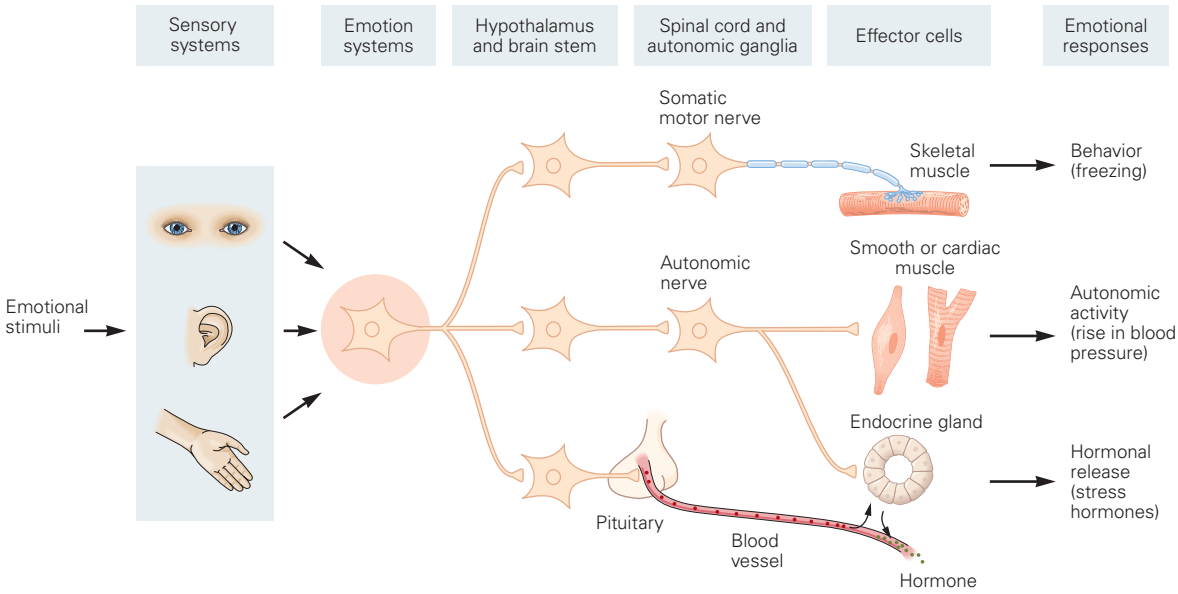

Figure 42–1 Neural control of emotional responses to external stimuli. External stimuli processed by sensory systems converge on "emotion systems" (eg, the amygdala). If the stimuli are emotionally salient, the emotion systems are activated, and their outputs are relayed to hypothalamic and brain stem regions that control physiological responses, including skeletomuscular action, autonomic nervous system activity, and hormonal release. The figure shows some responses associated with fear. It omits many of the complexities of emotion (eg, the effects of emotion states on cognition).

feeling of fear is a consequence of the bodily changes that occur during the act of running away—we feel afraid because we run. James's *peripheral feedback theory* drew on the knowledge of the brain at the time, namely, that the cortex had areas devoted to movement and sensation (Figure 42–2). Little was known at that time about specific areas of the brain responsible for emotion and feeling, but James's view is still debated to this day.

At the turn of the 20th century, researchers found that animals were still capable of emotional responses after the complete removal of the cerebral hemispheres, demonstrating that some aspects of emotion are mediated by subcortical regions. The fact that electrical stimulation of the hypothalamus could elicit autonomic responses similar to those that occur during emotional responses in an intact animal suggested to Walter B. Cannon that the hypothalamus might be a key region in the control of fight-or-flight responses and other emotions.

In the 1920s, Cannon showed that transection of the brain above the level of the hypothalamus (by means of a cut that separates the cortex, thalamus, and anterior hypothalamus from the posterior hypothalamus and lower brain areas) left an animal still capable of showing rage. By contrast, a transection below the hypothalamus, which left only the brain stem and the spinal cord, eliminated the coordinated reactions of natural rage. This clearly implicated the hypothalamus in organizing emotional reactions. Cannon called the hypothalamically mediated reactions "sham rage" because these animals lacked input from cortical areas, which he assumed were critical for the emotional experience of "real" rage (Figure 42–3).

Cannon and his student Phillip Bard proposed an influential theory of emotion centered on the hypothalamus and thalamus. According to their theory, sensory information processed in the thalamus is sent both to the hypothalamus and to the cerebral cortex. The projections to the hypothalamus were thought to produce emotional responses (through connections to the brain stem and spinal cord), while the projections to the cerebral cortex were thought to produce conscious feelings (Figure 42–2). This theory implied that the hypothalamus is responsible for the brain's evaluation of the emotional significance of external stimuli and that emotional reactions depend on this appraisal.

In 1937, James Papez extended the Cannon-Bard theory. Like Cannon and Bard, Papez proposed that sensory information from the thalamus is sent to both the hypothalamus and the cerebral cortex. The descending connections to the brain stem and spinal cord give rise to emotional responses, and the ascending connections to the cerebral cortex give rise to feelings. But Papez

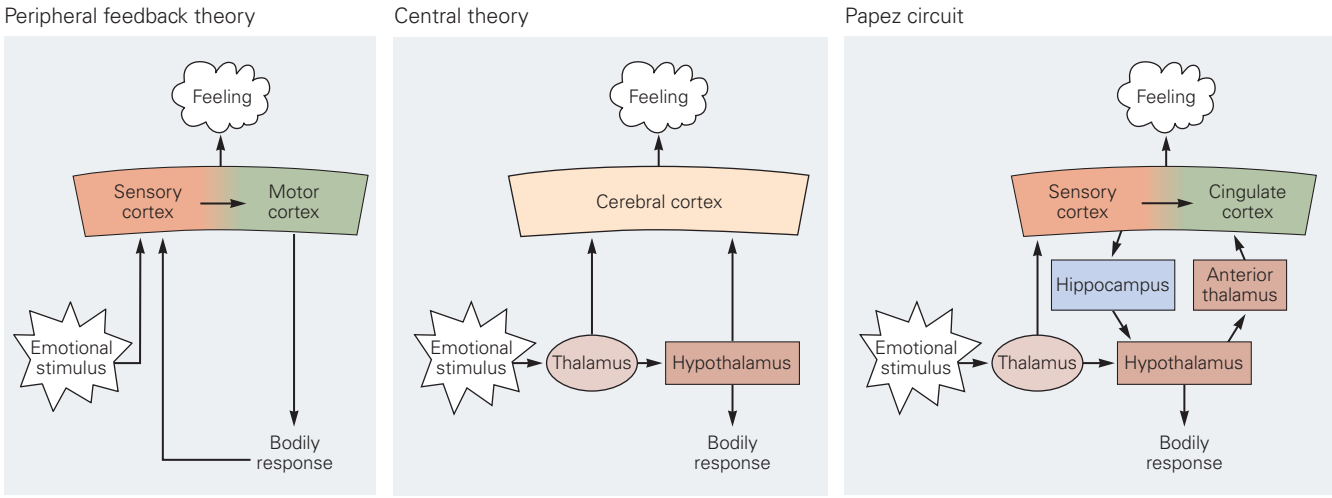

Figure 42–2 Early theories of the emotional brain. (Adapted, with permission, from LeDoux 1996.)

William James's peripheral feedback theory. James proposed that information about emotionally competent stimuli is processed in sensory systems and transmitted to the motor cortex to produce responses in the body. Feedback signals to the cortex convey sensory information about the body responses. The cortical processing of this sensory feedback is the "feeling," according to James.

The Cannon-Bard central theory. Walter Cannon and Philip Bard proposed that emotions are explained by processes within the central nervous system. In their model, sensory information is transmitted to the thalamus where it is then relayed to both the hypothalamus and the cerebral cortex. The hypothalamus evaluates the emotional qualities of the stimulus, and its descending connections to the brain stem and spinal cord give rise to somatic responses, while the thalamocortical pathways give rise to conscious feelings.

The Papez circuit. James Papez refined the Cannon-Bard theory by adding additional anatomical specificity. He proposed that the cingulate cortex is the cortical region that receives hypothalamic output in the creation of feelings. The outputs of the hypothalamus reach the cingulate via the anterior thalamus, and the outputs of the cingulate reach the hypothalamus via the hippocampus.

went on to expand the neural circuitry of feelings considerably beyond the Cannon-Bard theory by interposing a new set of structures between the hypothalamus and the cerebral cortex. He argued that signals from the hypothalamus go first to the anterior thalamus and then to the cingulate cortex, where signals from the hypothalamus and sensory cortex converge. This convergence accounts for the conscious experience of feeling in Papez's theory. The sensory cortex then projects to both the cingulate cortex and the hippocampus, which in turn makes connections with the mammillary bodies of the hypothalamus, thus completing the loop (Figure 42–2).

The hypothalamus is currently receiving intense interest in studies of emotion in animals, particularly in experiments using optogenetics to manipulate the activity of precise cell populations. These studies have shown that specific populations in the mouse ventromedial hypothalamus are necessary and sufficient for defensive emotion states. Thus the hypothalamus does not merely orchestrate emotional behaviors, but is part of the neural circuitry that constitutes the emotion state itself. The role of the hypothalamus in emotion is much less studied in humans, in part because functional magnetic resonance imaging (fMRI) does not have the spatial resolution to investigate specific hypothalamic nuclei, let alone neuronal subpopulations within them.

In the late 1930s, Heinrich Klüver and Paul Bucy removed the temporal lobes of monkeys bilaterally, thus lesioning all temporal cortex as well as subcortical structures like the amygdala and hippocampus, and found a variety of psychological disturbances, including alterations in feeding habits (the monkeys put inedible objects in their mouth) and sexual behavior (they attempted to have sex with inappropriate partners, like members of other species). In addition, the monkeys had a striking lack of concern for previously feared objects (eg, humans and snakes). This remarkable set of findings came to be known as the Klüver-Bucy syndrome and already suggested that the amygdala might be important for emotion (although it was not the only structure lesioned in these experiments).

Building on the Cannon-Bard and Papez models and the findings of Klüver and Bucy, Paul MacLean suggested in 1950 that emotion is the product of the "visceral brain." According to MacLean, the visceral brain includes the various cortical areas that had long been referred to as the limbic lobe, so named by Paul

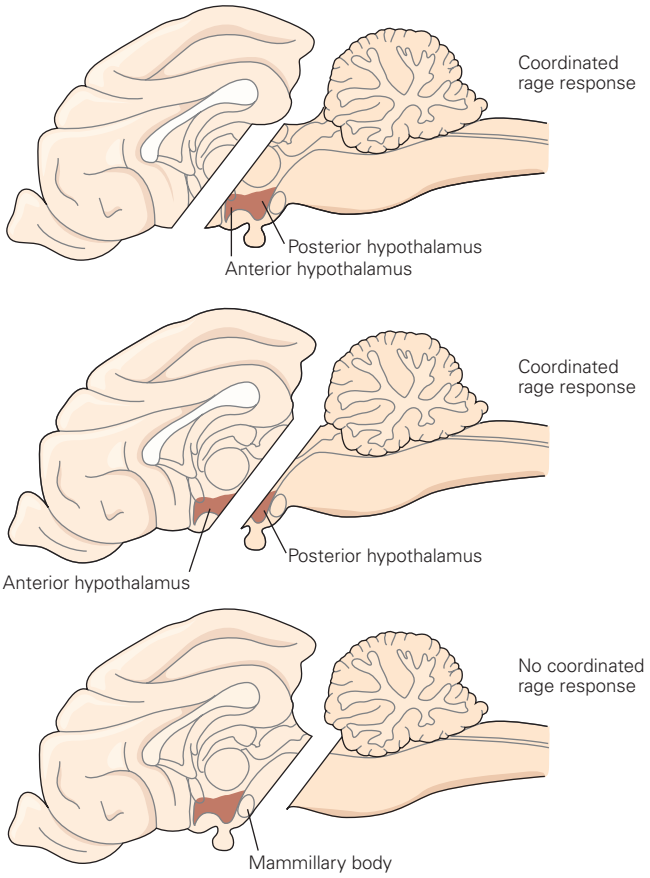

Figure 42–3 Sham rage. An animal exhibits sham rage following transection of the forebrain and the disconnection of everything above the transection (**top**) or transection at the level of the anterior hypothalamus and the disconnection of everything above it (**middle**). Only isolated elements of rage can be elicited if the posterior hypothalamus also is disconnected (**bottom**). This work derives from historical lesion studies in animals. More recent work suggests a more complex picture, in which the hypothalamus is intimately involved in creating the emotion state itself, not merely its behavioral expression.

Broca because these areas form a rim (Latin *limbus*) in the medial wall of the hemispheres. The visceral brain was later renamed the *limbic system*. The limbic system includes the various cortical areas that make up Broca's limbic lobe (especially medial areas of the temporal and frontal lobes) and the subcortical regions connected with these cortical areas, such as the amygdala and hypothalamus (Figure 42–4).

MacLean intended his theory to be an elaboration of Papez's ideas. Indeed, many areas of MacLean's limbic system are parts of the Papez circuit. However, MacLean did not share Papez's view that the cingulate cortex was the seat of feelings. Instead, he thought of the hippocampus as the part of the brain where the external world (represented in sensory regions of the lateral cortex) converged with the internal world (represented in the medial cortex and hypothalamus), allowing internal signals to give emotional weight to external stimuli and thereby to conscious feelings. For MacLean, the hippocampus was involved both in the expression of emotional responses in the body and in the conscious experience of feelings.

Subsequent findings raised problems for MacLean's limbic system theory. In 1957, it was found that damage to the hippocampus, the keystone of the limbic system, produced deficits in converting short- to long-term memory, a function that is distinct from emotions. In addition, animals with damage to the hippocampus are able to express emotions, and humans with hippocampal lesions appear to express and feel emotions normally. In general, damage to areas of the limbic system did not have the expected effects on emotional behavior.

Several of MacLean's other ideas on emotion are nevertheless still relevant. MacLean thought that emotional responses are essential for survival and therefore involve relatively primitive circuits that have been conserved in evolution, an idea already proposed by Charles Darwin almost a century earlier. This notion is key to an evolutionary perspective of emotion. It is now clear that emotions are processed by many subcortical and cortical regions and that the limbic system is by no means the primary system for emotion. Nonetheless, one component of the original limbic system, the amygdala, has received the most attention in studies of both humans and animals. Today, the role of the amygdala in learned fear is probably the best worked-out example of emotion processing in a specific brain structure, and therefore, we consider it next.

The Amygdala Has Been Implicated in Both Learned and Innate Fear

In Pavlovian fear conditioning, an association is learned between an unconditioned stimulus (US) (eg, electric shock) and a conditioned stimulus (CS) (eg, a tone) that predicts the US. For example, if an animal is presented with an emotionally neutral CS (a tone) for several seconds and then shocked during the final second of the CS, especially if this pairing of tone and shock is repeated several times, presentation of the tone alone will elicit defensive freezing and associated changes in autonomic and endocrine activity. In addition, many defensive reflexes, such as eyeblink and startle, will be facilitated by the tone alone.

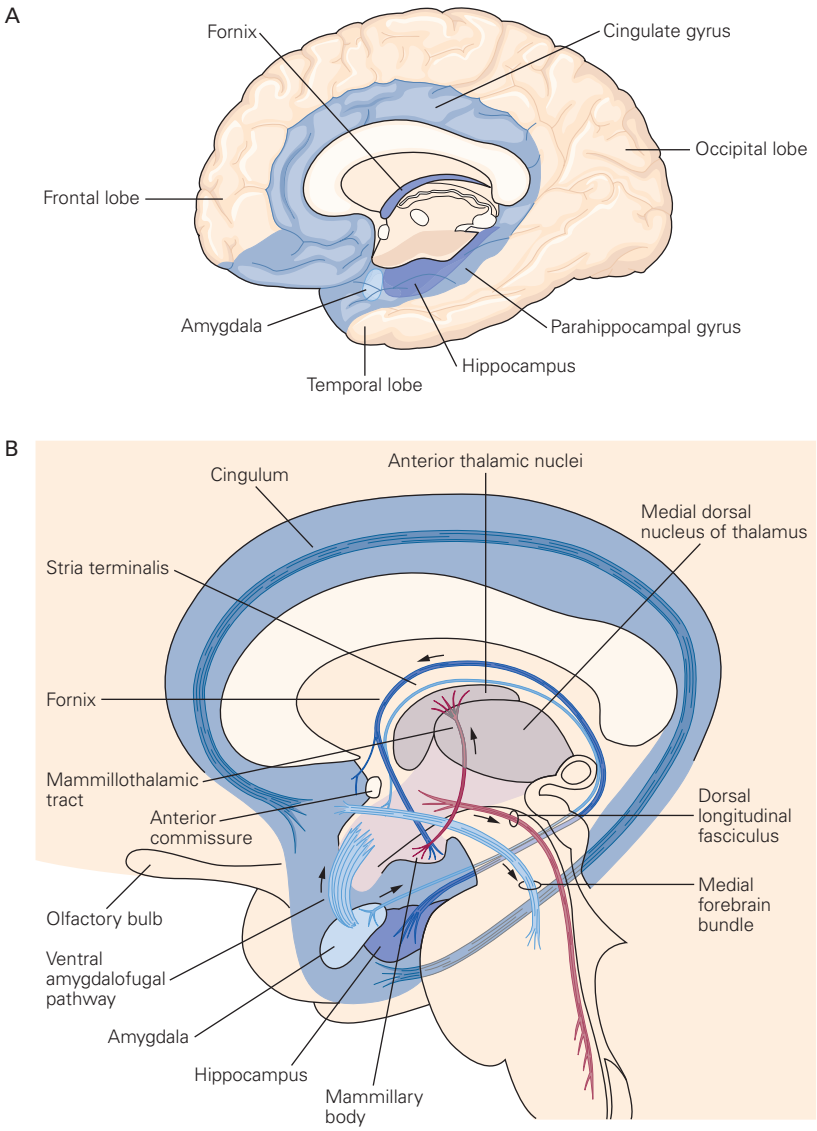

Figure 42–4 The limbic system consists of the limbic lobe and deep-lying structures. (Adapted, with permission, from Nieuwenhuys et al. 1988.)

A. This medial view of the brain shows the prefrontal limbic cortex and the limbic lobe. The limbic lobe consists of primitive cortical tissue (**blue**) that encircles the upper brain stem as well as underlying cortical structures (hippocampus and amygdala).

B. Interconnections of the deep-lying structures included in the limbic system. The **arrows** indicate the predominant direction of neural activity in each tract, although these tracts are typically bidirectional.

Research in many laboratories has established that the amygdala is necessary for Pavlovian fear conditioning: Animals with amygdala damage fail to learn the association between the CS and the US and thus do not express fear when the CS is later presented alone.

The amygdala consists of approximately 12 nuclei, but the lateral and central nuclei are especially important in fear conditioning (Figure 42–5). Damage to either nucleus, but not to other regions, prevents fear conditioning. The lateral nucleus of the amygdala receives most sensory input (but the medial nucleus receives olfactory input), including sensory information about the CS (eg, a tone) from both the thalamus and the cortex. The cellular and molecular mechanisms within the amygdala that underlie learned fear, especially in the lateral nucleus, have been elucidated in great detail. The findings support the view that the lateral nucleus is a site of memory storage in fear conditioning. Neurons in the central nucleus, by contrast, mediate outputs to brain stem areas involved in the control of defensive behaviors and associated autonomic and humoral responses (Chapter 41). The lateral and central nuclei are connected by way of several local circuits within the amygdala, including connections with the basal and intercalated masses. The actual circuitry for Pavlovian learning is thus considerably more complex than what is indicated by Figure 42–5, involving multiple relays among amygdala regions.

Sensory inputs reach the lateral nucleus from the thalamus both directly and indirectly. Much as

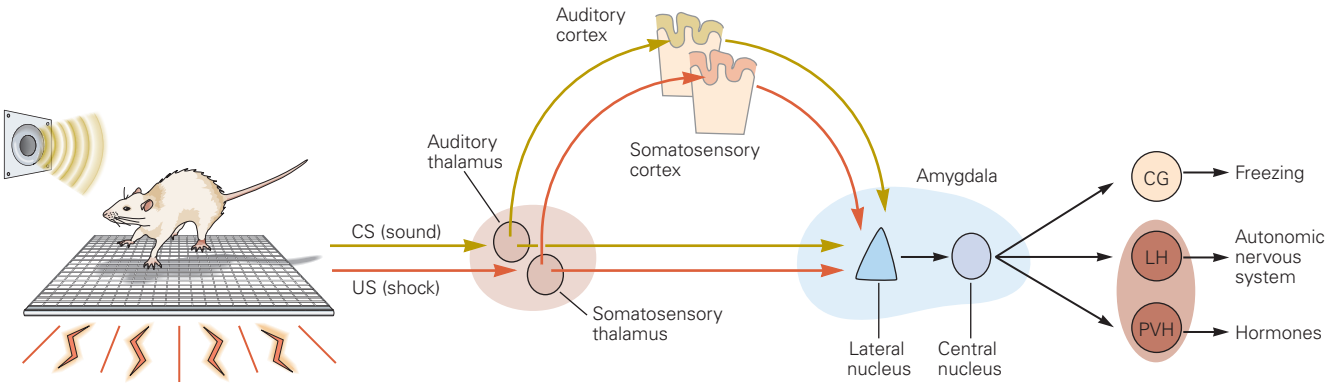

Figure 42–5 Neural circuits engaged during fear conditioning. The conditioned stimulus (**CS**) and unconditioned stimulus (**US**) are relayed to the lateral nucleus of the amygdala from the auditory and somatosensory regions of the thalamus and cerebral cortex. Convergence of the CS and US pathways in the lateral nucleus is believed to underlie the synaptic changes that mediate learning. The lateral nucleus communicates with the central nucleus both directly and through intra-amygdala pathways (not shown) involving the basal and intercalated nuclei. The central nucleus relays these signals to regions that control various motor responses, including the central gray region (**CG**), which controls freezing behavior; the lateral hypothalamus (**LH**), which controls autonomic responses; and the paraventricular hypothalamus (**PVH**), which controls stress hormone secretion by the pituitary–adrenal axis. (Adapted from Medina et al. 2002.)

predicted by the Cannon-Bard hypothesis, sensory signals from thalamic relay nuclei are conveyed to sensory areas of cerebral cortex. As a result, the amygdala and cortex are activated simultaneously. However, the amygdala is able to respond to an auditory danger cue before the cortex can fully process the stimulus information. This scheme is well worked out only for auditory fear conditioning in rodents, and it remains unclear how it applies to other cases, such as visually evoked fear in humans.

The lateral nucleus is thought to be a site of synaptic change during fear conditioning. The CS and US signals converge on neurons in the lateral nucleus; when the CS and US are paired, the effectiveness of the CS in eliciting action potentials is enhanced. This basic mechanism for a form of associative learning is similar to cellular mechanisms that underlie declarative memory in the hippocampus as well (Chapter 54). In particular, the synaptic plasticity found in the hippocampus has also been demonstrated in specific central amygdala circuits. The central amygdala thus does not simply drive motor outputs but is also part of the circuitry through which fear associations are formed and stored, very likely by transmitting information about the CS and US from the lateral nucleus. Neural plasticity likely also occurs in the basal and accessory basal nuclei during fear learning. As with the hypothalamus, recent work in rodents using tools such as optogenetics to manipulate specific subpopulations of amygdala neurons has begun to dissect this circuitry in further detail.

The emotional charge of a stimulus is evaluated by the amygdala together with other brain structures, such as the prefrontal cortex. If this system detects danger, it orchestrates the expression of behavioral and physiological responses by way of connections from the central amygdala and parts of prefrontal cortex to the hypothalamus and brain stem. For example, freezing behavior is mediated by connections from the central nucleus to the ventral periaqueductal gray region. In addition, the basal and accessory basal nuclei of the amygdala send projections to many parts of the cerebral cortex, including the prefrontal, rhinal, and sensory cortices; these pathways provide a means for neural representations in the amygdala to influence cognitive functions. For example, through its widespread projections to cortical areas, the amygdala can modulate attention, perception, memory, and decision making. Its connections with the modulatory dopaminergic, noradrenergic, serotonergic, and cholinergic nuclei that project to cortical areas also influence cognitive processing (Chapter 40). Given these very widespread connections and functional effects, the amygdala is well situated to implement one of the key features of an emotion: its coordinated and multicomponent responses.

The Amygdala Has Been Implicated in Innate Fear in Animals

Although the majority of stimuli acquire their emotional significance through learning, especially in

humans, many animals also rely on innate (unconditioned) signals in the detection of threats, mates, food, and so forth. For example, rodents exhibit freezing and other defensive behaviors when fox urine is detected. Recent studies have made considerable progress in uncovering the circuits underlying this innate fear.

In mammals, sensory signals of unconditioned threats involving predator or conspecific odors are transmitted from the vomeronasal component of the olfactory system (Chapter 29) to the medial amygdala. This stands in contrast to auditory and visual threats, which as noted above are processed via the lateral amygdala. Outputs of the medial amygdala reach the ventromedial hypothalamus, which connects with the premammillary hypothalamic nucleus. In contrast to learned fear, which depends on the ventral periaqueductal gray region, unconditioned fear responses depend on inputs from the hypothalamus to the dorsal periaqueductal gray region. There are other subcortical systems specialized for processing specific innate threats; for instance, the mouse superior colliculus is involved in detecting aerial predators, such as a hawk flying overhead.

It is difficult to study unconditioned emotional responses in humans because the possibility of learning begins right at birth and cannot be experimentally controlled, and because there appear to be large individual differences. For instance, it is thought that threat-related stimuli such as snakes and spiders may be innately fear-inducing stimuli for those people with phobias toward these animals but not for people who keep them as pets. These large individual differences, and the relative roles of innate and learned fear, are important topics for understanding psychiatric illnesses such as anxiety disorders.

The Amygdala Is Important for Fear in Humans

The basic findings from animal studies regarding the role of the amygdala in emotion have been confirmed in studies of humans. Patients with damage to the amygdala fail to show fear conditioning when presented with a neutral CS paired with a US (electric shock or loud noise). In normal human subjects, activity in the amygdala increases during CS–US pairing, as measured with fMRI.

Studies of rare human patients with bilateral amygdala lesions have led to the surprising finding of a dissociation in fear reactions to exteroceptive and interoceptive stimuli (Figure 42–6). Not only do such patients fail to show any autonomic fear reactions to exteroceptive stimuli, to either the CS or the US, but they also appear to lack any conscious experience of fear, as evidenced either from behavioral observation or through subjective verbal report on a questionnaire. In one study, such a patient was confronted with snakes and spiders in an exotic pet store, with monsters in a haunted house, and with autobiographical recollections of highly traumatic personal events (eg, being threatened with death by another person). In none of these instances was there any evidence of fear, and the patient reported feeling no fear at all (even though the patient was able to feel other emotions). These findings argue that the amygdala is necessary for the induction and experience of fear in humans.

By striking contrast, the very same patients with amygdala lesions report intense panic when they are made to feel as though they are suffocating (an interoceptive fear cue, achieved by inhaling carbon dioxide, which lowers blood pH). The dissociation of fear reactions to exteroceptive and interoceptive stimuli supports the idea that there are multiple fear systems in the human brain and that the amygdala cannot be the only structure essential for all forms of fear. Ongoing work is providing more insight, such as mapping out the specific amygdala nuclei that are damaged in these patients and which nuclei are responsible for what types of deficits. This level of resolution is standard in animal studies of the amygdala but has been difficult to achieve in humans, since the amygdala lesions cannot be made experimentally but instead must rely on rare patients that reflect accidents of nature. Equally important, there are theoretical frameworks for how to subdivide the different types of fear. For example, fear can be mapped onto a dimension of threat imminence, which may cover a range from threats that are very far away (perhaps evoking mild anxiety, and engaging monitoring and attention), to threats that are more proximal (evoking fear, and engaging responses such as freezing), to threats that are about to cause death (evoking panic, and engaging defensive behaviors). Eventually, we will need to have a more fine-grained mapping between brain systems and varieties of emotion that incorporates all of these details.

Certain forms of fear learning are relatively unique to humans. For example, simply telling a human subject that the CS may be followed by a shock is enough to allow the CS to elicit fear responses. The CS elicits characteristic autonomic responses even though it was never associated with the delivery of the shock. Humans can also be conditioned by allowing them to observe someone else being conditioned—the observer learns to fear the CS even though the CS or US was never directly presented to the observing subject. Some other animals also are able to learn fear through such observational learning, although this seems to be more rare than is the case in humans. One form of learning that is ubiquitous in humans appears to be unique to our species: active pedagogy, whereby another person teaches somebody that a stimulus is dangerous. While learning what to avoid

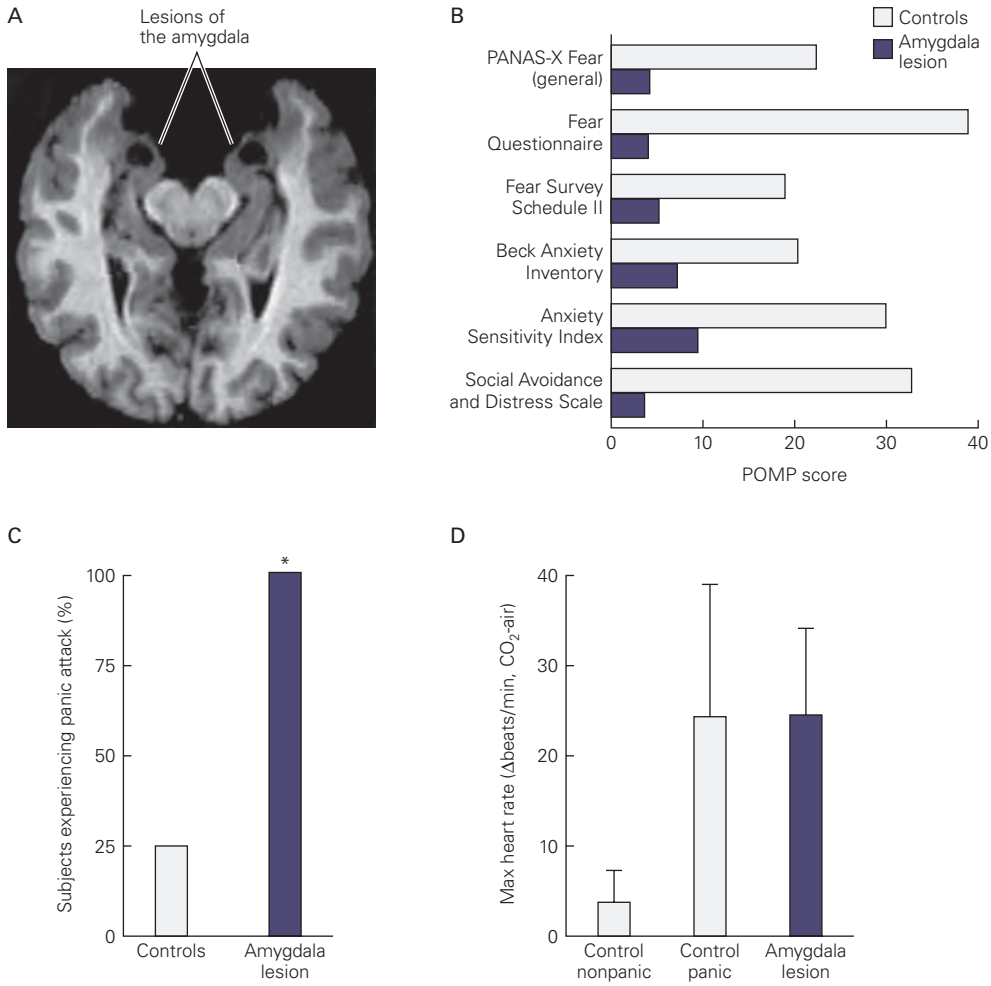

Figure 42–6 In humans, the amygdala is necessary for fear responses to external, but not internal, stimuli.

A. Magnetic resonance imaging scan of a subject's brain with bilateral amygdala lesions. Lesions were relatively restricted to the entire amygdala, a very rare lesion in humans.

B. The subject with bilateral amygdala lesions, S.M., did not report feeling fear for any of the questionnaire-based measures normally used to assess fear and anxiety (percentage of maximum score possible [POMP]). This was consistent with other findings: She did not exhibit fear when watching horror movies, when confronted with large spiders and snakes, or when visiting a haunted house during Halloween. These findings show that the human amygdala is necessary for inducing fear in response to these external stimuli. (Abbreviation: PANAS, Positive and Negative Affect Schedule.)

C. By contrast, a study of S.M. and two other subjects with bilateral amygdala lesions found that they exhibited strong panic when given an internal stimulus. They were asked to inhale carbon dioxide (CO_2), which produces a feeling of suffocation. This caused all three patients with amygdala lesions and 3 out of 12 of the control subjects with intact amygdalae to experience panic attacks.

D. Change from baseline in maximum heart rate during CO_2 inhalation relative to air trials. Both the amygdala lesion patients (n = 2) and the control subjects who panicked (n = 3) had higher increases in heart rate than the control subjects who did not panic (n = 9). (Mean ± standard error of the mean.) (Adapted, with permission from Feinstein et al 2011, 2013.)

and what to approach in the world is a large part of development in the young of all species, active teaching about the significance of stimuli has not been found in any species other than humans so far (learning through passive observation is more common).

The emotional learning and memory capacities of the human amygdala fall into the category of *implicit learning* and memory, which includes forms of memory such as the unconscious recall of perceptual and motor skills (Chapter 53). In situations of danger, however, the hippocampus and other components of the medial temporal lobe system that participate in *explicit learning* and memory (the conscious recall of people, places, and things) will be recruited as well and will encode aspects

of the learning episode. As a result, the learned indicators of danger can also be recalled consciously, at least in humans and probably in some other species as well.

Studies of patients with bilateral damage to the amygdala or hippocampus illustrate the separate contributions of these structures to implicit and explicit memory for emotional events, respectively. Patients with damage to the amygdala show no conditioned skin-conductance responses to a CS (suggesting no implicit emotional learning) but have normal declarative memory of the conditioning experience (indicating intact explicit learning). By contrast, patients with hippocampal damage show normal conditioned skin-conductance responses to the CS (suggesting intact implicit emotional learning) but have no conscious memory of the conditioning experience (indicating impaired explicit learning).

Amygdala function is altered in a number of psychiatric disorders in humans, especially disorders of fear and anxiety (Chapter 61). In addition, the amygdala plays an important role in processing cues related to addictive drugs (Chapter 43). In all of these cases, the amygdala is but one component of a distributed neural network that includes other cortical and subcortical regions. For instance, declarative memory for highly emotional events involves interactions between the amygdala and hippocampus; motivational consequences of Pavlovian conditioning involve interactions between the amygdala and the ventral striatum; and learning that a previously dangerous stimulus is now safe involves interactions between the amygdala and the prefrontal cortex. An important future direction will be to go beyond examining each component in isolation in order to better understand how emotions are processed by complex multicomponent networks of brain regions. This level of analysis is common in studies of human emotion using fMRI (see below).

The Amygdala's Role Extends to Positive Emotions

Although most work on the neural basis of emotion during the past half century has focused on aversive responses, especially fear, other studies have shown that the amygdala is also involved in positive emotions, in particular the processing of rewards. In monkeys and rodents, the amygdala participates in associating neutral stimuli with rewards (appetitive Pavlovian conditioning), just as it participates in associating neutral stimuli with punishments, and there appear to be distinct populations of neurons that encode rewards and punishments in the amygdala. This is broadly similar to findings from the rodent hypothalamus, where neurons involved in defense and in mating are also close together and only modern molecular techniques can test their independent roles.

Studies in nonhuman primates and rodents have investigated a suggestion first made by Larry Weiskrantz that the amygdala represents stimulus reward as well as punishment. For example, in a recent study, monkeys were trained to associate abstract visual images with rewarding or aversive USs. The meaning was then reversed (eg, by pairing an aversive outcome with a visual image that had previously been associated with a reward). In this way, it was possible to distinguish the role of the amygdala in representing visual information from its role in representing the reinforcement (a rewarding or aversive stimulus) predicted by a visual image. Changes in the type of reinforcement associated with an image modulated neural activity in the amygdala, and the modulation occurred rapidly enough to account for behavioral learning.

Subsequent studies using modern molecular and genetic techniques have demonstrated that distinct circuitry within the amygdala mediates a neural representation of rewarding USs, as well as rewarding experiences. The activation of a neural representation of an appetitive US in the amygdala is sufficient to induce innate valenced physiological responses as well as appetitive learning. Moreover, reactivation of neurons activated earlier by an enjoyable experience appears to be sufficient to elicit positive emotions. These findings are consistent with a growing number of functional imaging studies in humans that have shown that the amygdala is involved in emotions quite broadly. For example, the human amygdala is activated when subjects observe pictures of stimuli associated with food, sex, and money or when people make decisions based on the reward value of stimuli.

Emotional Responses Can Be Updated Through Extinction and Regulation

Once conditioned fear has been learned, it can be extinguished by later experiencing that the CS is now safe, for instance, by repeatedly presenting the CS without any US pairing. The circuitry underlying fear extinction has been studied in detail as it is highly relevant to psychiatric illnesses such as post-traumatic stress disorder (PTSD). Projections from the prefrontal cortex to the amygdala are required to override the conditioned fear in the amygdala. While conditioned fear responses decline during extinction, they are never completely erased, as demonstrated by the phenomenon of reinstatement, where fear can suddenly reappear.

Cognitive therapies for changing emotion states have also been studied, primarily in humans. For instance, a focused effort to increase or decrease the intensity of an emotion like fear has some effect on the emotion state. Indeed, neuroimaging studies have found that people can, to some degree, change their amygdala activation to fear-inducing stimuli just by how they think about those stimuli. Emotion regulation is a complex phenomenon, since there are multiple strategies for changing the emotion, ranging from just suppressing the motor behaviors to better control over how we evaluate a situation. These multiple sources of emotion regulation, especially in humans, highlight the fact that emotions must often be adjusted in keeping with complex social norms.

Emotion Can Influence Cognitive Processes

As evidenced in the above examples, emotion interacts with many other aspects of cognition, including memory, decision making, and attention. We discussed above an example of nondeclarative emotional memory, Pavlovian fear conditioning, but emotions can also influence declarative memory. Projections from the amygdala to the hippocampus can influence how learning is encoded and consolidated into long-term declarative memory. This accounts for why we remember best those events in our lives that are the most emotional, such as weddings and funerals.

Emotion has complex effects on decision making, as one might expect, since the subjective evaluation of such variables as risk, effort, and value is modulated by emotion. For instance, different choices with the same objective risk can elicit different behavioral decisions depending on whether they are framed as a win or a loss. For example, subjects typically prefer a sure gain of $5 to a 50% chance of winning $10, but prefer a 50% chance of losing $10 to a sure loss of $5. Interestingly, fMRI studies have revealed that such framing modulates amygdala activation. There is greater amygdala activation in the "win" frame when subjects choose a sure amount over a risky gamble, and greater amygdala activation in the "loss" frame when subjects choose the gamble over the sure amount. Thus, value representations in the amygdala are not rigidly associated with stimuli but are modulated by context-dependent evaluation.

Because emotionally relevant stimuli are highly salient to an organism's self-interest, they typically capture attention. For instance, people tend to orient toward, and look at, emotionally relevant visual stimuli, even when those stimuli are presented under conditions where they cannot be consciously perceived. One intriguing finding is that patients with bilateral amygdala lesions are impaired not only in their experience and expression of fear, as described above, but also in their recognition of fear in other people. One such patient, a woman called S.M., was selectively impaired in recognizing fear from facial expressions. This impairment in turn appears to result from a more basic impairment in allocating visual attention to those regions of the face that normally signal fear. S.M. does not spontaneously fixate on the eye region of the face when she looks at facial expressions and therefore does not process detailed visual information from wide eyes that would normally contribute to the recognition of fear when one is looking at a fearful face (Figure 42–7).

These findings suggest an important role for the amygdala in attention and highlight the possibility that apparently specific deficits for certain emotions (like fear) might arise from more basic attentional or motivational effects. There is ongoing debate about the precise role of the human amygdala in attentional aspects of emotion processing: Some studies argue that it comes into play even for nonconscious threat-related stimuli and in a very automatic fashion; other studies argue that the amygdala requires more elaborated and conscious processing once attention has already been allocated. Single-neuron recordings from the human amygdala support the latter view, whereas some fMRI studies support the former view. All of the findings from human lesion studies will need to be more finely dissected; some recent work on patients who have damage only to specific amygdala subnuclei is yielding further insights.

Many Other Brain Areas Contribute to Emotional Processing

As seen in the case of conditioned and unconditioned fear, the amygdala contributes to emotional processing as part of a larger circuit, or set of circuits, that includes regions of the hypothalamus and brain stem, eg, the periaqueductal gray region in the brain stem. Cortical areas are also important components of this circuit.

A number of human studies have implicated the ventral region of the anterior cingulate cortex, the insular cortex, and the ventromedial prefrontal cortex in various aspects of emotional processing. The medial prefrontal cortex and amygdala are closely connected with one another, and neurons in these brain regions show complex responses that encode information about many emotional and cognitive variables. These findings contribute to an emerging picture of a dynamic neural substrate for emotion states: Individual states are not the outcome of a single structure or specific neurons, but are more

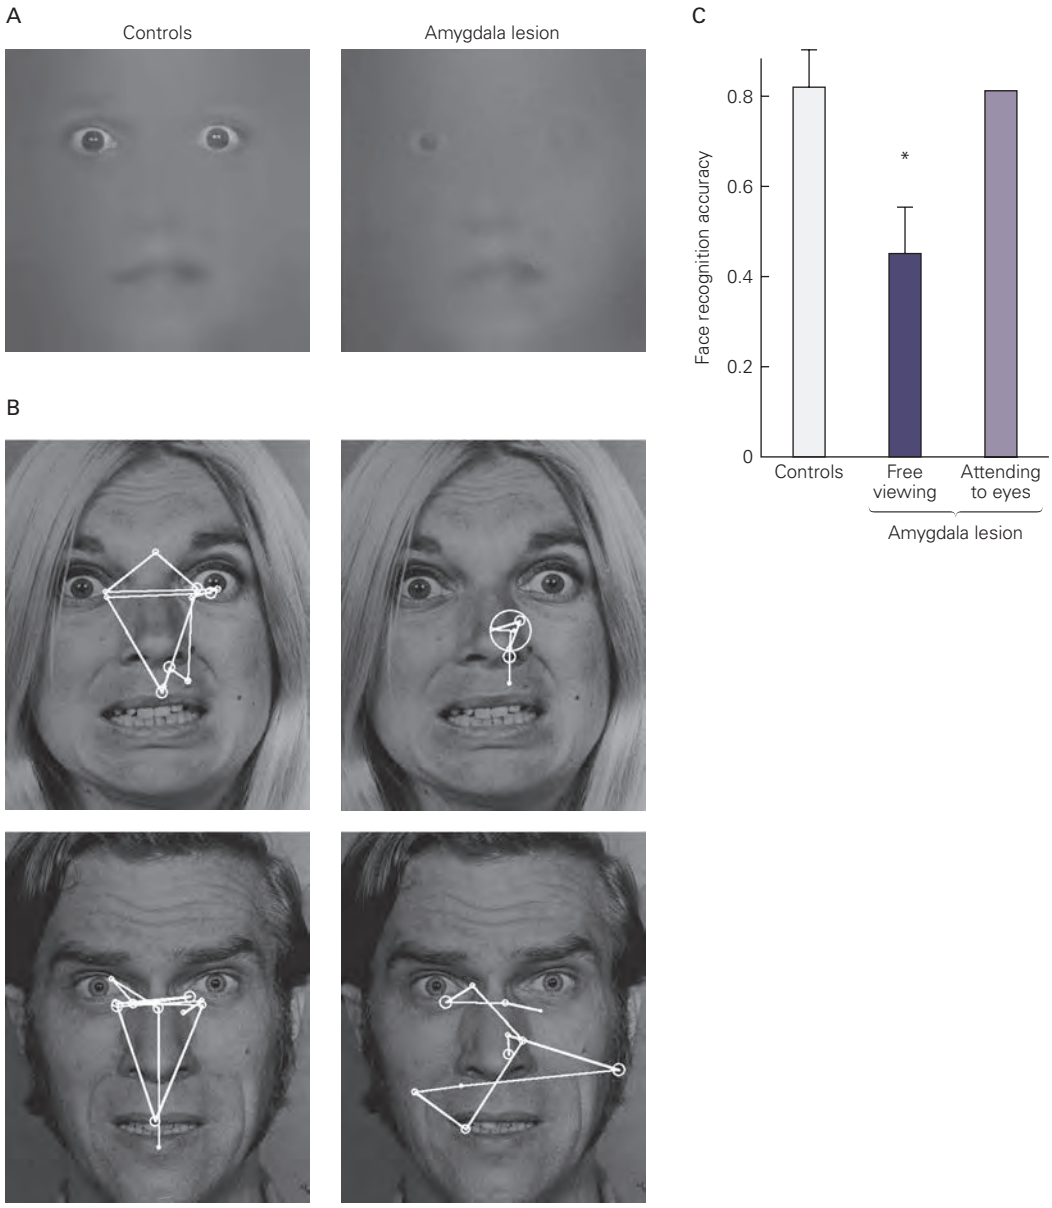

Figure 42–7 **Bilateral amygdala lesions impair the recognition of fear in the facial expressions of others.** This impairment may be due to abnormal processing of information from the face. (Reproduced, with permission, from Adolphs et al. 2005.)

A. S.M. made significantly less use of information from the eye region of faces when judging emotion. These images show the regions of the face from which control subjects (*left*) or S.M. (*right*) were able to recognize fear. The results were obtained by showing subjects many trials with only small parts of the face revealed. All those trials in which subjects were able to recognize fear could then be summed to produce an image like this, which shows the regions of the face that viewers make use of in order to discriminate fearful from happy faces (these particular parts of the face allow viewers to tell apart fearful from happy faces, whereas other parts do not help with this discrimination).

B. While looking at whole faces, S.M. (*right*) exhibited abnormal face gaze (indicated by **white lines**), making far fewer fixations to the eyes than did controls (*left*). This shows that S.M. failed to attend to and hence process visual information from the eye region. This deficit was observed across all emotions, but was most important for fear recognition because wide eyes normally predict fear.

C. S.M. showed poor ability to recognize fear when freely observing whole faces (**free viewing**), but her performance improved remarkably when instructed to look at the eyes (**attending to eyes**). This result shows that the role of the amygdala in processing fearful expressions involves directing attention onto features that are particularly significant (the eyes), rather than the downstream process of interpreting the sensory input.

flexibly assembled over a distributed population of multifunction neurons.

Some emotions are associated with social interaction and range from empathy and pride to embarrassment and guilt. Like the primary emotions such as fear, pleasure, or sadness, these social emotions produce various bodily changes and behaviors and can be experienced consciously as distinct feelings. This class of emotions may depend especially on cortical regions in the prefrontal cortex.

Studies of patients with neurological disease and focal brain lesions have advanced the understanding of the neural circuitry of emotions (Box 42–2). For example, damage to some sectors of the prefrontal cortex markedly impairs social emotions and related feelings. In addition, these patients show marked changes in social behavior that resemble the behavior of patients with developmental sociopathic personalities. Patients with damage to some sectors of the prefrontal cortex are unable to hold jobs, cannot maintain stable social relationships, are prone to violate social conventions, and cannot maintain financial independence. It is common for family ties and friendships to break after the onset of this condition. Recent studies reveal that, under controlled experimental conditions, the moral judgments of these patients can also be flawed.

Patients with medial and ventral frontal lobe damage, unlike patients with more dorsal or lateral frontal lobe damage, do not have motor defects such as limb paralysis or speech defects and thus may appear at first to be neurologically normal. Their perceptual abilities, attention, learning, recall, language, and motor abilities often show no signs of disturbance. Some patients have IQ scores in the superior range.

Box 42–2 Lesion Studies of Emotion

Examination of patients with focal lesions complements neuroimaging studies of the neural correlates of emotions. In addition to studies of the amygdala, lesion studies have provided insights into the role of several other brain regions in processing emotions.

One of the most famous set of studies harks back to the accident of Phineas Gage, who in 1848 suffered an injury to his ventromedial prefrontal cortex. Gage was working on constructing a railway in Vermont and was tamping gunpowder into a hole with a long metal rod, called a tamping iron. By accident, he struck a spark in the rock and the gunpowder exploded, shooting the tamping iron straight through his head.

Amazingly, Gage lived for many years after this horrible accident, but he was a changed person with notable changes in his social and emotional behavior. This was the first evidence that parts of the prefrontal cortex played a role in emotions. Since Gage, several patients with damage centered on the ventromedial prefrontal cortex have been described. These patients have poor insight and decision-making abilities and tend to have blunted or unusual emotional responses, especially for social emotions.

Unlike normal individuals, patients with these frontal lesions do not exhibit changes in heart rate or degree of palm sweating when shown pictures that have emotional content, although they can describe the pictures flawlessly. Likewise, patients with frontal lesions do not show skin conductance changes, a sign of sympathetic activation, during the period that precedes making risky and disadvantageous decisions, suggesting that their emotional memory is not engaged during that critical period. Also unlike normal subjects, these patients fail in tasks in which they have to make a decision under conditions of uncertainty, and in which reward and punishment are important factors.

Several brain regions are also more specifically involved in feelings. Damage to the right somatosensory cortex (primary and secondary somatosensory cortices and insula) impairs social feelings such as empathy. Consistent with this finding, patients with lesions in the right somatosensory cortex fail to guess accurately the feelings behind the facial expressions of other individuals. This ability to read faces is not impaired in patients with comparable lesions of the *left* somatosensory cortex, indicating that the right cerebral hemisphere is dominant in the processing of at least some feelings. Body sensations such as pain and itch remain intact, as do feelings of basic emotions such as fear, joy, and sadness.

On the other hand, damage to the human insular cortex, especially on the left, can suspend addictive behaviors, such as smoking. This suggests that the insular cortices play a role in associating external cues with internal states such as pleasure and desire. Interestingly, complete bilateral damage to the human insular cortices, as caused by herpes simplex encephalitis, does not eliminate emotional feelings or body sensations, suggesting that the somatosensory cortices and subcortical nuclei in the hypothalamus and brain stem are also involved in generating feeling states.

For these reasons, they sometimes attempt to return to their work and social activities after their initial recovery from brain damage. Only when they start to interact with others are their defects noticed.

In the prefrontal cortex, the ventromedial sector is particularly important for such interactions. In most patients with impaired social emotions, this sector is damaged bilaterally, although damage restricted to the right side can be sufficient to cause impairments. The critical region encompasses Brodmann's areas 12, 11, 10, 25, and 32, which receive extensive projections from the dorsolateral and dorsomedial sectors of the prefrontal cortex. Some of these areas project extensively to subcortical areas related to emotions: the amygdala, the hypothalamus, and the periaqueductal gray region in the brain stem.

Interestingly, when asked about punishment, reward, or responsibility, adult patients with damage to the ventromedial prefrontal cortex often respond as if they still have the basic knowledge of the rules, but their actions indicate that they fail to use them in real-life situations. This dissociation suggests that their behavioral defects are not caused by a loss of factual knowledge but rather by impairment of the brain's assignment of motivational value to factors that normally exert control over behavior. In some respects, this dissociation is similar to the dissociation between explicit and implicit emotional learning vis-à-vis the hippocampus and the amygdala. An interesting hypothesis arising from these dissociations is that one might find greater deficits following lesions to emotion-related structures, like the amygdala or ventromedial prefrontal cortex, in other species, or in children, in whom explicit behavioral control has not yet evolved or developed to the degree that it has in adults. There is some support for this idea: Lesions to these structures early in life can result in more severe deficits in emotional and social behaviors than if the lesions are sustained in adulthood (a pattern opposite to that of most other lesions, which show better recovery of function the earlier the onset). These findings also suggest hypotheses for neural dysfunction that may contribute to the emotional difficulties seen in developmental psychiatric disorders, such as autism.

The above lesion studies have been complemented by controlled experimental studies using fMRI, which provide further insight into mechanisms. Functional imaging of value-based decision making in healthy human subjects shows that the ventromedial prefrontal cortex is activated during the period before making a choice. That same region is activated also just by the administration of punishment and reward, supporting the notion that the emotional significance of anticipated punishments and rewards is computed as part of the mechanism that guides this kind of decision making. Punishment and reward are frequently featured in experiments involving economic and moral decisions, and such decision making prominently involves many of the same structures that are also involved in processing emotions.

The prefrontal cortex, especially areas in the ventromedial sector, operates in parallel with the amygdala. During an emotional response, ventromedial areas govern the attention accorded to certain stimuli, influence the content retrieved from memory, and help shape mental plans for responding to the triggering stimulus. By influencing attention, both the amygdala and the ventromedial prefrontal cortex are also likely to alter cognitive processes, for example, by speeding up or slowing down the flow of sensory representations (Chapter 17).

Functional Neuroimaging Is Contributing to Our Understanding of Emotion in Humans

Neuroimaging studies of emotions typically use fMRI. These studies have contributed to our understanding of emotion in three important ways. First, they have begun to dissociate and experimentally manipulate specific aspects of emotion, such as feelings, value, or concepts of emotions. These studies are beginning to show how all these different aspects can be coordinated by activity in different brain regions.

Second, fMRI studies on emotion have been accumulating at an ever-increasing pace, and much of the data from such studies are now widely available. This provides the opportunity for meta-analyses of many studies, avoiding the limitations that may be inherent in any one study in isolation. For instance, some meta-analyses have confirmed the role of the ventromedial prefrontal cortex in representing value for many different kinds of stimuli, including food and money. Other meta-analyses have suggested that specific basic emotions (eg, fear, anger, or happiness) activate a widely distributed and overlapping set of brain regions, confirming the view that no brain structure is responsible for a single emotion.

Finally, fMRI studies have begun to use novel methods in their analyses. For example, the pattern of activation seen across many voxels in a brain region, rather than the mean level of activation in that region, is used to train powerful machine-learning algorithms to classify emotion states. This approach is demonstrating that it is possible to decode specific emotion states from distributed patterns of brain activation.

Functional Imaging Has Identified Neural Correlates of Feelings

Conscious experiences of an emotion are generally referred to as feelings. Evidence for the neural correlates of feelings comes primarily from functional imaging studies of humans and from neuropsychological testing of patients with specific brain lesions. A main challenge for these studies is in dissociating the conscious experience of the emotion from other aspects of the emotion, such as the elicitation of physiological responses, since these tend to occur contemporaneously. Another challenge is how to connect such studies with studies of emotion in animals, where we have no agreed-upon dependent measures to assay what they consciously experience.

One early functional imaging study used positron emission tomography to test the idea that feelings are correlated with activity in those cortical and subcortical somatosensory regions that specifically receive inputs related to the internal environment—the viscera, endocrine glands, and musculoskeletal system. Healthy subjects were asked to recall personal episodes and to attempt to reexperience as closely as possible the emotions that accompanied those events. Activity changed in many regions known to represent and regulate body states, such as the insular cortex, secondary somatosensory cortex (S-II), cingulate cortex, hypothalamus, and upper brain stem. These results support the idea that at least a part of the neural substrate for feelings involves brain regions that regulate and represent bodily states, a finding that bears some resemblance to the hypothesis of William James mentioned earlier, that feelings are based on an awareness of bodily reactions.

The importance of both cortical and subcortical structures in processing feelings is also borne out by more recent fMRI studies. One such study examined the feeling of fear induced by anticipation of electrical shock (Figure 42–8). In this study, subjects lay in the scanner while they saw a game on a video screen in which a virtual predator (a red dot) gets closer to the subject. Once the predator caught them, they could receive a painful electric shock to the hand. The anxiety produced when the predator was some distance away was associated with activation of the medial prefrontal cortex; as the predator closed in, the periaqueductal gray became activated, and this was correlated with reports by the subjects of a feeling of dread. This finding supports a role for the medial prefrontal cortex in planning and anticipation related to a distant threat and a role for the periaqueductal gray in mounting the defensive responses required for coping with an immediate threat.

Another brain region of interest in relation to feelings is the subgenual sector of the anterior cingulate cortex (Brodmann's area 25), which has been found in neuroimaging studies to be activated when subjects are experiencing sadness. This region is of special interest because it is also differentially activated in patients with bipolar depression, and it appears thinned in structural MRI scans of patients with chronic depression. Direct electrical stimulation of this brain region (deep brain stimulation) can dramatically improve the mood of some patients with severe depression.

Emotion Is Related to Homeostasis

While it seems clear that no brain region is specialized for any specific emotion, it is even doubtful that there are any brain regions specialized for emotions in general. It may be that all brain regions involved in emotions also carry out other functions. In fact, those nonemotional functions may give us clues about how emotions evolved and, indeed, may be the basic building blocks through which emotion states are assembled.

For example, sectors of the human insular cortex that are activated during recall of feelings are also activated during the conscious sensation of pain and temperature. The insular cortex receives homeostatic information (about temperature and pain, changes in blood pH, carbon dioxide, and oxygen) through pathways that originate in peripheral nerve fibers. These afferent fibers include, for example, the C and Aδ fibers that form synapses with neurons in lamina I of the posterior horn of the spinal cord or the pars caudalis of the trigeminal nerve nucleus in the brain stem. The pathways from lamina I and the trigeminal nucleus project to brain stem nuclei (nucleus of the solitary tract and parabrachial nucleus) and from there to the thalamus and on to the insular cortex. The identification of this functional system is further support for the idea that signals in the afferent somatosensory pathways play a role in the processing of feelings.

Moreover, in patients with pure autonomic failure, a disease in which visceral afferent information is severely compromised, functional imaging studies reveal a blunting of emotional processes *and* attenuation of activity in the somatosensory areas that contribute to feelings. Like other feelings, social feelings engage the insular cortices and the primary and secondary somatosensory cortices (S-I and S-II), as has been found in functional neuroimaging experiments evaluating empathy for pain and, separately, admiration and compassion.

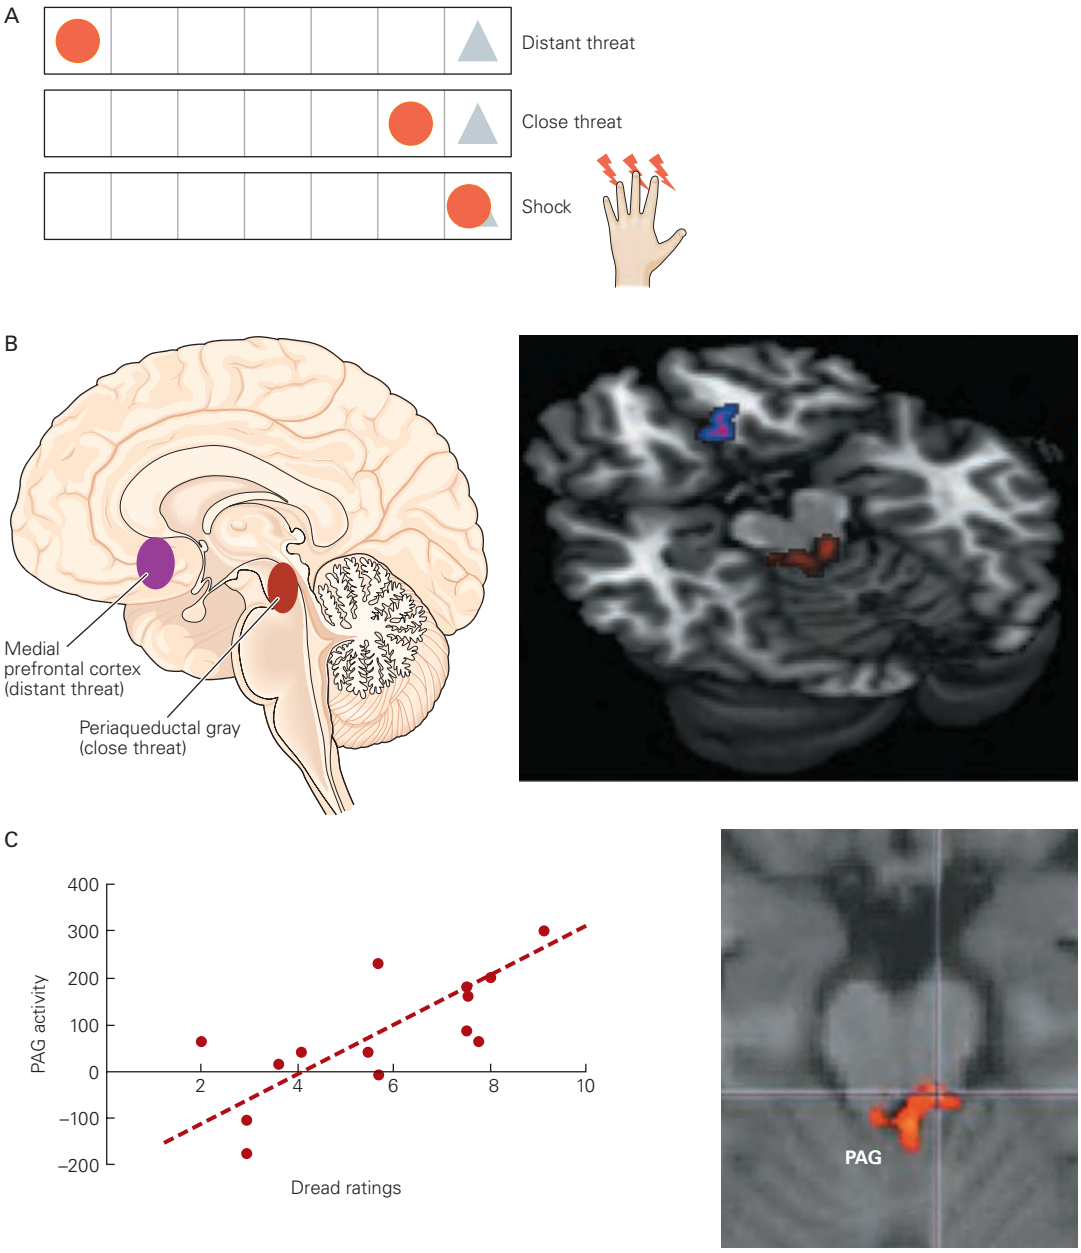

Figure 42–8 Both cortical and subcortical regions come into play during emotion states. Results are from a functional magnetic resonance imaging study in which a subject lies in the scanner while watching a virtual predator (**red dot**) move around on the screen and get closer to a subject (**blue triangle**, representing the actual research participant). (Reproduced, with permission, from Mobbs et al. 2007. Copyright © 2007 AAAS.)

A. Once the predator catches up to the subject, there is a chance that a real and painful electric shock will be delivered to the hand.

B. When the predator gets closer to the subject, activity in the prefrontal cortex and periaqueductal gray matter increases. Notably, this pattern of neural activation shifts such that a distant predator elicits greater activity in the medial prefrontal cortex, whereas a predator close by elicits more activity in the periaqueductal gray.

C. Activation of the periaqueductal gray (**PAG**) is correlated with the subjective sense of dread measured by ratings that subjects gave while in the scanner.

Using these data as support, some influential modern theories build on William James's original hypothesis and propose that the feeling of all emotions is grounded in the brain's representation of bodily homeostasis. As in the case of the amygdala's role in both positive and negative emotions, the insula's role in processing both interoceptive and emotional information is still compatible with the possibility that these processes are distinct. That is, different populations of neurons within these structures may be involved in processing different emotions. Therefore, fMRI may not provide the level of resolution needed to elucidate distinct yet anatomically intermingled neuronal populations, and cellular techniques in animal models may be required.

Although most neuroscience research thus far has focused on negatively valenced emotions, the neural circuitry for positively valenced emotions is being elucidated in studies in both humans and animals. These studies consistently implicate the medial prefrontal cortex in computing the subjective value of rewards, as well as the nucleus accumbens and other nuclei of the basal ganglia in processing the hedonic component (or pleasure) of positive emotions. A growing number of functional imaging studies in humans—especially in the fields of neuroeconomics and social neuroscience—links the role of these structures in emotion processing to their role in value-based decision making and social behavior.

Highlights

1. In the overall physiology of regulating the body and behavior of organisms, emotion states carry out functions intermediate to those of the simpler processes of reflexes and homeostatic regulation, on the one hand, and those of cognitive processes and deliberate behavior on the other. Emotions are more flexible, context-dependent, and controlled than are simple reflexes, but less flexible, context-dependent, and controlled than deliberate behavior. Emotions evolved to produce behavior in response to recurring environmental and internal challenges that are too varied for reflexes, but sufficiently stereotyped that they do not require the full flexibility of cognition.
2. Emotion states need to be carefully distinguished from the conscious experience of emotion (feelings) and also from the concepts and words that we have in everyday language to describe emotions. For example, a hissing cat's behavior is caused by an emotion state, but whether the cat consciously feels afraid is unclear. The cat probably has no concept, and certainly no words, with which to think about the emotion. Human subjects who recognize fear while observing a facial expression are attributing fear to another person and are thinking about a particular emotion, but are not themselves necessarily in a state of fear or experiencing fear. It is a major challenge in designing experiments, especially in humans, to independently control and manipulate these different components of emotion.
3. Emotions coordinate integrated changes in many organismal parameters, including effects on somatic behavior, autonomic and endocrine responses, and cognition. We do not yet understand how this coordination arises, although it is probably achieved through a combination of hierarchical control (through brain regions that function as "command centers" of sorts) and distributed dynamics. Understanding how this is accomplished in biological organisms will also inform how we might engineer robots that exhibit emotional behaviors in the future.
4. Different specific emotions can be thought of categorically (eg, happiness, fear, anger) or dimensionally (in terms of arousal and valence or other dimensional frameworks). It is likely that many of the categories for which we have words in a particular language (like the examples just given) will need to be revised once we have a more scientific understanding. New analytic methods applied to data acquired using fMRI, including methods that take into account the spatial and temporal patterns of brain activity and utilize powerful machine-learning algorithms, may provide new insights into how the brain mediates a broad range of emotions.
5. In humans, emotions can be regulated by several mechanisms. Thus, we have some control over how we feel and some control over how we express emotional behaviors, for instance, through facial expressions. Nonhuman animals do not have this same level of control, and so their emotional behaviors will generally be honest signals of their emotion state, whereas humans often engage in strategic deception.
6. Fear is probably the emotion whose neurobiology is best understood. It depends on the amygdala, in both animals and humans. However, some data suggest that certain types of fear, such as the panic of suffocating induced by inhaling carbon dioxide, are independent of the amygdala. Indeed, we now know that the amygdala is part of a distributed

brain system, and therefore, many other brain regions also participate in processing fear. Increasingly, modern studies use sophisticated genetic and cellular techniques to image and to causally manipulate brain function, allowing us to understand the necessary and sufficient roles of multiple brain structures in mediating different emotional behaviors.

7. The ventral and medial prefrontal cortex is intimately involved in emotion and connected with the amygdala. Social emotions, reward representations, and emotion regulation and extinction all involve specific sectors of prefrontal cortex. This region of the brain, together with the insula, may also be the most important for our conscious experience of emotions, an aspect of emotion that remains the most challenging to study.

Motivation, Reward, and Addictive States

Motivational States Influence Goal-Directed Behavior

One day a cheetah, taking refuge from the mid-day sun in the shade of a tree, views a distant antelope with apparent indifference. Later in the afternoon, the sighting of the antelope provokes immediate orienting and stalking behavior. The stimulus is the same, but the behavioral responses are very different. What has changed is the motivational state of the animal.

Motivational states influence attentiveness, goal selection, investment of effort in the pursuit of goals, and responsiveness to stimuli. They thus drive approach, avoidance, and action selection. This chapter focuses on the neurobiological basis of motivational states related to rewards and the manner in which reward-related brain circuits are implicated in mechanisms underlying drug addiction.

Both Internal and External Stimuli Contribute to Motivational States

Motivational states reflect one's desires, and desires can be influenced by physiological status as well as by stimuli that predict future rewarding and aversive events. Motivational states thus depend on both internal and external variables. Internal variables include physiological signals concerning hunger or thirst, as well as variables related to the circadian clock. For example, the frequency and duration of foraging vary with the time of day, the time since an animal has last eaten, and whether, if female, she is lactating.

Other internal variables are related to cognitive processes. In the game of blackjack, for instance, being dealt the same card in different hands can cause a player to go bust or make 21, leading to very different emotional responses and adjustments in subsequent decision making and action selection. The differential meaning of the same stimulus (a particular card) is made possible by the cognitive understanding of the rules of the game of blackjack. The cognitive understanding of

a rule is an internal variable. Similarly, different social situations often elicit distinct behavioral responses to the same stimulus, such as whether one chugs wine at a college party or sips it at a formal dinner.

External variables also influence motivational states. These variables include *rewarding incentive stimuli.* For example, when a dehydrated cheetah comes across a watering hole during a search for antelopes, the sight of the water may serve as an incentive stimulus, tipping the balance between hunger and thirst and driving the animal to interrupt its quest for food to drink. However, an internal variable—the state of the cheetah's hydration—can also lead to a different reward value being assigned to the same sensory stimulus, the watering hole. Even innately rewarding stimuli, such as a sweet tastant that normally elicits pleasure, can in some circumstances become unpleasurable. Chocolate cake may be innately rewarding to chocolate lovers, but satiation to the chocolate—which involves modulation of an internal variable—can decrease the reward value of this stimulus and thereby affect motivational state.

Rewards Can Meet Both Regulatory and Nonregulatory Needs on Short and Long Timescales

Feeding, drinking, and thermoregulatory behaviors and their underlying motivational states typically arise in response to (or anticipation of) a physiological imbalance. In these cases, actions acquire rewards in a relatively short timescale. In contrast, some motivational states serve biological imperatives other than short-term physiological homeostasis. More complex long-term goals, such as finding and sustaining a love partner or achieving an educational or professional goal, require goal-oriented actions on longer timescales. Nonregulatory motivational states may resemble those arising from physiological signals, but motivated behaviors often involve sequences of actions in which not every action is immediately rewarded (except in the sense of making progress toward a longer-term goal).

In general, incentive stimuli, even stimuli that only signal progress toward a longer-term goal, can influence motivational states so that complex behavioral sequences are completed. A simple example of this concept is when a cheetah must stalk, chase, run down, and kill an antelope, and then drag the carcass to a refuge before beginning to feed. Of course, even the complexity of the actions involved in foraging and feeding is far simpler than the steps required of a student motivated to achieve a graduate degree and develop an academic career. Motivational states must be sustained across challenging circumstances in order to achieve such goals.

The Brain's Reward Circuitry Provides a Biological Substrate for Goal Selection

Rewards are objects, stimuli, or activities that have positive value. Rewards can incite an animal to switch from one behavior to another or to resist interruption of ongoing action. For example, a rat that encounters a seed while scouting the environment may cease exploring in order to eat the seed or carry it to a safer place; while nibbling the seed, the rat will resist the efforts of another rat to steal the food from its paws. If seeds are made available only at a particular location and time, the rat will go to that location as the expected moment of reward delivery approaches.

Much contemporary work in neuroscience is directed at elucidating the neural systems that process different types of rewards. These systems must link the initial sensory representation of a reward to different behaviors that respond to physiological needs and environmental challenges and opportunities. Pathologies such as addiction can highjack these reward systems, resulting in maladaptive behavior (discussed in the latter part of this chapter).

Goal-directed behaviors entail the assessment of risks, costs, and benefits. Straying from the herd may offer an antelope better opportunities for foraging but only at the risk of becoming an easier target for a lurking cheetah. Attacking the venturesome antelope offers the cheetah an easier promise of a meal but at the risk that energetic and hydromineral resources will be depleted needlessly if the antelope gets away. Thus, the neural mechanisms responsible for goal selection must weigh the costs and benefits of different behaviors that might attain a specific goal.

In 1954, James Olds and Peter Milner reported their work on the neural pathways responsible for reward-related behaviors. These classic studies employed electrical brain stimulation as a goal. Rats and other vertebrates ranging from goldfish to humans will work for electrical stimulation of certain brain regions. The avidity and persistence of this self-stimulation are remarkable. Rats will cross electrified grids, run uphill while leaping over hurdles, or press a lever for hours on end in order to trigger the electrical stimulation. The phenomenon that leads the animal to work for self-stimulation is called *brain stimulation reward* (Figure 43–1A). Brain stimulation, therefore, elicits a motivational state, a strong drive to perform an action (eg, lever pressing) that will deliver further stimulation.

Although brain stimulation reward is an artificial goal, it mimics some of the properties of natural goal objects. For example, brain stimulation can compete with, summate with, or substitute for other reward-predictive stimuli to induce motivational states that

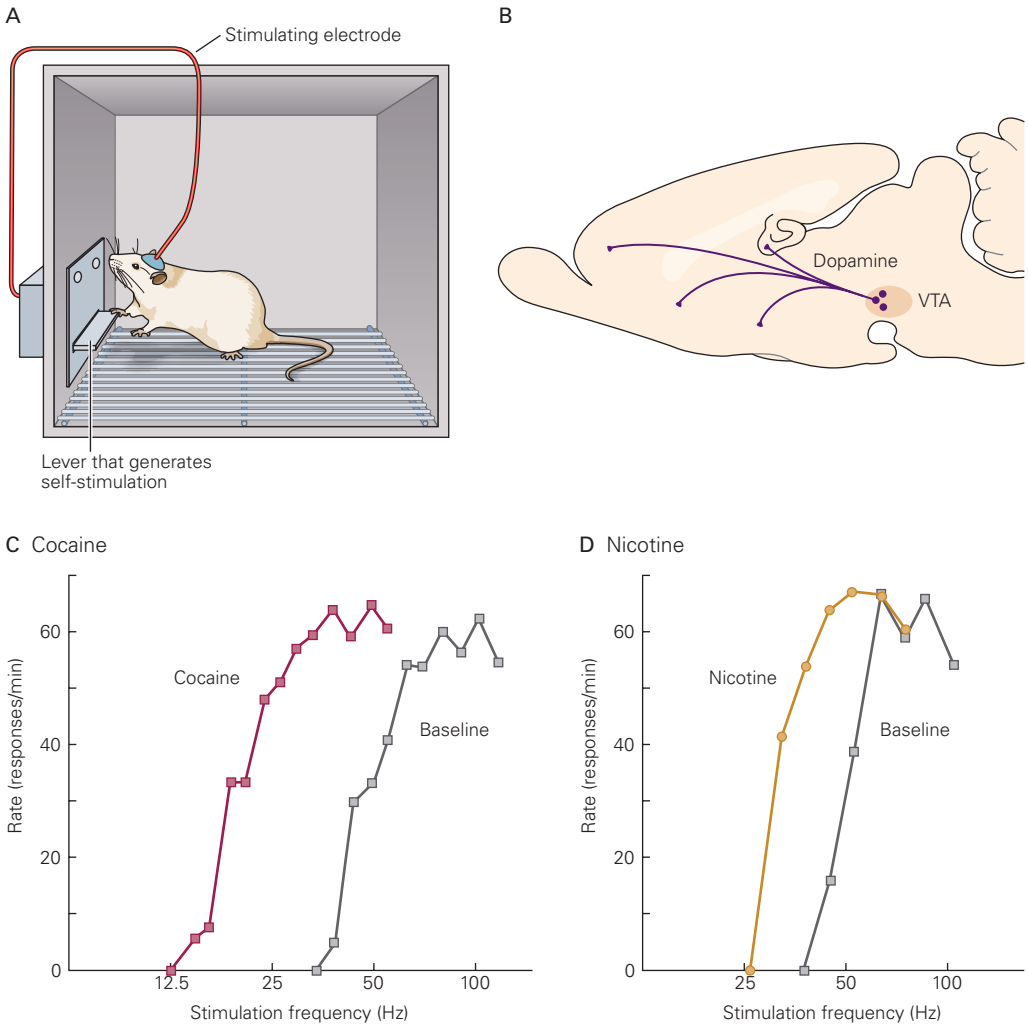

Figure 43–1 Intracranial self-stimulation recruits reward circuitry and dopaminergic neural pathways.

A. Classic testing apparatus for self-stimulation experiments. In this example, an electrode is implanted in a brain region of a rodent. Lever pressing by the rodent triggers electrical stimulation of that brain area.

B. Brain structures that produce self-stimulation behavior typically activate dopaminergic pathways emanating from the ventral tegmental area (VTA), among other pathways.

C–D. Cocaine and nicotine affect the rate of electrical self-stimulation. The rate at which the animal presses the stimulation lever increases with increases in the frequency of the self-stimulation current. In the presence of the drugs, animals press the lever at lower stimulation frequencies, indicating that the drugs augment the effects of the electrical stimulation.

drive goal-directed behaviors. The circuitry that mediates brain stimulation reward is broadly distributed. Rewarding effects can be produced by electrical stimulation of sites at all levels of the brain, from the olfactory bulb to the nucleus of the solitary tract.

Particularly effective sites lie along the course of the medial forebrain bundle and along longitudinally oriented fiber bundles coursing near the midline of the brain stem. Stimulation of either of these pathways results in activation of dopaminergic neurons in the ventral tegmental area of the midbrain. These neurons project to several areas of the brain, including the nucleus accumbens (the major component of the ventral striatum), the ventromedial portion of the head of the caudate nucleus (in the dorsal striatum), the basal forebrain, and regions of the prefrontal cortex (Figure 43–1B).

Activation of dopaminergic neurons in the ventral tegmental area plays a crucial role in brain stimulation reward. The effects of this activation are strengthened

by increases in dopaminergic synaptic transmission and weakened by decreases. These dopaminergic neurons are excited by glutamatergic cells in the prefrontal cortex and amygdala as well as from cholinergic cells in the laterodorsal tegmental and pedunculopontine nuclei of the hindbrain, and are inhibited by local GABAergic cells within or just caudal to the ventral tegmental area. Brain stimulation is thought to activate dopaminergic neurons in the ventral tegmental area in part through the activation of these hindbrain cholinergic neurons. Blockade of this cholinergic input reduces the rewarding effects of the electrical stimulation. While most attention has focused on dopamine pathways in mediating brain stimulation reward, it is important to emphasize the involvement of non-dopaminergic pathways as well.

The strength of brain stimulation reward is indicated by the finding that starving rats provided with brief daily access to food will forego eating to press a lever for brain stimulation. The heedless pursuit of an artificial goal to the detriment of a biological need is one of many parallels between self-stimulation and drug abuse. Indeed, drugs of abuse augment the rewarding effects of activation of dopaminergic pathways with brain stimulation (Figure 43–1C,D). Lower frequencies of stimulating currents accompanied by cocaine or nicotine administration—both of which enhance dopaminergic neurotransmission through different mechanisms—produce a rate of lever pressing equivalent to that obtained during self-stimulation at higher stimulating currents in the absence of these drugs. These results indicate that cocaine and nicotine amplify the effects of neuronal activation elicited by microstimulation.

Dopamine May Act as a Learning Signal

An earlier view of the function of dopamine was that it conveyed "hedonic signals" in the brain and that, in humans, it was directly responsible for subjective pleasure. From this point of view, addiction would reflect the habitual choice of short-term pleasure despite a host of long-term life problems that emerge. In fact, however, new research indicates that the hedonic principle cannot easily explain the persistence of drug use by addicted persons as negative consequences mount.

The effects of dopamine have proven to be far more complex than was first thought. Dopamine can be released by aversive as well as by rewarding stimuli, and the short latency component of a dopamine neuron's response may not be related to the rewarding or aversive qualities of a stimulus at all. Moreover, rodents lacking dopamine—rats in which dopamine is depleted by 6-hydroxydopamine and mice genetically engineered so that they cannot produce dopamine—continue to exhibit hedonic responses to sucrose. Dopamine delivery itself is not currently considered to produce hedonic qualities. Instead, the degree to which a particular sensory stimulus is rewarding is thought to be processed by a broad network of brain areas, spanning sensory cortices of different modalities, association cortex, prefrontal cortex (in particular, orbitofrontal regions), and many subcortical areas such as the amygdala, hippocampus, nucleus accumbens, and ventral pallidum.

Many of the brain areas whose activity is modulated by reward anticipation or receipt receive dopaminergic input. What information do dopaminergic neurons transmit to these brain areas? Wolfram Schultz and his colleagues discovered that dopaminergic neurons often have a complex and changing pattern of responses to rewards during learning. In one experiment, Schultz trained monkeys to expect juice at a fixed interval after a visual or auditory cue. Before the monkeys learned the predictive cues, the appearance of the juice was unexpected and produced a transient increase in firing above basal levels by ventral tegmental area dopaminergic neurons. As the monkeys learned that certain cues predict the juice, the timing of the firing changed. The neurons no longer fired in response to presentation of the juice—the reward—but earlier, in response to a predictive visual or auditory cue. If a cue was presented but the reward was withheld, firing paused at the time the reward would have been presented. In contrast, if a reward exceeded expectation or was unexpected, because it appeared without a prior cue, firing was enhanced (Figure 43–2).

These observations suggest that dopamine release in the forebrain serves not as a pleasure signal but as a *prediction error* signal. A burst of dopamine would signify a reward or reward-related stimulus that had not been predicted; pauses would signify that the predicted reward is less than expected or absent. If a reward is just as expected based on environmental cues, dopaminergic neurons would maintain their tonic (baseline) firing rates. Alterations in dopamine release are thus thought to modify future responses to stimuli to maximize the likelihood of obtaining rewards and to minimize fruitless pursuits. For natural rewards, like the sweet juice consumed by the monkeys in Schultz's experiments, once the environmental cues for a reward are learned, dopaminergic neuron firing returns toward baseline levels. Schultz has interpreted this to mean that as long as nothing changes in the environment, there is nothing more to learn and therefore no need to alter behavioral responses.

Experiments using functional magnetic resonance imaging in humans have provided further evidence

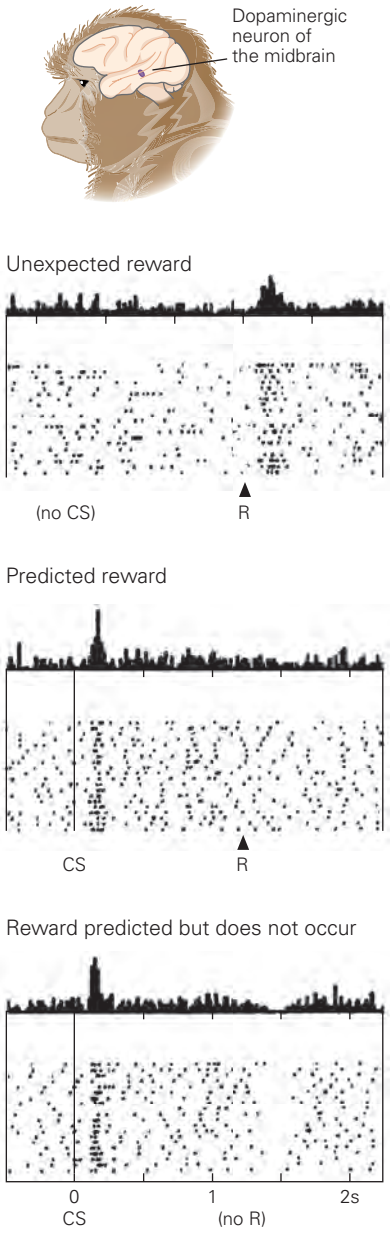

Figure 43–2 Dopaminergic neurons report an error in reward prediction. Graphs show firing rates recorded from midbrain dopaminergic neurons in awake, active monkeys. **Top:** A drop of sweet liquid is delivered without warning to a monkey. The unexpected reward (**R**) elicits a response in the neurons. The reward can thus be construed as a positive error in reward prediction. **Middle:** The monkey has been trained that a conditioned stimulus (**CS**) predicts a reward. In this record, the reward occurs according to the prediction and does not elicit a response in the neurons because there is no error in the prediction of reward. The neurons are activated by the first appearance of a predicting stimulus but not by the reward. **Bottom:** A conditioned stimulus predicts a reward that fails to occur. The dopaminergic neurons show a decrease in firing at the time the reward would have occurred. (Reproduced, with permission, from Schultz, Dayan, and Montague 1997. Copyright © 1997 AAAS.)

that dopaminergic agonists and antagonists modulate reward learning and the blood oxygen level–dependent (BOLD) signal in the nucleus accumbens. However, in some experiments, mice that lack a dopamine synthesis gene can still learn where to find a sugar or cocaine reward, suggesting that dopamine is not required for all forms of reward learning. In addition, rodents who receive amphetamines to elevate presynaptic dopamine levels over a more extended time interval exhibit enhanced "wanting" behavior (ie, increased responding in the presence of a Pavlovian cue predicting sucrose reward).

These considerations have led some investigators to suggest that dopamine has a broader role than simply driving reinforcement learning by providing prediction-error signals. Indeed, several recent studies have demonstrated considerable variation in the response properties of different subpopulations of midbrain dopaminergic neurons. Some neurons are activated by both rewarding and aversive stimuli, while others are activated preferentially by one of the two types of stimuli, and still others show opposite responses (activated by rewards and suppressed by aversive stimuli). There is some evidence that these neuronal differences are related to differences in afferent inputs and efferent projections between subpopulations of dopaminergic neurons. Understanding the precise role of this complex mixture of dopamine signals—in learning, in driving goal-directed behavior, and especially in more complex forms of learning that involve longer timescales of sequences of actions to acquire distant rewards—remains an active area of investigation.

Unlike natural rewards, addictive drugs cause dopamine release in the reward circuitry no matter how often they are consumed, and the magnitude of this release is often greater than that seen with natural rewards—dopamine is released even when the drug no longer produces subjective pleasure. To the brain, consumption of addictive drugs might always signal "better than expected" and in this way would continue to influence behavior to maximize drug seeking and drug taking. If this idea is correct, it might explain why drug seeking and consumption become compulsive and why the life of the addicted person becomes focused increasingly on drug taking at the expense of all other pursuits.

Drug Addiction Is a Pathological Reward State

Drug addiction is a chronic and sometimes fatal syndrome characterized by compulsive drug seeking and consumption despite serious negative consequences such as medical illness and inability to function in the

family, workplace, or society. Many drug addicts are aware of the destructive nature of their addiction but are unable to alter their addictive behavior despite numerous attempts at treatment.

An interesting feature of drug addiction is that only a minute fraction of all chemical substances can cause the syndrome. These so-called drugs of abuse do not share a common chemical structure, and they produce their effects by binding to different protein targets in the brain. Rather, these diverse substances can each cause a similar behavioral syndrome of addiction because their actions converge on the brain circuits that control reward and motivation (Figure 43–3).

Advances in understanding these actions have come about in large part based on studies of laboratory animals that self-administer the same drugs that cause addiction in humans. In fact, when animals are given free and unlimited access to these drugs, a subset will lose control over drug consumption—which becomes increasingly involuntary—at the expense of eating and sleeping, and some will even die by overdose. Drug self-administration and other animal models of addiction (Box 43–1) have made it possible to study both the neural circuitry through which drugs of abuse act to produce their initial rewarding effects and the molecular and cellular adaptations that drugs induce in this circuitry after repeated exposures cause an addiction-like syndrome. Over the past decade, these studies in animals, together with brain imaging studies in human addicts, have provided an increasingly complete view of the addiction process.

All Drugs of Abuse Target Neurotransmitter Receptors, Transporters, or Ion Channels

A great deal is known about the initial interactions of addictive drugs with the nervous system. Virtually all of the proteins with which such drugs interact have been cloned and characterized (Table 43–1).

Each class of drug of abuse produces a different range of acute behavioral effects, consistent with the fact that each class acts on different targets and that these targets have distinct patterns of expression throughout the nervous system and peripheral tissues. Cocaine and other psychostimulants are activating and can cause cardiac side effects because their targets

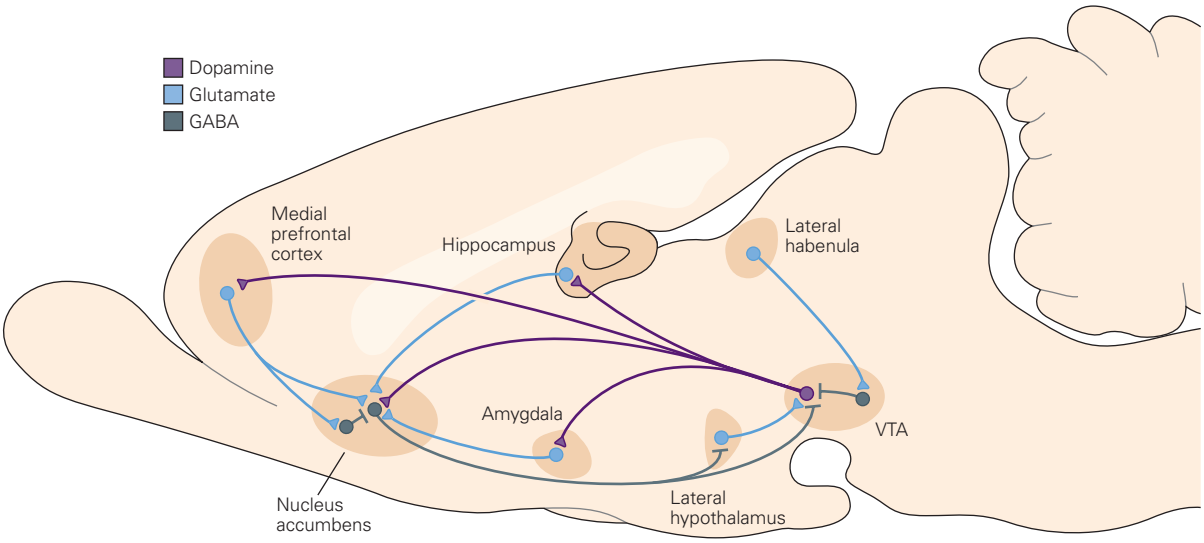

Figure 43–3 Brain reward circuits. A schematic drawing of the major dopaminergic, glutamatergic, and γ-aminobutyric acid (GABA)-ergic connections to and from the ventral tegmental area (VTA) and nucleus accumbens (NAc) in the rodent brain. The primary reward circuit includes dopaminergic projections from the VTA to the NAc. The VTA projections release dopamine in response to reward-related stimuli (and in some cases aversion-related stimuli). There are also GABAergic projections from the NAc to the VTA, with some in a direct pathway innervating the VTA and some in an indirect pathway innervating the VTA via intervening GABAergic neurons in the ventral pallidum (not shown). The NAc also contains numerous types of interneurons. The NAc receives dense innervation from glutamatergic monosynaptic circuits from the medial prefrontal cortex, hippocampus, lateral habenula, and amygdala, among other regions. The VTA receives such inputs from the amygdala and prefrontal cortex and from several brain stem nuclei that use the transmitter acetylcholine (not shown). It also receives the peptidergic terminals of neurons in the lateral hypothalamus as well as other inputs. These various inputs control aspects of reward-related perception and memory. (Adapted from Russo and Nestler 2013.)

Box 43–1 Animal Models of Drug Addiction

Several animal models have played an important role in understanding how addictive drugs produce reward acutely and an addiction-like syndrome after repeated exposures.

Drug Self-administration

The reinforcing effects of a drug can be demonstrated in experiments in which animals perform a task (eg, press a lever) to receive an intravenous drug injection. In addition to studying acquisition of this behavior, scientists assess how hard an animal will work to deliver the drug by use of progressive ratio procedures, where each successive drug dose requires an increasing number of lever presses.

Animals reach a so-called break point when they stop self-administering the drug. After weeks or months of withdrawal from or extinction of drug self-administration, animals display a relapse-like behavior: They will press the stimulation lever, which no longer delivers the drug, in response to a test dose of the drug, cues associated previously with the drug (a light or tone), or stress. These various self-administration behaviors are considered the best-validated models of human addiction.

Conditioned Place Preference

Animals learn to associate a particular environment with passive exposure to drugs. For example, a rodent will spend more time on the side of a box where it was given cocaine than on the side where it received saline. This paradigm offers an indirect measure of potency of a drug reward and demonstrates the strong cue-conditioned effects of addictive drugs.

Locomotor Sensitization

All drugs of abuse stimulate locomotion in rodents upon initial drug exposure, with increasing locomotor activation seen after repeated drug doses. Since the neural circuitry that mediates locomotor responses to drugs of abuse partly overlaps with the circuitry that mediates reward and addiction, locomotor sensitization provides a model with which to study plasticity in this circuitry during a course of chronic drug exposure.

Intracranial Self-Stimulation

Animals will work (eg, press a lever) to deliver electrical current into parts of the brain's reward circuitry (see Figure 43–1). Drugs of abuse reduce the stimulation threshold for such self-stimulation, meaning that in the presence of drug animals will work for stimulation frequencies that have no effect under control conditions.

(monoamine transporters) are expressed in peripheral nerves that innervate the heart. In contrast, opiates are sedatives and potent analgesics because their targets (opioid receptors) are expressed in sleep and pain centers.

Nevertheless, all drugs of abuse acutely induce reward and reinforcement, and this shared action reflects the fact that the drugs, despite their very different initial targets, induce some common functional effects on the brain's reward circuitry (Figure 43–4). The best established of these shared initial effects is increased dopaminergic neurotransmission in the nucleus accumbens, albeit via different mechanisms. For example, cocaine produces this effect by blocking dopamine reuptake transporters located on the terminals of the ventral tegmental neurons, whereas opiates activate ventral tegmental area dopamine neuron cell bodies by inhibiting nearby GABAergic interneurons.

Opiates also produce reward through dopamine-independent actions (eg, by activating opioid receptors on nucleus accumbens neurons themselves). All other drugs of abuse act through a combination of dopamine-dependent and -independent mechanisms (eg, activation of endogenous opioid and cannabinoid signaling) to produce some of the same functional effects on nucleus accumbens neurons. Importantly, by increasing dopaminergic neurotransmission, all such drugs also produce some of the same functional effects mediated by activation of dopamine receptors on the many other projection targets of ventral tegmental dopamine neurons (Figure 43–3), actions that are also instrumental in reward and in initiating some of the deleterious actions of repeated drug exposure.

Repeated Exposure to a Drug of Abuse Induces Lasting Behavioral Adaptations

The acute rewarding actions of drugs of abuse do not account for addiction. Rather, addiction is mediated by the brain's adaptations to the repeated exposure to such acute actions. Two main questions in the field

Table 43–1 Major Classes of Addictive Drugs

Class	Source	Molecular target	Examples
Opiates	Opium poppy	μ opioid receptor (agonist)[1]	Morphine, methadone, oxycodone, heroin, many others
Psychomotor stimulants	Coca leaf Synthetic[2] Synthetic	Dopamine transporter (antagonist)[3]	Cocaine Amphetamines Methamphetamine
Cannabinoids	Cannabis	CB1 cannabinoid receptors (agonist)	Marijuana
Nicotine	Tobacco	Nicotinic acetylcholine receptor (agonist)	Tobacco
Ethyl alcohol	Fermentation	$GABA_A$ receptor (agonist), NMDA-type glutamate receptor (antagonist), and multiple other targets	Various beverages
Phencyclidine-like drugs	Synthetic	NMDA-type glutamate receptor (antagonist)	Phencyclidine (PCP, angel dust)
Sedative/hypnotics	Synthetic	$GABA_A$ receptor (positive allosteric modulator)	Barbiturates, benzodiazepines
Inhalants	Varied	Unknown	Glues, gasoline, nitrous oxide, others

[1]The signaling pathways induced by μ receptor activation differ between opiates, differences that might be related to different addiction liabilities. Additionally, most opiates activate the δ opioid receptor, although the action at μ receptors is most important for reward and addiction.
[2]The original synthesis of amphetamine was based on the natural plant product ephedrine.
[3]While cocaine is an antagonist of the transporter, amphetamine and methamphetamine act differently: They are substrates for the transporter and, once in the nerve terminal cytoplasm, act to stimulate dopamine release.
GABA, γ-aminobutyric acid; **NMDA**, *N*-methyl-D-aspartate.
Note: Caffeine can produce mild physical dependence but does not result in compulsive use. Some illegal drugs that are abused can be harmful but do not generally produce addiction; these include the hallucinogens lysergic acid diethylamide (LSD), mescaline, psilocybin, and 3,4-methylenedioxymethamphetamine (MDMA), popularly known as ecstasy.

remain: What specific adaptations mediate the behavioral syndrome of addiction, and why are some individuals more likely to become addicted?

We know—in both animals and humans—that roughly 50% of the risk for addiction across all drugs of abuse is genetic, but the specific genes that confer risk remain largely unknown. As for most other common chronic conditions, the genetic risk for addiction is highly complex, reflecting the combined actions of hundreds of genetic variations, each of which has a very small effect. The other 50% of the risk, while incompletely understood, involves a host of environmental factors including early life stress, stress throughout life, and peer pressure.

Historically, the adaptations induced by repeated drug exposure have been described by a series of pharmacological terms. *Tolerance* refers to the diminishing effect of a drug after repeated administration at the same dose or to the need for an increase in dose to produce the same effect. *Sensitization*, also known as reverse tolerance, occurs when repeated administration of the same drug dose elicits escalating effects. *Dependence* is defined as an adaptive state that develops in response to repeated drug administration and is unmasked during *withdrawal*, which occurs when drug taking stops. The symptoms of withdrawal vary from drug to drug and include effects opposite to a drug's acute actions. Tolerance, sensitization, and dependence/withdrawal are seen with many drugs that are not addicting. For instance, two drugs used to treat hypertension, the β-adrenergic antagonist propranolol and the α_2-adrenergic agonist clonidine, produce strong dependence as evidenced by severe hypertension upon their sudden withdrawal.

Drugs of abuse are unique in causing tolerance, sensitization, and dependence/withdrawal in reward- and motivation-related behaviors, and these behaviors contribute to the syndrome of addiction. Reward tolerance, which can be viewed as homeostatic suppression of endogenous reward mechanisms in response to repeated drug exposure, is one factor leading to escalating patterns of drug use. Motivational dependence, which is manifested as negative emotional (eg, depression- and anxiety-like) symptoms seen during early drug withdrawal and also mediated by

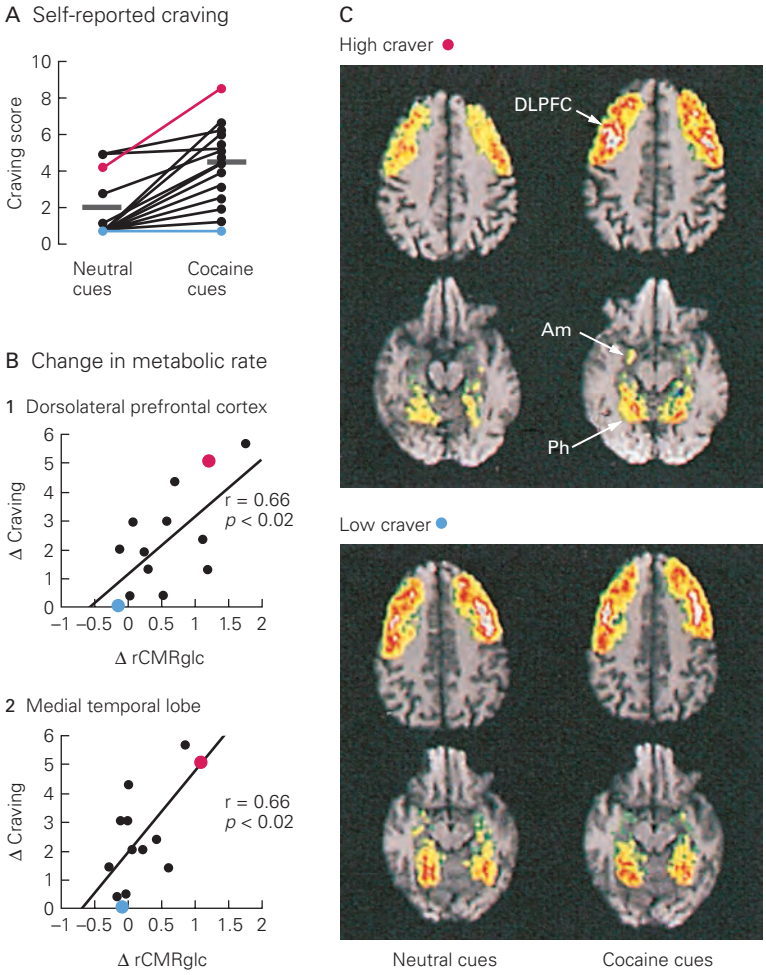

Figure 43–4 Positron emission tomography (PET) imaging reveals neural correlates of cue-induced cocaine craving. (Adapted, with permission, from Grant et al. 1996.)

A. Subjects were shown neutral or cocaine-related cues and asked, "How do you rate your craving or urge for cocaine on a scale of 1–10?" The mean craving score (**horizontal bar**) is significantly higher for exposure to cocaine-related cues than for exposure to neutral stimuli, even though the magnitude of the response across individuals varies considerably. Two subjects, identified by **red** and **blue dots**, represent high-level and low-level craving, respectively.

B. Changes in self-reported craving are correlated with changes in metabolic rate in the dorsolateral prefrontal cortex and medial temporal lobe during exposure to cocaine-related cues. The abscissa plots the difference in metabolic rate between the two sessions (activity with cocaine cues minus activity with neutral cues). Metabolic rate is measured as the regional cerebral metabolic rate for glucose (**rCMRglc**). The ordinate plots the difference between the average of the responses to the question, "Do you have a craving or urge for cocaine?" in separate sessions with neutral and cocaine-related cues. (Each session lasted 30 minutes, and in each session, the question was asked three times.)

C. When subjects report a craving for cocaine, metabolic activity increases in the dorsolateral prefrontal cortex (**DLPFC**) and in two medial temporal lobe structures, the amygdala (**Am**) and parahippocampal gyrus (**Ph**). Pseudocolored PET images of metabolic activity are spatially aligned with high-resolution structural magnetic resonance images. Metabolic rate markedly increased in the amygdala and parahippocampal gyrus in one subject who reported a large increase in craving during presentation of cocaine-related cues (**red dots** in parts **A** and **B**). This effect is not evident in a subject who reported no increase in craving while exposed to the cocaine-related cues (**blue dots** in parts **A** and **B**). Metabolic activity outside the dorsolateral prefrontal cortex and medial temporal lobe is not shown.

suppressed endogenous reward mechanisms, is a leading factor in driving the return to drug use, or *relapse*. Reward sensitization, which typically occurs after longer withdrawal periods, can trigger relapse in response to exposure to the drug itself or to drug-associated cues (eg, being with people or in a place where drug was previously used).

Interestingly, a given drug can produce all of these adaptations—tolerance, sensitization, and dependence—simultaneously, due to different acute effects of the drug; this phenomenon emphasizes the involvement of multiple cell types and circuits in mediating a drug's global actions. The key challenge for neuroscientists is to identify the changes in specific types of neurons and glia—and in their consequent contributions to circuit function—that are induced by repeated drug exposure and that mediate the behavioral features that define a state of addiction.

Lasting Molecular Adaptations Are Induced in Brain Reward Regions by Repeated Drug Exposure

An extensive literature shows that repeated exposure to a drug of abuse in animal models alters the levels of many neurotransmitters and neurotrophic factors, their receptors and intracellular signaling pathways, and transcriptional regulatory proteins throughout the brain's reward circuitry. Most of these changes cannot be studied in living patients—only a small number of neurotransmitters and receptors can be assessed in patients with brain imaging—although studies of postmortem human brain tissue are being used increasingly to validate findings from animal models. Most of the reported research has focused on the ventral tegmental area and nucleus accumbens, although an increasing number of studies are examining other parts of the reward circuitry.

The most robust experimental findings are available for psychostimulants and opiates, probably because the changes induced by these drugs are larger in magnitude than those of other drugs of abuse. This likely reflects the greater inherent addictiveness of psychostimulants and opiates: With equivalent exposures, a larger fraction of people will become addicted to these drugs as compared with other classes of abused substances. Nevertheless, given the dominant public health consequences of alcohol, nicotine, and marijuana addictions, more attention should be given to these drugs.

Below, we summarize this large literature by focusing on a small number of drug-induced adaptations that have been linked causally to specific behavioral features of addiction in animal models. As will be clear in the next section, the present research focus is on relating these and many other molecular changes to synaptic and circuit adaptations also implicated in addiction.

Upregulation of the cAMP-CREB Pathway

Several drugs of abuse activate G_i protein–linked receptors, such as the D_2 dopamine receptor; the μ, δ, and κ opioid receptors; and the CB1 cannabinoid receptor. This means that, to a certain extent, many drugs of abuse will activate G_i protein–linked signaling pathways, with effects such as inhibition of adenylyl cyclase (Chapter 14), in the nucleus accumbens and other target neurons.

Work over the past two decades has established that, after repeated exposure, the affected neurons adapt to this sustained suppression of the cyclic adenosine monophosphate (cAMP) pathway by upregulating it, including induction of certain isoforms of adenylyl cyclase and protein kinase A. Repeated drug exposure likewise induces upregulation of the transcription factor CREB, which is normally activated by the cAMP pathway. Such upregulation of the cAMP-CREB pathway can be seen as a molecular mechanism of tolerance and dependence: It restores normal activity of these pathways despite the presence of a drug (tolerance and dependence), and when the drug is removed, the upregulated pathway is unopposed, causing abnormally high activity of the pathway (withdrawal) (Figure 43–5). Indeed, upregulation of the cAMP-CREB pathway in nucleus accumbens neurons has been shown to mediate both reward tolerance and motivational dependence and withdrawal in animal models.

Induction of ΔFosB

ΔFosB is a member of the Fos family of transcription factors. It is a truncated product of the *FosB* gene generated through alternative splicing. In contrast to all other members of the Fos family, which are induced rapidly and transiently in response to many perturbations in neural activity or cell signaling, ΔFosB is induced only slightly by initial presentation of stimuli. However, with repeated drug exposure, ΔFosB accumulates in neurons because of its unusual stability, unique among all Fos family proteins.

This phenomenon occurs within neurons of the nucleus accumbens and several other brain reward areas after repeated exposure to virtually any drug of abuse, including cocaine and other psychomotor stimulants, opiates, nicotine, ethanol, cannabinoids, and phencyclidine. Recent studies involving the selective

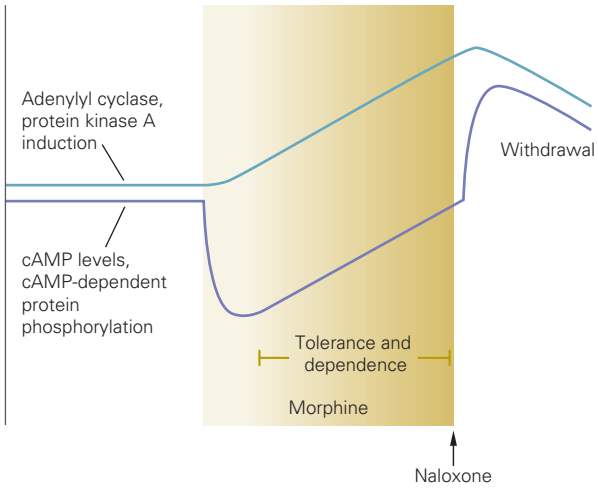

Figure 43–5 Upregulation of the cAMP-CREB pathway is a molecular mechanism underlying drug tolerance and dependence. Morphine or other μ opioid receptor agonists acutely inhibit the functional activity of the cyclic adenosine monophosphate (**cAMP**) pathway in brain reward neurons, as indicated, for example, by cellular levels of cAMP or protein kinase A (PKA)–dependent phosphorylation of substrates such as CREB. With continued drug exposure (**shading**), functional activity of the cAMP-CREB pathway is gradually upregulated and increases far above control levels upon removal of the drug (eg, by administration of the μ opioid receptor antagonist naloxone). These changes in the functional state of the cAMP-CREB pathway are mediated via the induction of adenylyl cyclase and PKA and activation of PKA substrates such as CREB in response to repeated drug administration. Induction of these proteins accounts for the gradual recovery in the functional activity of the cAMP-CREB pathway seen during chronic drug exposure (tolerance and dependence) and for the elevated activity of the cAMP-CREB pathway seen upon removal of the drug (withdrawal). First demonstrated for opiate drugs, similar regulation is seen in response to several other types of drugs of abuse. (Reproduced, with permission, from Nestler et al. 2020.)

expression or knockdown of ΔFosB in the nucleus accumbens of adult mice have provided direct evidence that induction of ΔFosB mediates reward sensitization, including increased drug self-administration and relapse. This is yet another example of a common adaptation to drugs of abuse that contributes to aspects of addiction shared across numerous drugs of abuse.

CREB and ΔFosB are two of many transcription factors implicated in drug addiction. Ongoing research is focused on characterizing the chromatin regulatory mechanisms through which these factors cooperate to regulate the expression of specific genes in the affected neurons and glia. Work is also underway to understand how these target genes drive their associated behavioral abnormalities via altered expression of proteins involved in synaptic, cell, and circuit function (Figure 43–6).

Lasting Cellular and Circuit Adaptations Mediate Aspects of the Drug-Addicted State

Repeated exposure to a drug of abuse can alter a neural circuit in two major ways. One mechanism, referred to as whole-cell or homeostatic plasticity, involves altering the intrinsic excitability of a nerve cell that will ultimately alter functioning of the larger circuit of which it is a part. It is easy to imagine how whole-cell plasticity in neurons within the brain's reward circuitry might mediate aspects of reward tolerance, sensitization, and dependence and withdrawal.

The other mechanism is synaptic plasticity, where connections between particular neurons are either strengthened or weakened. These synapse-specific adaptations could mediate the features of addiction that involve maladaptive memories, such as memories of the association of drug exposure with a host of environmental cues. This pathological learning and memory can increasingly focus an individual on the drug at the expense of natural rewards. Most attention in the field to date has concentrated on synaptic plasticity.

Synaptic Plasticity

As discussed elsewhere in this book, two major forms of synaptic plasticity have been described at glutamatergic synapses: *long-term depression* (LTD) and *long-term potentiation* (LTP). Over the past two decades, the molecular basis of both adaptations has been established, with distinct mechanisms underlying each of several distinct subtypes of LTD and LTP that occur throughout the nervous system. We now know that several types of drugs of abuse, in particular psychomotor stimulants and opiates, cause LTD- and LTP-like changes at particular classes of glutamatergic synapses in the brain's reward circuitry, with most work to date focused on the ventral tegmental area and nucleus accumbens.

Changes in the nucleus accumbens show interesting time-dependent adaptations as a function of drug withdrawal. At early withdrawal points (hours to days), glutamatergic synapses on neurons of the nucleus accumbens display LTD-like changes, which evolve into LTP-like changes after longer periods of withdrawal (weeks to months). Drug-induced LTD- and LTP-like adaptations in the nucleus accumbens involve morphological changes similar to those in other brain regions (mostly the hippocampus and cerebral cortex) where LTD and LTP occur in association with morphological changes in individual dendritic spines. During early withdrawal, LTD-like responses occur coincidently with increased numbers of

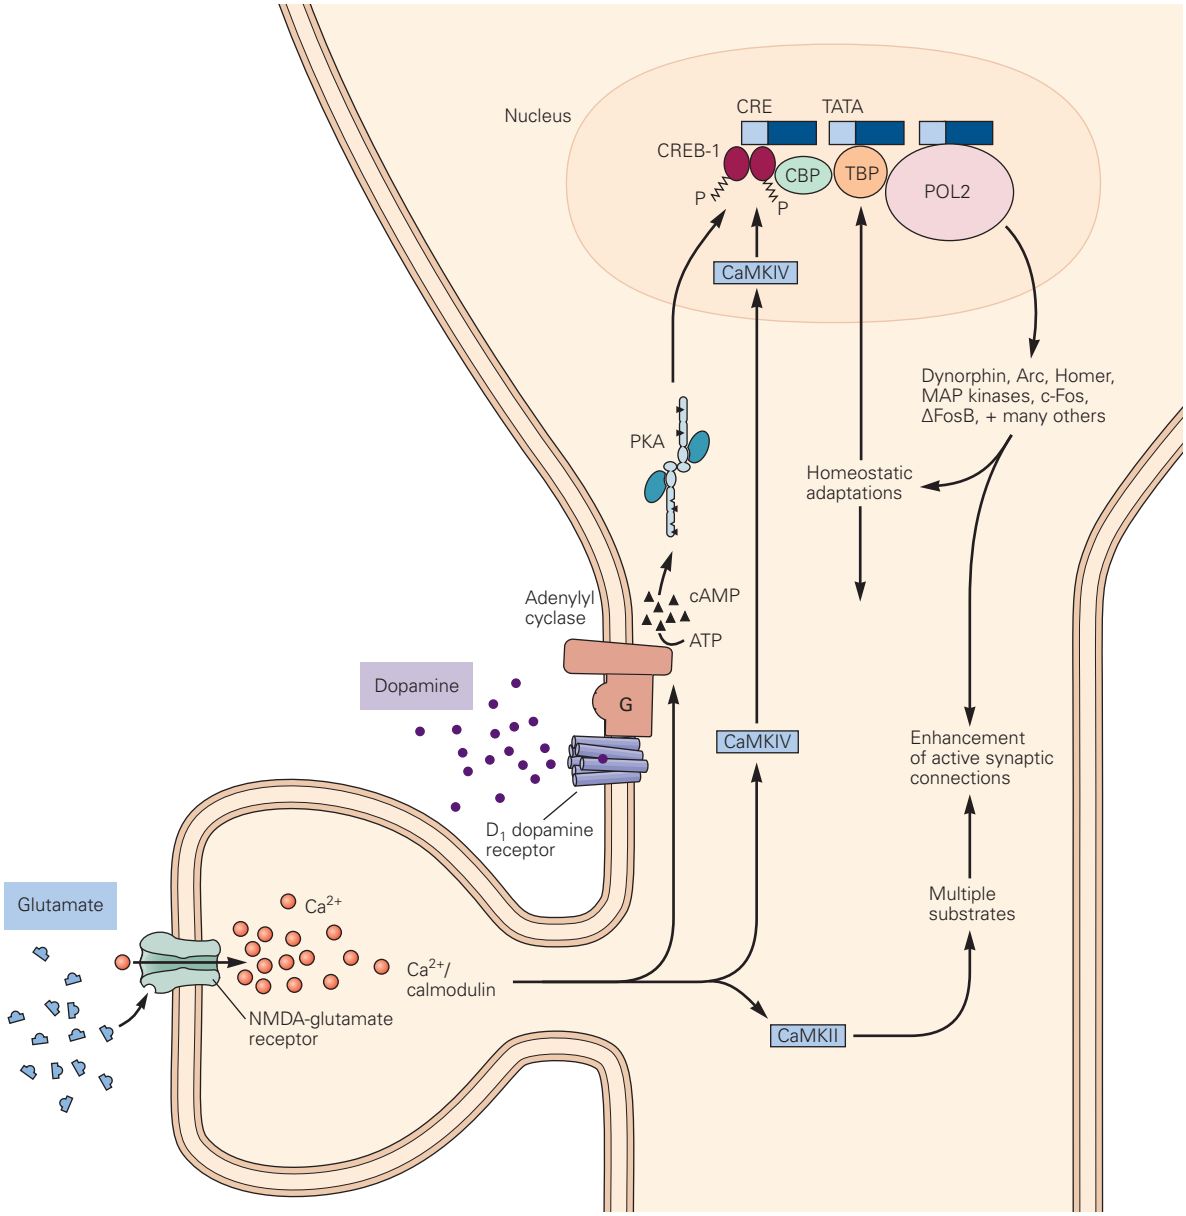

Figure 43–6 Dopamine- and glutamate-activated intracellular signaling pathways implicated in drug addiction. NMDA-type glutamate receptors permit Ca^{2+} entry, which binds calmodulin. The Ca^{2+}/calmodulin complex activates two types of Ca^{2+}/calmodulin-dependent protein kinases, CaMKII in the cytoplasm and CaMKIV in the cell nucleus. Certain dopamine receptors activate a stimulatory G protein that in turn activates adenylyl cyclase to produce cyclic adenosine monophosphate (**cAMP**). The cAMP-dependent protein kinase A (**PKA**) catalytic subunit can enter the nucleus. Once activated in the nucleus, both PKA and CaMKIV phosphorylate and thus activate cAMP response element binding protein (**CREB**). CREB recruits CREB-binding protein (**CBP**) and many other chromatin regulatory proteins and thereby activates the RNA polymerase II–dependent transcription of many genes, giving rise to proteins that can alter cellular function. Arc and Homer are localized in synaptic regions; mitogen-activated protein (**MAP**) kinases are protein kinases that control numerous cellular processes; Fos and ΔFosB are transcription factors; and dynorphin is a type of endogenous opioid peptide. These proteins are thought to contribute both to homeostatic responses to excessive dopamine stimulation and to the morphological and functional changes in synapses associated with memory formation. (Abbreviations: **ATP**, adenosine triphosphate; **NMDA**, *N*-methyl-D-aspartate; **POL 2**, RNA polymerase 2; **TBP**, TATA binding protein.)

immature, thin dendritic spines, whereas during later withdrawal, LTP-like responses occur coincidently with increased numbers of mature, mushroom-shaped spines. These findings suggest that repeated drug use weakens certain glutamatergic synapses with nucleus accumbens neurons via the induction of so-called *silent synapses* (Chapter 54), with a subset of these synapses strengthening during prolonged withdrawal.

These advances now define several ongoing lines of investigation. We need to understand which particular glutamatergic connections are affected and how those changes contribute to behavioral features of addiction. We need to define the molecular basis of this time-dependent synaptic plasticity, which is mediated in part through transcriptional mechanisms and altered expression levels of a host of proteins, including glutamate receptors, postsynaptic density proteins, proteins that regulate the actin cytoskeleton, and so on (Figure 43–6). In addition, we need to examine drug-induced glutamatergic synaptic plasticity at the several other reward-related brain regions that become corrupted in an addicted state, beyond the ventral tegmental area and nucleus accumbens. Finally, we need to understand how repeated exposure to drugs of abuse also corrupts inhibitory GABAergic synaptic transmission throughout this circuitry.

Whole-Cell Plasticity

As with synaptic plasticity, most examples of drug-induced whole-cell plasticity involve the ventral tegmental area and nucleus accumbens. For example, repeated cocaine exposure increases the intrinsic excitability of nucleus accumbens neurons, which contributes to reward tolerance. This adaptation is due in part to a decrease in expression of specific types of K^+ channels mediated by CREB, thus linking molecular-transcriptional adaptations to altered neural activity and an addiction-related behavioral abnormality. Repeated opiate exposure also increases the intrinsic excitability of dopaminergic neurons in the ventral tegmental area, but in a manner that impedes dopaminergic transmission to the nucleus accumbens. As with repeated cocaine exposure, this adaptation too is mediated by suppression of certain K^+ channels and contributes to reward tolerance.

Circuit Plasticity

Advanced tools are making it possible for the first time to track the activity of specific nerve cell types in the brain in awake, active animals and to experimentally manipulate the activity of those cells and study the behavioral consequences (Chapter 5). This is enabling scientists to define the precise ensembles of neurons within a given brain region that are affected by drug exposure over the life cycle of addiction—from initial drug exposure to compulsive drug consumption to withdrawal and relapse—and to provide causal evidence for the involvement of those neurons and the microcircuits within which they function. This work is beginning to define the distinct roles that various glutamatergic projections to the nucleus accumbens—from the prefrontal cortex, hippocampus, amygdala, and thalamus—play in controlling different cell types in the nucleus accumbens and the broader reward circuitry and in producing distinct addiction-related behavioral abnormalities.

While we have focused exclusively in this chapter on the effects of acute and chronic actions of drugs of abuse on the neural control of behavior, we realize that this is an oversimplification. As discussed in Chapter 7, neuronal function is intricately controlled by a host of nonneural cells in the brain, including astroglia, microglia, oligodendrocytes, and endothelial cells. There is growing evidence that each of these cell types is affected both directly and indirectly by drugs of abuse and that these nonneuronal actions also affect the long-term behavioral consequences of drug exposure. Integrating such actions with the neuronal effects of drugs of abuse will be required to achieve a comprehensive understanding of addiction.

Natural Addictions Share Biological Mechanisms With Drug Addictions

As previously indicated, the brain's reward circuitry evolved to motivate individuals to pursue natural rewards such as food, sex, and social interactions. Just as drug-addicted individuals display compulsive consumption of drugs of abuse, some people exhibit compulsive consumption of nondrug rewards (eg, compulsive overeating, shopping, gambling, video gaming, and sex), with behavioral consequences very similar to those observed in drug addiction. An interesting question for the field is whether these so-called "natural addictions" are mediated by some of the same molecular, cellular, and circuit adaptations that underlie drug addiction.

It is possible that these normal pleasurable behaviors excessively activate reward mechanisms in certain individuals who are particularly susceptible due to genetic or nongenetic factors. As with drugs, such activation may result in profound alterations in motivation that promote the repetition of initially rewarding behavior, despite the impact of negative consequences

associated with the resulting compulsive behavior. It is far more difficult to study the neurobiological basis of natural addictions because of limitations in animal models (imagine a mouse model of compulsive shopping!), although progress is being made in developing such paradigms. In any event, brain imaging studies in humans support the notion that addictions to both drugs and behavioral rewards are associated with similar dysregulation of the brain's reward circuitry (Figure 43–3).

Highlights

1. Motivational states drive behaviors that either seek rewards or defend against or avoid aversive stimuli. Motivational states themselves are determined by a variety of internal and external variables. Internal variables include both physiological states and cognitive states. External variables include stimuli that possess innately rewarding or aversive properties, although the motivational significance of these properties may be modified by internal variables.
2. Rewards are desirable objects, stimuli, or actions. Rewards tend to elicit motivational states that drive approach behaviors. Rewards can meet regulatory needs on a short timescale, but can also result from complex sequences of behavior that achieve a long-term goal.
3. Key components of reward-related circuitry in the brain include dopaminergic neurons and brain areas targeted by dopaminergic neurons, such as the nucleus accumbens, ventral pallidum, amygdala, hippocampus, and parts of the prefrontal cortex. However, dopamine itself does not account for hedonic experiences.
4. Many dopaminergic neurons exhibit physiological response properties that suggest they communicate a prediction-error signal, with enhanced activity occurring when something better than expected occurs. This type of signal could play a critical role in different forms of reinforcement learning, learning that links stimuli or actions to rewards. However, recent studies have revealed more response heterogeneity in dopaminergic neurons than previously appreciated, including responses to aversive stimuli. This heterogeneity and its complex effects on neural circuit function remain active areas of investigation.
5. Drug addiction can be defined as the compulsive seeking and taking of a drug despite negative consequences to one's physical health or occupational and social functioning. The risk for addiction is roughly 50% genetic, with many hundreds of genes, each of which contributes a very small effect to this heritability. Important nongenetic risk factors include a history of adverse life events.
6. Drugs of abuse compose only a very small fraction of known chemical compounds. These drugs are chemically diverse, with each type acting initially on a distinct protein target. Nevertheless, the drugs can induce a common behavioral syndrome because their actions at these targets converge in producing similar functional effects on midbrain dopaminergic neurons or their projection regions such as the nucleus accumbens.
7. Addiction requires repeated exposure to a drug of abuse. Such repeated exposure is often accompanied by tolerance, sensitization, and dependence/withdrawal. While many nonabused drugs can produce tolerance and dependence/withdrawal, drugs of abuse are unique in their ability to produce these adaptations as well as sensitization in motivational and reward states.
8. The adaptations underlying drug addiction are mediated in part through lasting changes in gene expression, which result in altered intrinsic activity of neurons as well as structural and functional alterations in their synaptic contacts within the brain's reward circuitry.
9. An important goal of current research is to understand how a myriad of molecular changes summate to underlie specific changes in neural and synaptic function. Likewise, it will be important to understand how these neural and synaptic changes combine to alter the functioning of the brain's larger reward-related circuitry, so as to mediate specific behavioral abnormalities that define an addicted state.
10. This delineation of molecular, cellular, and circuit mechanisms of addiction will require increased attention to the specific cell types (neuronal and nonneuronal) in which certain drug-induced adaptations occur and to the specific microcircuits within the reward pathways affected by those adaptations.
11. A subset of individuals show addiction-like behavioral abnormalities to nondrug rewards, such as food, gambling, and sex. Evidence suggests that such so-called natural addictions are mediated by the same brain circuitry involved in drug addiction, with some common molecular and cellular abnormalities implicated as well.
12. These considerations highlight the need to learn more about the precise molecular, cellular, and

circuit bases of drug addiction. Nonetheless, our evolving understanding of the brain's reward circuitry and how individual synapses and cells in that circuitry are altered by drug exposure in a way that corrupts circuit function and usurps normal systems of reward and associative memory provides a compelling notion of what happens in the addicted brain.

Sleep and Wakefulness

Sleep is a remarkable state. It consumes fully a third of our lives—approximately 25 years in the average lifetime—yet we know little about what happens in the brain during this daily excursion. Perhaps even more surprising, the exact functions of sleep and of dreaming, one of the more noteworthy components of sleep, are still unknown.

Although the psychological content of dreams has been a rich subject of speculation from Plato and Aristotle to Sigmund Freud, we still do not understand whether dreams carry deep personal meaning, as Freud hypothesized, or represent the brain "throwing out its trash," the bits and pieces of daily experience that are not worth retaining, as Francis Crick speculated. One function of sleep may be to allow synaptic remodeling and consolidation of memory traces reflecting the day's experiences, but the role of dreaming in this process remains a subject of intense debate.

When studying sleep and wakefulness, researchers typically use a polysomnogram, which consists of three physiological measures: brain activity measured by an electroencephalogram (EEG) (see Figure 58–1), eye movements recorded by an electro-oculogram (EOG), and muscle tone measured by an electromyogram (EMG) (Figure 44–1B). In clinical polysomnograms, respiration is also measured, as breathing during sleep is disrupted in many patients with sleep disorders.

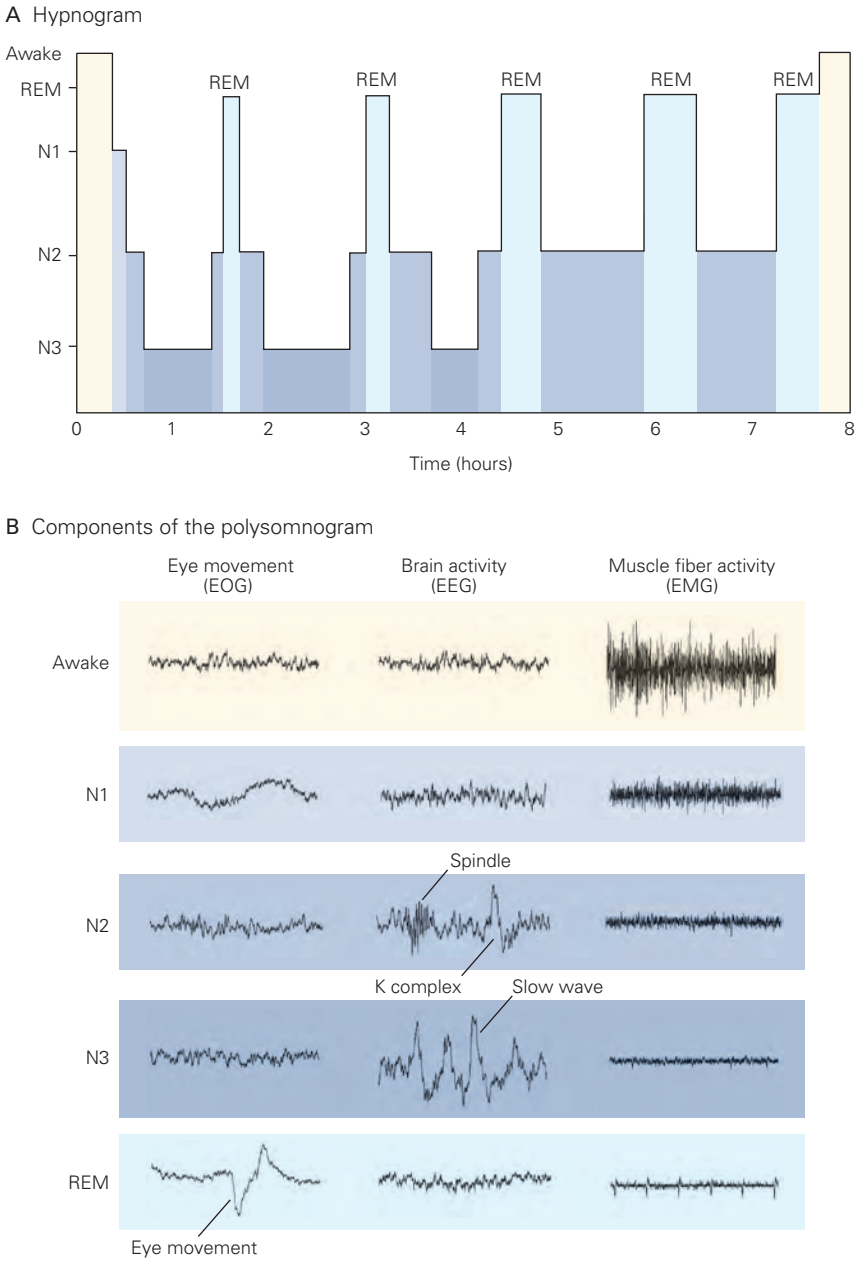

Figure 44–1 Electrophysiological patterns of wakefulness and sleep.

A. A hypnogram or graph showing the progression of sleep stages over a typical night in a healthy young person. Periods of rapid eye movement (**REM**) sleep alternate with non-REM sleep about every 90 minutes. An individual typically progresses from the awake state into light non-REM sleep (N1) then progressively deeper non-REM sleep (N2, N3), then back to lighter non-REM sleep before the first period of REM sleep occurs (**light blue bars**). As the night progresses, the individual spends less time in the deepest stage of non-REM sleep, and the duration of REM sleep periods increases.

B. The records show the components of the polysomnogram used to distinguish sleep stages. The electro-oculogram (**EOG**) records eye movements from electrodes on either side of the eyes. The electroencephalogram (**EEG**) records cortical field potentials from the scalp; the electromyogram (**EMG**) records muscle fiber firing through the skin. During the awake state, the EOG shows voluntary eye movements, the EEG shows fast low-amplitude activity, and the EMG shows variable muscle tone. Stage N1 sleep is characterized by a slight slowing of EEG frequencies and slow roving eye movements, with less EMG activity; stage N2 is characterized by bursts of 12- to 14-Hz activity called sleep spindles and high-voltage slow waves called K-complexes; stage N3 is dominated by high-voltage slow waves. During REM sleep, the EEG is similar to that of the awake state. Rapid eye movements can be seen on the EOG, but the EMG is so silent that contamination by tiny electrocardiogram signals can sometimes be seen (as in the illustrated case).

During wakefulness, the EEG is characterized by mainly high-frequency, low-voltage activity, indicative of the unique activity of individual cortical neurons; the EOG shows frequent eye movements; and the EMG shows moderate and variable muscle tone. During quiet wakefulness, with eyes closed, rhythmic EEG waves in the alpha range (8–13 Hz) are common, particularly over the occipital region. For most of the sleep period, the EEG shows slower activity, but periodically during the night, there are shifts into a sleep state with a faster, lower-voltage EEG, loss of muscle tone, and rapid eye movements called rapid eye movement (REM) sleep. The entire period of slow EEG activity, from light drowsiness to deep sleep, is referred to as non-REM sleep and is divided into three stages, N1 to N3 (Figure 44–1).

Sleep Consists of Alternating Periods of REM Sleep and Non-REM Sleep

As an individual becomes drowsy and transitions into light non-REM sleep (stage N1), the EEG slows and shows waves in the theta range (4–7 Hz) (Figure 44–1B).

Consciousness begins to fade during stage N1, but the individual may still be awakened by minimal stimulation. Stage N2 often contains some slow EEG activity in the theta and delta range (0.5–4 Hz) as well as *sleep spindles*, 10- to 16-Hz waxing and waning EEG oscillations lasting 1 to 2 seconds, typically with a gradual onset and offset so the EEG waves resemble an old-fashioned spindle tapered at both ends. The EEG also may show large, single slow waves called *K-complexes* (Figure 44–1B). During stage N3, the EEG shows abundant, very slow EEG delta activity. During stages N2 and N3, people are generally unconscious of the world around them as the slow cortical activity disrupts information processing. Across all stages of non-REM sleep, eye movements are absent, muscle tone is low, breathing is slow and regular, and body temperature falls.

Slow EEG activity and sleep spindles arise, respectively, from cortico-cortical and cortico-thalamic electrophysiological interactions. During non-REM sleep, the membrane potential of cortical pyramidal neurons fluctuates between *Up states* (when they are depolarized and fire) and *Down states* (when they are hyperpolarized and silent). These slow oscillations in membrane potential, which occur even in an isolated cortical slab, correlate with slow waves in the EEG. During stage N2 sleep, spindles arise from an interaction of neurons in the reticular nucleus of the thalamus and thalamocortical relay neurons. Thalamocortical neurons are generally hyperpolarized and inactive during non-REM sleep, but inhibition from the reticular thalamic neurons can result in the opening of low-threshold Ca^{2+} channels, which drive a burst of Na^{+} spikes in the thalamocortical neurons. The thalamocortical neurons then excite and recruit more reticular neurons, initiating the next cycle of the sleep spindle. This pattern of inhibition and excitation repeats about every 100 ms, and after several cycles, the spindle activity wanes as the reticular neurons become less responsive (Figure 44–2).

After about 90 minutes of sleep, people usually enter the stage known as REM sleep, a period in which dreams are often vivid and sometimes bizarre. REM sleep was discovered in 1953 when Eugene Aserinsky and Nathaniel Kleitman observed that across a night of sleep, adults have several episodes of jerky conjugate eye movements, and when awakened from this state, about three-fourths of subjects reported dreams with visual imagery.

Muscle tone is extremely low during REM sleep, owing to inhibition of motor neurons by descending pathways from the brain stem. This paralysis affects nearly all motor neurons except those that support respiration, eye movements, and a few other functions such as sphincter control. As discussed later in this chapter, this inhibition of motor neurons is crucial as it prevents the physical enactment of dreams.

During REM sleep, the body undergoes many additional physiological changes. Body temperature falls during non-REM sleep, and it can fall further during REM sleep as the generation and retention of heat are minimal. Autonomic regulation is altered such that heart rate and blood pressure can vary wildly. In addition, men experience penile erections and women experience physiological signs of sexual arousal during REM sleep.

Across the night, episodes of non-REM sleep alternate with REM sleep, and each of these sleep cycles takes about 90 minutes. Sleep in a healthy young adult usually begins with a rapid descent into stage N3 non-REM sleep, followed by lighter non-REM sleep and then some REM sleep, and with each cycle, non-REM sleep becomes lighter and the periods of REM sleep become longer (Figure 44–1A). At the end of the sleep period, people often wake spontaneously from an episode of REM sleep.

The Ascending Arousal System Promotes Wakefulness

Modern perspectives of the neural basis of sleep and wakefulness go back about 100 years to the concepts derived by the neurologist and neuropathologist Baron Constantin von Economo. Around World War I, he observed an unusual type of encephalitis, believed to be a viral infection of the brain that specifically attacked the sleep–wake control circuitry. In most cases, patients had "encephalitis lethargica," sleeping 20 or more hours per day. When they awoke, they were generally cogent, but they would stay awake only long enough to eat and then go right back to sleep. This intense sleepiness would persist for many months before improving. But in patients who died during this interval, von Economo found focal damage to the brain, at the junction of the midbrain and diencephalon, leading him to hypothesize that the upper brain stem and posterior hypothalamus contain critical circuitry that activates the forebrain, producing a normal wakeful state.

Other patients afflicted in the same epidemic had just the opposite problem: unrelenting severe insomnia. They would be restless and, despite feeling sleepy, unable to fall asleep. Eventually, they would fall into a fitful sleep for only a few hours each day, but would waken without feeling refreshed. In post mortem examinations of these patients, von Economo found

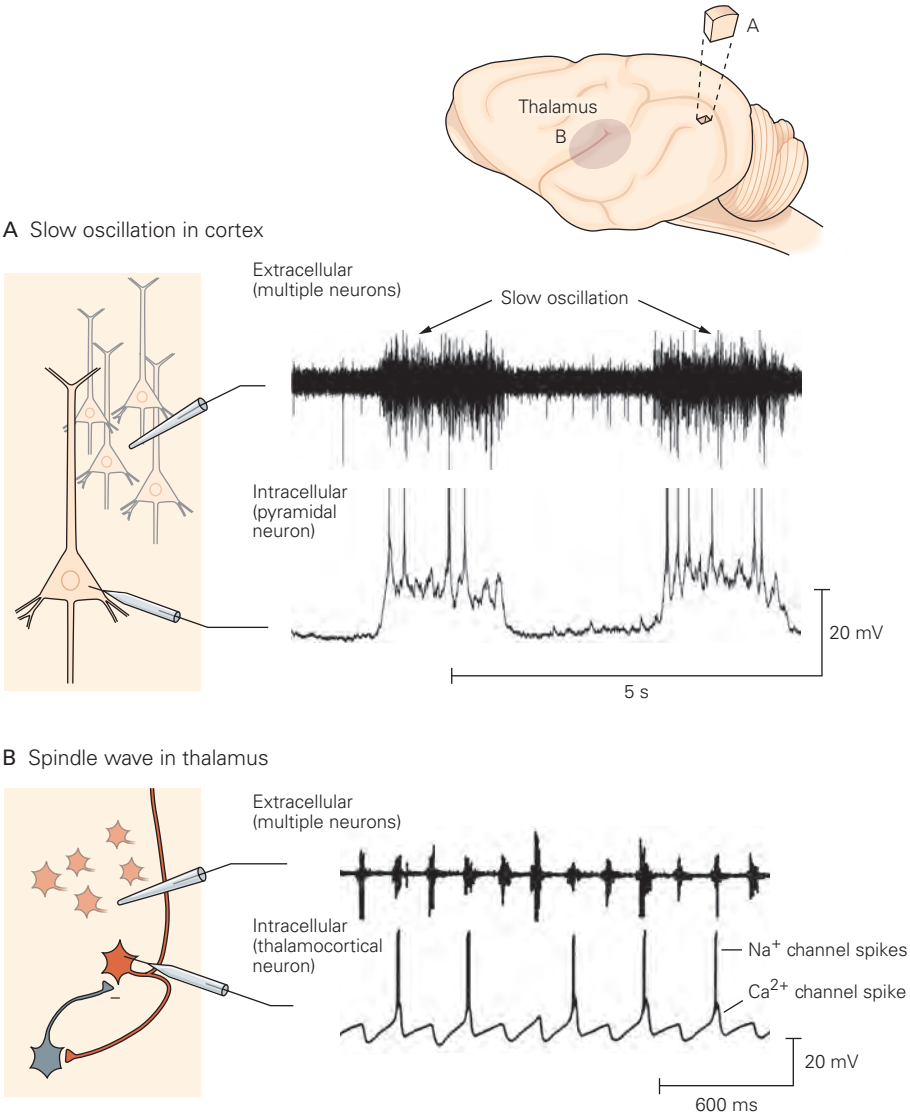

Figure 44–2 Cellular mechanisms of electroencephalogram rhythms during sleep.

A. The slow oscillation that underlies the slow waves of the EEG during non-REM sleep is generated within the cerebral cortex by intrinsic massively recurrent excitatory and inhibitory connections. Slow waves will continue even in an isolated cortical slab. Intracellular recordings from such neurons during slow oscillations show rhythmic down states when the individual neurons are hyperpolarized and do not fire, alternating with up states when the membrane potential is more depolarized and the neurons fire multiple action potentials. This synchronous firing produces waves of dendritic potentials, which appear as slow waves in the EEG. (Data from Dr. David McCormick.)

B. Similarly, in a thalamic slice, recurrent circuitry generates spindle waves. A burst of spikes in reticular nucleus neurons (**gray**) hyperpolarizes thalamocortical relay neurons (**red**) sufficiently to de-inactivate low-threshold (T-type) Ca^{2+} channels. As the hyperpolarization wanes, these Ca^{2+} channels open and the resultant Ca^{2+} current depolarizes the relay neuron, producing a brief burst of Na^+ channel spikes on top of a Ca^{2+} channel spike plateau. Meanwhile, as the burst in the relay cell continues, its excitatory output generates a T-type Ca^{2+} channel spike in the reticular neuron, which drives another burst of Na^+ spikes. The resultant volley of feedback inhibition to the relay cells initiates a new burst cycle. This firing pattern recurs 12 to 14 times per second, and the resulting waves of thalamocortical action potentials reaching the cortex produce sleep spindles in the EEG. The upper trace shows action potentials from a local population of relay cells. The lower trace shows inhibitory postsynaptic potentials and spike bursts from an individual relay cell; on this slow time base, each upstroke in the intracellular record represents a burst of up to six action potentials. As the trace shows, individual relay neurons do not reach spike threshold during every cycle of the spindle wave. As a result, the amplitude of the extracellular spike activity varies from cycle to cycle, depending on which neurons happen to fire and their distances from the extracellular electrode tip. However, each burst of thalamic firing would produce a volley of excitatory postsynaptic potentials in the cortex, resulting in an electroencephalogram wave, time-locked to the thalamic firing. lesions in the anterior hypothalamus. He proposed that neurons in this area are important for inhibiting the brain stem arousal system to allow sleep. Modern studies have shown a system of wake–sleep circuitry in the brain that is remarkably close to von Economo's model.

The Ascending Arousal System in the Brain Stem and Hypothalamus Innervates the Forebrain

The composition of the ascending arousal system has been debated since von Economo's time. In the late 1940s and early 1950s, lesion studies confirmed that damage to the upper midbrain reticular formation could cause coma, whereas electrical stimulation of this region could arouse animals. The location and nature of the wake-promoting neurons were unknown.

In the succeeding decades, it became clear that these lesions damaged the axons of neurons in the upper brain stem that project to the forebrain, including noradrenergic neurons in the locus ceruleus, serotonergic neurons in the dorsal and median raphe, and midbrain dopaminergic neurons (Chapter 40). The axons of other neurons in the posterior hypothalamus, including those producing histamine and orexin, also join this pathway, which splits into two bundles, with some projections innervating the thalamus and others the hypothalamus, basal forebrain, and cerebral cortex (Figure 44–3).

Neurons contributing to all of these ascending pathways fire fastest during the awake state but much slower during sleep, suggesting that they are wake-promoting. However, although many monoamine antagonists cause sleepiness, and lesions of the

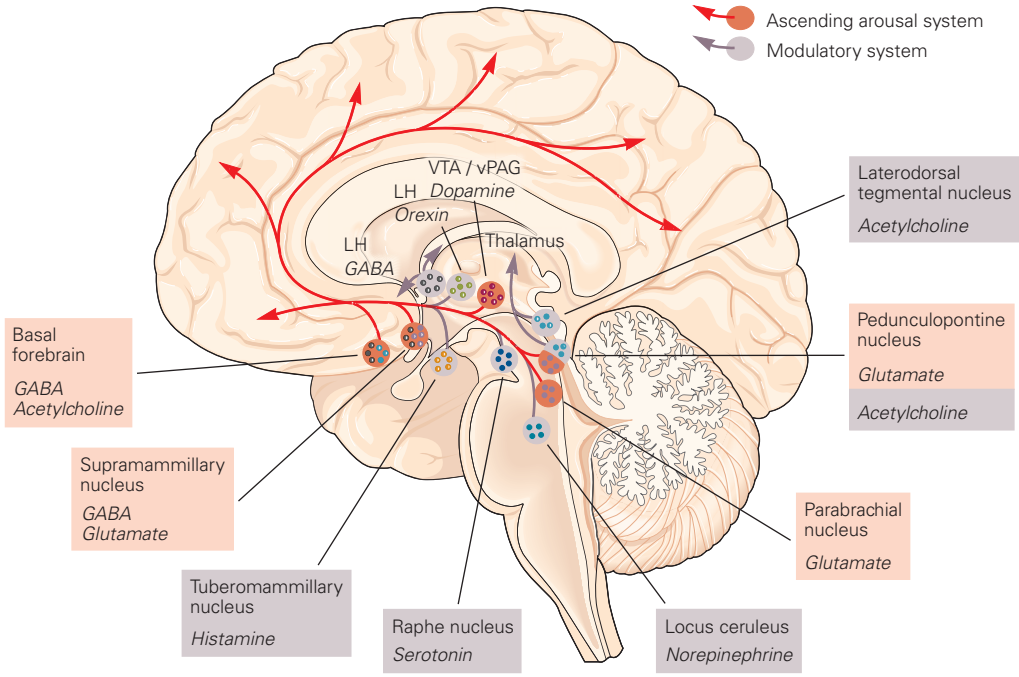

Figure 44–3 The ascending arousal system. The ascending arousal system comprises primarily axons from glutamatergic neurons in the parabrachial and pedunculopontine tegmental nuclei and cholinergic and GABAergic (**dark gray**) neurons in the basal forebrain. Lesions of either the parabrachial and pedunculopontine nuclei or the basal forebrain cause coma. Of somewhat lesser importance are dopaminergic neurons in the ventral tegmental area (**VTA**) and ventral periaqueductal gray (**vPAG**) matter and glutamatergic and GABAergic neurons in the supramammillary nucleus, where lesions can increase sleep by about 20%. In addition, populations of modulatory neurons can strongly promote wakefulness when stimulated, but when damaged cause minimal changes in wake–sleep amounts. These include the monoaminergic neurons in the noradrenergic locus ceruleus, the serotonergic dorsal and median raphe nuclei, and the histaminergic tuberomammillary nucleus; the cholinergic neurons in the pedunculopontine and lateral dorsal tegmental nuclei; and the orexinergic neurons in the lateral hypothalamus (**LH**). All of these neurons send their axons through the hypothalamus and basal forebrain directly to the cerebral cortex, where their net effect is to increase cortical arousal. Many of the modulatory pathways also activate the thalamus, enabling thalamic transmission of sensory information to the cerebral cortex. GABAergic neurons in the lateral hypothalamus also promote wakefulness by inhibiting neurons in the ventrolateral preoptic area and reticular nucleus of the thalamus that oppose wakefulness.

monoaminergic cell groups impair the ability to stay awake under adverse conditions, such lesions have little lasting effect on the amount or timing of wake or sleep.

Lesions of the orexinergic neurons in the lateral hypothalamus cause narcolepsy, a condition in which sleep–wake states are present in normal amounts but are unstable, as discussed later. In fact, of all of the monoaminergic cell groups that are thought to contribute to arousal, only lesions of the dopaminergic neurons near the dorsal raphe nucleus cause small but long-lasting reductions in arousal, resulting in about a 20% increase in total sleep time. Interestingly, the ability of drugs such as amphetamine or modafinil to promote wakefulness appears to depend upon their ability to block dopamine reuptake, as mice with deletions of the dopamine transporter do not respond to these drugs.

Because lesions of the ascending monoaminergic and orexinergic pathways have little if any effect on the total amount of wakefulness, recent work has emphasized the role of glutamatergic, cholinergic, and GABAergic neurons in maintaining wakefulness. Lesions of glutamatergic neurons in the dorsolateral rostral pons, including the parabrachial nucleus and adjacent pedunculopontine tegmental nucleus, cause a comatose state from which the animals cannot be awakened. Lesions confined to the thalamus impair the content of consciousness but have relatively little effect on wake–sleep cycles. On the other hand, lesions of the posterior lateral hypothalamus cause profound sleepiness, which cannot be accounted for by damage to the orexinergic or histaminergic neurons in this region. Glutamatergic neurons in the supramammillary region, which activate the cortex, and GABAergic neurons in the lateral hypothalamus that inhibit sleep-promoting circuits, may account for this arousal effect. Finally, large bilateral lesions of the basal forebrain also can produce coma, similar to lesions of the dorsolateral pons. Optogenetic or chemogenetic activation of cholinergic, GABAergic, or glutamatergic neurons in the basal forebrain indicates that neurons of all three types may produce arousal.

Thus, the current view of the ascending arousal system is that the crucial components are glutamatergic neurons in the dorsolateral pons, supramammillary hypothalamus, and basal forebrain; cholinergic neurons in the dorsolateral pons and basal forebrain; and GABAergic neurons in the lateral hypothalamus and basal forebrain. These are likely to be augmented by modulatory pathways containing orexin and monoamines, needed to allow full and sustained wakefulness particularly under adverse conditions (Figure 44–3).

Damage to the Ascending Arousal System Causes Coma

Consciousness depends upon the activity of the cerebral hemispheres during the awake state. Hence, loss of consciousness occurs when there is injury to the ascending arousal system or to both cerebral hemispheres, or there is a severe metabolic derangement (eg, low blood sugar, inadequate oxygenation, various forms of drug intoxication) that affects both the arousal system and its cortical targets. A patient who cannot be awakened, even by vigorous stimulation, is said to be in a coma. Those who can be partially awakened by such stimuli are said to be stuporous or obtunded.

The clinical approach to a comatose or obtunded patient is first to determine if there is injury to the ascending arousal system. Because of the proximity of the arousal pathways to those that control eye movement and pupillary responses, as well as respiration and some motor responses (Chapter 40), clinicians examine these brain stem functions carefully. If these functions are intact, it is likely that the problem is due to a metabolic condition, which can be assessed by various blood and spinal fluid tests. In addition, a computed tomographic (CT) scan of the brain is needed to look for pathology affecting both cerebral hemispheres (eg, a large tumor or blood clot).

Circuits Composed of Mutually Inhibitory Neurons Control Transitions From Wake to Sleep and From Non-REM to REM Sleep

In contrast to coma, sleep is a temporary, reversible loss of consciousness produced by specific brain circuitry that inhibits the ascending arousal system. Neurons in the ventrolateral preoptic nucleus contain the inhibitory neurotransmitters GABA and galanin and project extensively to most parts of the ascending arousal system. These preoptic neurons fire slowest during wakefulness, increase their firing as animals fall asleep, and fire fastest during deep sleep after a period of sleep deprivation.

Similarly, GABAergic neurons in the nearby median preoptic nucleus also promote sleep and project to some components of the arousal system. Lesions of these preoptic neurons result in fragmented sleep and cause animals to lose as much as half of their total sleep. Of clinical relevance, elderly people often have fragmented sleep, and those with the most fragmented sleep show the greatest loss of the sleep-promoting ventrolateral preoptic galanin neurons in postmortem examination. In addition, a population of GABAergic neurons in the parafacial zone, a region near the facial

nerve as it courses through the brain stem, inhibits the parabrachial nucleus. Lesions of the parafacial zone also result in loss of up to half of total sleep time.

Interestingly, the ventrolateral preoptic neurons receive inhibitory inputs from neurons throughout the arousal system. Mutually inhibitory connections between the ventrolateral preoptic neurons and the arousal system result in a neural circuit with properties similar to an electrical flip-flop switch, in which each side of the circuit turns the other off. Such a circuit produces rapid and full transitions between two states. Although it may sometimes appear that it takes a long time to fall asleep, the actual transitions from wake to sleep, or vice versa, are generally quick, taking only a few seconds to a few minutes. In fact, most animals spend nearly their entire day clearly awake or asleep, with very little time spent in transitions. These rapid transitions are behaviorally adaptive as an animal would be vulnerable in an intermediate, drowsy state. A neural flip-flop switch prevents this situation because when either side of the switch gains advantage over the other, the circuit produces a rapid and complete transition in state (Figure 44–4).

REM sleep is generated by a network of brain stem neurons centered in the pons. The fast EEG rhythms and dream activity of REM sleep are thought to be driven by coordinated activity of glutamatergic neurons in the subceruleus region (ventral to the locus ceruleus in the pons) plus cholinergic and glutamatergic neurons in the parabrachial and pedunculopontine tegmental nucleus that innervate the basal forebrain and thalamus. Other glutamatergic subceruleus neurons produce the paralysis of REM sleep via projections to the ventromedial medulla and spinal cord, where they activate GABAergic and glycinergic neurons that deeply hyperpolarize motor neurons.

The subceruleus area in turn receives input from a population of GABAergic neurons in and just lateral to the periaqueductal gray matter, where the cerebral aqueduct opens into the fourth ventricle. These neurons are most active during wake and non-REM sleep, and they inhibit the subceruleus neurons, preventing entry into REM sleep. Conversely, GABAergic neurons in the subceruleus area also project back to the ventrolateral periaqueductal gray region. The mutual inhibition between the two populations of neurons may form another flip-flop switch that promotes rapid and complete transitions into and out of REM sleep.

Interestingly, the noradrenergic locus ceruleus and serotonergic dorsal raphe nucleus innervate and inhibit the subceruleus region. Thus, REM sleep is often reduced when people take antidepressants that increase brain levels of serotonin or norepinephrine. In addition, as these monoaminergic neurons are active during wakefulness, they prevent direct transitions from wake into REM sleep (Figure 44–5).

Sleep Is Regulated by Homeostatic and Circadian Drives

The circadian regulation of sleep obeys a 24-hour biological clock (described later), whereas the homeostatic drive for sleep gradually accumulates during the awake state. After a period of sleep deprivation, much of the lost sleep is recovered over the next few nights, which in younger people may involve deeper and longer periods of stage N3 non-REM sleep.

REM sleep is also recovered after REM deprivation; rebound REM sleep can include especially intense dreams, long periods of REM sleep, and occasional breakthrough of REM sleep phenomena into wakefulness, such as dream-like hallucinations or brief paralysis when falling asleep or waking up. Rebound sleep on a weekend is commonly enriched in REM sleep in people who wake up early to an alarm clock on workdays and miss out on the last portion of sleep, which is mainly REM sleep.

The Homeostatic Pressure for Sleep Depends on Humoral Factors

Humoral factors circulating in the brain signal the homeostatic pressure for non-REM sleep. The brain is metabolically quite active during wakefulness and uses ATP, but with sustained periods of wakefulness, ATP is dephosphorylated to adenosine, which acts as a local neuromodulator in the extracellular environment. Adenosine type 1 receptors are inhibitory receptors that are expressed on wake-promoting neurons and in many other parts of the brain, so higher adenosine levels may produce sleepiness by inhibiting these neurons. In addition, adenosine can excite neurons via adenosine type 2a receptors; these receptors are common in the shell of the nucleus accumbens and may cause sleepiness by means of projections to the hypothalamus that activate the ventrolateral preoptic neurons.

The pressure for sleep can be measured by the time it takes an individual to fall asleep if given the opportunity in a comfortable environment. This approach is used by sleep clinicians in the Multiple Sleep Latency Test, in which an individual is given 20-minute intervals to try to fall asleep in a comfortable, quiet bed every 2 hours beginning at 9 am, for five sleep opportunities. An individual who is well rested generally

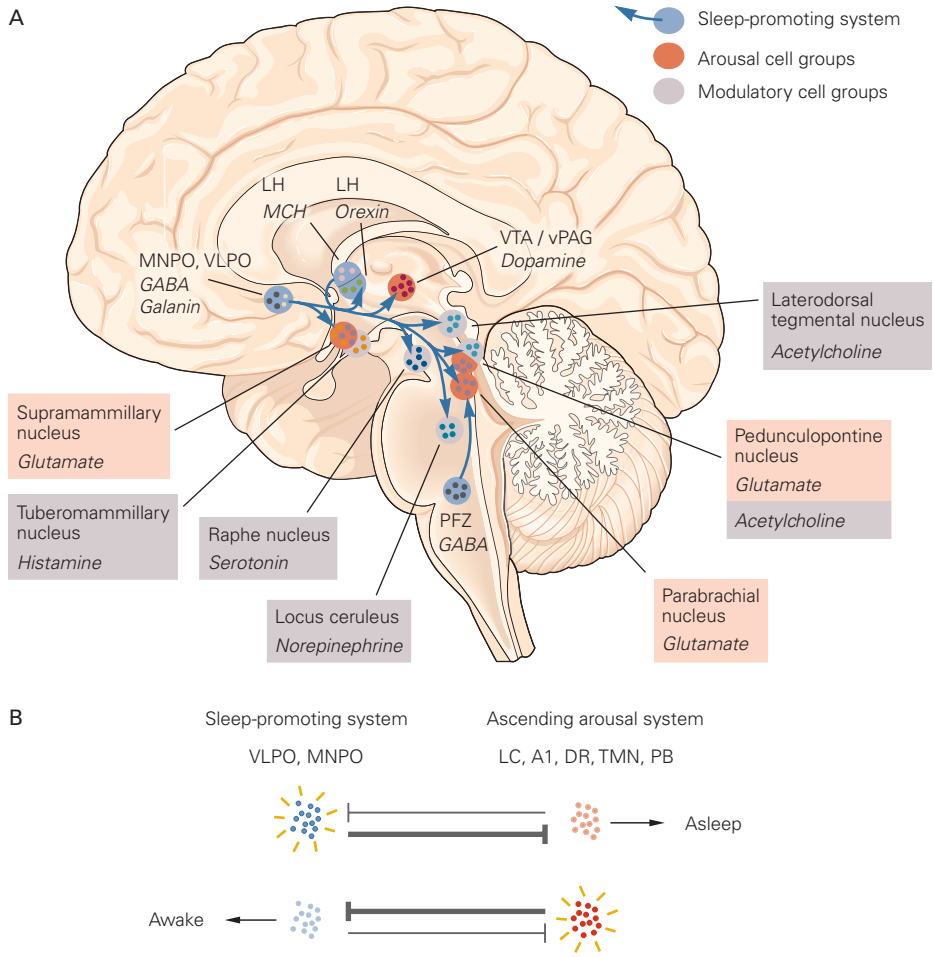

Figure 44–4 Sleep-promoting pathways.

A. The components of the ascending arousal system (Figure 44–3) receive inhibitory, largely GABAergic inputs from sleep-promoting neurons. Neurons in the ventrolateral and median preoptic nuclei (**VLPO, MNPO**) innervate the entire arousal-promoting system, while those in the parafacial zone (**PFZ**) innervate mainly the parabrachial area. Many of the VLPO neurons also contain galanin (GAL), an inhibitory peptide. Neurons in the lateral hypothalamus (**LH**) that release melanin-concentrating hormone (**MCH**) may promote REM sleep by inhibiting both nearby orexinergic neurons as well as neurons in the periaqueductal gray matter that prevent REM sleep (see Figure 44–5). (Abbreviations: **vPAG**, ventral periaqueductal gray; **VTA**, ventral tegmental area.)

B. The flip-flop switch relationship of the ventrolateral and median preoptic nuclei and the mutually inhibitory components of the ascending arousal system (**LC**, locus ceruleus; **A1**, noradrenergic neurons; **DR**, dorsal raphe; **TMN**, tuberomammillary nucleus; **PB**, parabrachial nucleus). When activated, the sleep-promoting neurons inhibit the components of the ascending arousal system. However, the sleep-promoting cell groups are also inhibited by the arousal system. The net effect is that the individual spends most time fully awake or asleep while minimizing time in transitional states.

takes at least 15 to 20 minutes to fall asleep, but a very sleepy person can easily fall asleep within a few minutes in each nap. Another test of sleep pressure is the Psychomotor Vigilance Task. The subject is told to watch a small lamp and press a button as soon as they see the light turned on. The light then turns on at random times over a 5- to 10-minute test period; sleepy subjects are inattentive and intermittently are slow or completely fail to respond to the light stimulus.

Circadian Rhythms Are Controlled by a Biological Clock in the Suprachiasmatic Nucleus

Circadian rhythms are roughly 24-hour physiological rhythms that synchronize the internal state of an animal with the external daily environment and anticipate various physiologic demands that occur on a daily basis. In humans, circadian wake-promoting signals during the day counterbalance the rising homeostatic

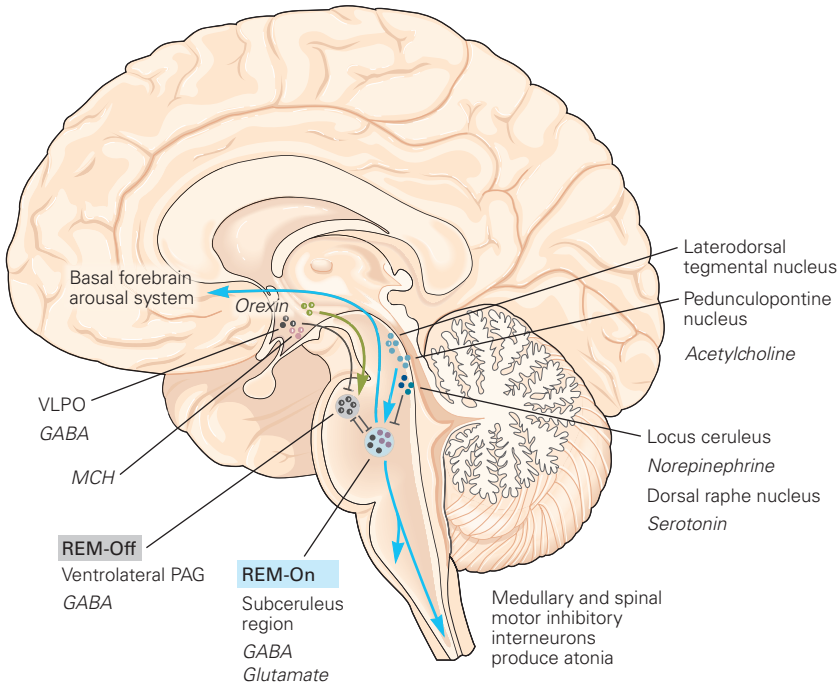

Figure 44–5 The REM sleep switch. Brain stem neurons are essential for controlling the transitions between non–rapid eye movement (**REM**) and REM sleep. REM sleep is generated by a population of neurons in the rostral pons, just ventral to the laterodorsal tegmental nucleus and locus ceruleus, in what is called the sublaterodorsal area in rodents and the subceruleus region in humans. These glutamatergic neurons project to other parts of the brain stem, where they initiate the motor and autonomic manifestations of REM sleep, and to the forebrain, where they mediate behavioral and electroencephalographic components of REM sleep. The descending projection activates inhibitory interneurons in the medulla and spinal cord that profoundly hyperpolarize motor neurons and prevent the individual from acting out his or her dreams. These REM-on neurons are inhibited by GABAergic neurons in the ventrolateral periaqueductal gray matter and adjacent pontine reticular formation, while the latter are themselves inhibited by neurons in the REM-on region, thus forming a flip-flop switch (see Figure 44–4B). These REM-off neurons are under the control of forebrain neurons, including neurons that release the excitatory orexin neuropeptides, neurons in the ventrolateral preoptic nucleus (**VLPO**) that release the inhibitory signaling molecules γ-aminobutyric acid (**GABA**) and galanin, and hypothalamic neurons that release the inhibitory neuropeptide melanin-concentrating hormone (**MCH**). In addition, modulatory neurons in the locus ceruleus and dorsal raphe inhibit the REM generator, whereas cholinergic neurons in the pedunculopontine and laterodorsal tegmental nuclei promote REM sleep. This model explains many clinical observations, such as the fact that cholinergic agonist drugs promote REM sleep, whereas drugs such as antidepressants that increase monoamine levels suppress REM sleep. Loss of orexinergic neurons can cause abrupt onset of REM sleep, whereas loss of REM-on neurons in the sublaterodorsal area abolishes atonia during REM sleep. Thus, individuals with this condition act out their dreams (*REM sleep behavior disorder*).

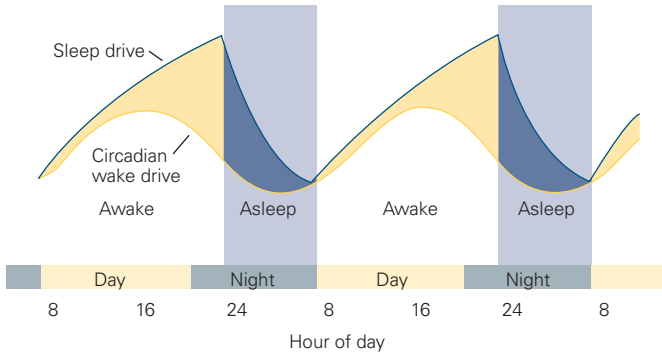
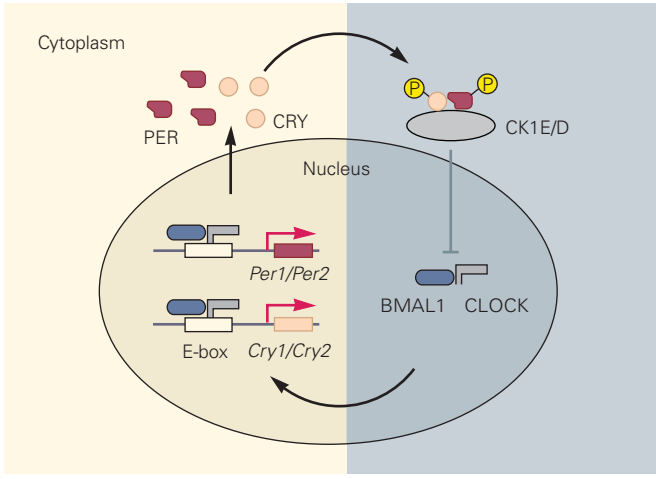
sleep pressure. The circadian wake-promoting signal dips slightly in the mid-afternoon, when many people take a nap or siesta. Around the habitual bedtime, this circadian waking influence rapidly collapses, the homeostatic drive for sleep is unopposed, and sleep ensues. In the hour or two before the customary waking time, circadian promotion of sleep occurs to ensure an adequate amount of sleep, since homeostatic sleep pressure is low late in the sleep period (Figure 44–6A).

Circadian rhythms are driven by a small group of GABAergic neurons in the suprachiasmatic nucleus located in the hypothalamus just above the optic chiasm. The 24-hour rhythm of activity in this biological clock is driven by a set of "clock genes," which undergo a transcriptional-translational cycle with an approximately 24-hour period. The positive limb of the loop consists of two proteins, BMAL1 and CLOCK, which dimerize and form a transcription factor that binds to the E-box motif, which is found in the promoter region of hundreds of genes that undergo daily cycles in their expression. Among those genes whose expression is increased by BMAL1 and CLOCK are the *Period* and *Cryptochrome* genes. Their protein products also dimerize, form a complex with casein kinase 1 delta or epsilon, and are translocated to the nucleus of the cell, where they cause BMAL1 and CLOCK to dissociate

A Wake–sleep cycle with light cues



B Genetic clock of the wake–sleep cycle



C Wake–sleep cycle without light cues

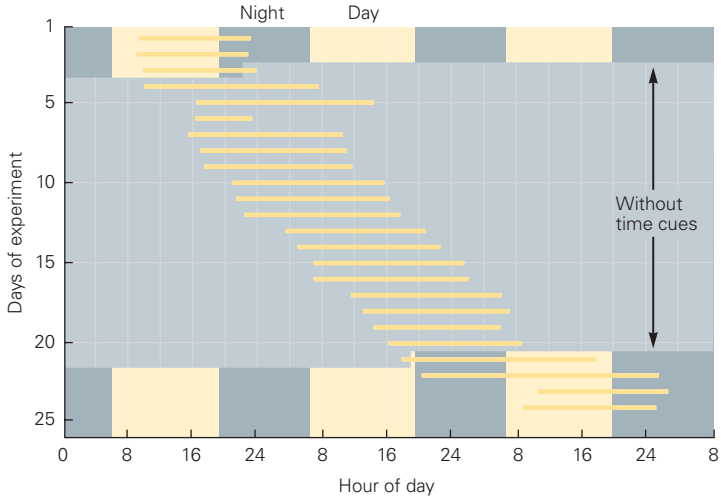


Figure 44–6 The circadian drive for wakefulness interacts with the homeostatic drive for sleep to shape wake–sleep cycles.

A. Sleep drive builds up gradually over the course of a long period of wakefulness, whereas the circadian drive for wakefulness varies on a 24-hour cycle, regardless of previous sleep. The peak of this circadian wake cycle occurs in the hours before bed, as the homeostatic sleep drive is rising, whereas the low point occurs in the hours just before the habitual time of awakening, when the homeostatic drive for sleep is ebbing.

B. The 24-hour rhythm in mammalian cells is regulated by a set of proteins that form a transcriptional-translational loop. BMAL1 and CLOCK form a dimer that binds to the E-box motif found on many genes that have circadian rhythms of transcription. Among these are the *Period 1* and *2* genes (*Per1, Per2*) and the *Cryptochrome 1* and *2* genes (*Cry1, Cry2*). Their products dimerize and form a complex with casein-1 kinase epsilon or delta (**CK1E/D**). The complex translocates to the nucleus, where it inhibits the dimerization of BMAL1 and CLOCK, causing it to fall off the E-box. This reduces the transcription of *Period* and *Cryptochrome* genes; as PER and CRY proteins are degraded, BMAL1 and CLOCK dimerize once more, and the cycle repeats.

C. Circadian rhythms regulate the timing of sleep and wake. The plot shows the wake cycles (**yellow bars**) of an individual who initially lives under regular lighting conditions for 3 days and then lives in a dimly lit environment with no time cues for 18 days. The individual maintains daily cycles of about 25.2 hours, drifting an entire day over this period. Blind people who cannot relay light signals to the suprachiasmatic nucleus (see Figure 44–7) often live continuously like this, a condition called non–24-hour wake–sleep disorder.

from the E-box, reducing transcription of many genes, including themselves. This results in a fall in Period and Cryptochrome proteins until BMAL1 and CLOCK can once more dimerize, restarting the cycle. In addition to this core loop, additional genetic side loops modulate the period of the circadian clock (Figure 44–6B).

This daily gene cycle functions in almost all cells in the body, including those in the brain, and it is essential for driving a wide range of circadian rhythms, from secretion of hormones and digestive enzymes to readying the liver for metabolic processing of food and the cardiovascular system for the active period of the day. When removed from the body and placed in a culture dish, most cells in the body rapidly fall out of synchrony, as the individual cellular clock cycles vary between cells by as much as an hour or two from the 24-hour mean. However, when neurons of the suprachiasmatic nucleus are cultured they continue to communicate with one another and thereby synchronize their cellular rhythms. This coordinated activity by suprachiasmatic neurons results in a close to 24-hour rhythm; the average period in humans who are placed in a continuous dim light environment is 24.1 hours, resulting in a slow drift in circadian rhythms (Figure 44–6C).

The suprachiasmatic nucleus exerts control over all of the other body clocks by regulating body temperature as well as autonomic, endocrine, and behavioral functions. Interestingly, although the daily rhythm in body temperature can adjust the timing of rhythms in many organs, the rhythm of the suprachiasmatic nucleus itself is highly resistant to changes in temperature, so its fundamental pacemaking is unaltered. In the end, the circadian timing of the brain and body runs on suprachiasmatic time.

Still, the suprachiasmatic clock must be entrained to the external world. If it were not, each person with a 24.1-hour cycle would progressively wake up six minutes later each day than the day before and would be unable to adjust to seasonal variations in sunrise and sunset. To avoid this situation, the suprachiasmatic nucleus receives direct inputs from a special class of retinal ganglion cells that signal light levels, rather than participating in image formation. Like all retinal ganglion cells, these neurons receive inputs from rods and cones, but they also contain melanopsin, a photopigment that makes them intrinsically photosensitive and hence they function as luminance detectors. In addition to entraining internal circadian rhythms to the ambient light cycle, these cells also regulate other non–image-forming visual functions such as the pupillary light reflex and the feeling of pain that can occur when one looks into bright lights.

Some individuals have unusually short circadian periods due to mutations in clock genes or their regulatory elements. For example, individuals with *familial advanced sleep-phase syndrome* prefer to go to bed early in the evening and cannot sleep past 3 or 4 am. In families with this disorder, mutations in the genes coding for Period or Casein kinase-1 delta result in more rapid cycling of the clock.

Blind people in whom the melanopsin-containing neurons are damaged lack visual input to their suprachiasmatic nucleus, often resulting in *non–24-hour sleep–wake rhythm disorder*. Because most people have an intrinsic cycle longer than 24 hours, circadian rhythms in these individuals drift, becoming a few minutes later each day, so that most of the time they are out of synch with the rest of the world. They lack the ability to entrain to external light–dark conditions because the suprachiasmatic nucleus lacks the crucial resetting signal from the retina. This problem is most common in people who have lost their eyes (eg, due to trauma or infection), but it is not seen in blind people in whom the melanopsin-containing neurons are intact (eg, blindness due to degeneration of rods and cones, or problems with the cornea or lens) and who also retain their pupillary light reflexes.

In contrast to light, which is signaled by the melanopsin neurons, the hormone melatonin signals darkness. Melatonin is made by the pineal gland, and the suprachiasmatic neurons time its release through communication with neurons in the paraventricular nucleus of the hypothalamus that activate sympathetic innervation of the pineal gland. Neurons in the suprachiasmatic nucleus contain melatonin receptors, which reinforce circadian rhythms. Similarly, exogenous melatonin or melatonin agonists can entrain circadian rhythms, promoting sleep by regularizing sleep onset. This treatment approach is particularly useful in entraining circadian rhythms in individuals with non–24-hour sleep–wake rhythm disorder.

Circadian Control of Sleep Depends on Hypothalamic Relays

The suprachiasmatic nucleus is most active during the daily light period in all mammalian species. While humans are diurnal (awake during the day and asleep during the night), nocturnal mammals have the opposite activity cycle. How can such opposite behavioral patterns be set by the suprachiasmatic nucleus if it is most active during the light period?

The answer appears to lie in a series of relays interposed between the suprachiasmatic nucleus and the wake–sleep control circuitry, which give the circadian

timing system flexibility in meeting the needs of the individual. The suprachiasmatic neurons are GABAergic, and they send the bulk of their output to an adjacent region called the subparaventricular zone. This area in the anterior hypothalamus contains mostly GABAergic neurons that fire in antiphase to the suprachiasmatic nucleus, ie, are most active at night. The targets of the subparaventricular zone largely overlap those of the suprachiasmatic nucleus, including parts of the paraventricular, dorsomedial, ventromedial, and lateral hypothalamus that regulate various physiological and behavioral systems. Presumably, then, the timing of a particular physiological or behavioral function would depend upon the relationships of these two antiphase circadian inputs to their target neurons.

One crucial target of the subparaventricular zone is the dorsomedial nucleus of the hypothalamus, which regulates a number of circadian behaviors, including the wake–sleep cycle. Lesions of the dorsomedial nucleus severely disrupt circadian rhythms of sleep, feeding, locomotor activity, and corticosteroid secretion. The dorsomedial nucleus is thought to promote wakefulness via GABAergic projections to the ventrolateral preoptic nucleus and glutamatergic projections to the lateral hypothalamus (Figure 44–7).

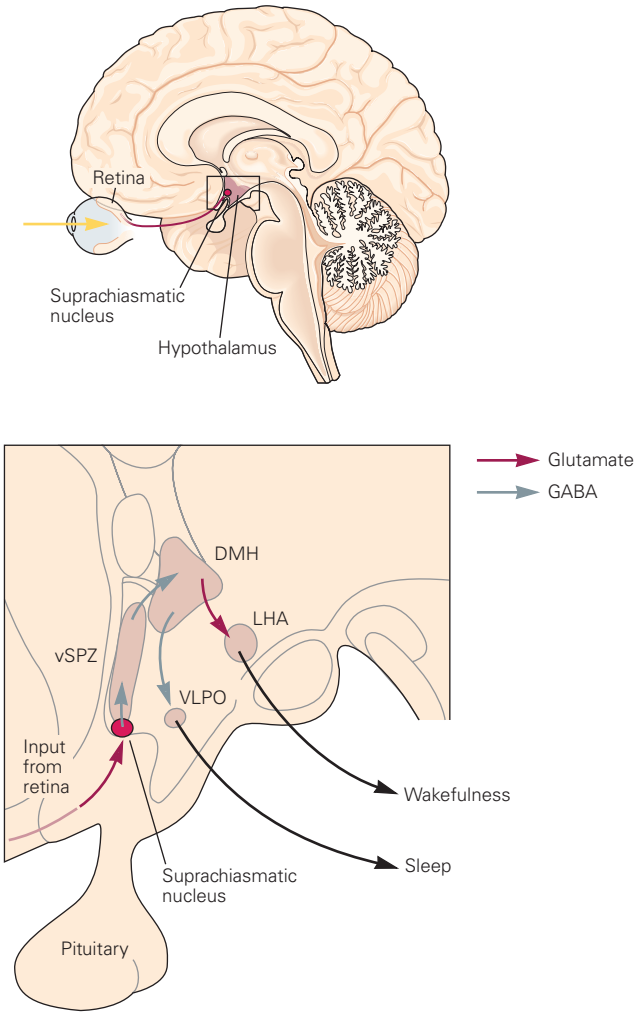

Figure 44–7 **Neurons in the suprachiasmatic nucleus provide a master clock for wake–sleep.** Retinal inputs signaling light activate the suprachiasmatic nucleus (**upper figure**), which then drives the wake–sleep cycle through a series of relays in the hypothalamus (**lower figure**). The sagittal section through the hypothalamus shows the suprachiasmatic nucleus projecting to neurons in the ventral subparaventricular zone (**vSPZ**), which in turn project to the dorsomedial nucleus of the hypothalamus (**DMH**). The DMH contains glutamatergic neurons that excite orexinergic and glutamatergic neurons in the lateral hypothalamic area (**LHA**), causing wakefulness. GABAergic neurons in the DMH inhibit the ventrolateral preoptic nucleus (**VLPO**), turning off the sleep-promoting system. Animals with DMH lesions fail to show circadian rhythms of wake–sleep and sleep about an hour more per day.

Sleep Loss Impairs Cognition and Memory

When people are sleepy, they often have impaired vigilance, working memory, judgement, and insight. Some of the attentional problems may be caused by *microsleeps*, brief periods of slower cortical activity. For example, subjects who rarely miss stimuli on the Psychomotor Vigilance Task when well rested may miss over 20% of the visual stimuli when sleepy. In addition to these global lapses in cortical function, sleepiness can also produce *local sleep* with slow EEG waves in focal cortical areas. Executive function is often the first thing to fail with sleepiness, and sleep-deprived people show reduced metabolism and focal slowing in the frontal cortex in EEGs.

While sleepiness impairs cognition, sleep itself helps consolidate memories. When subjects are taught a simple motor task, such as pressing buttons in a predetermined sequence, they become more efficient with practice. Robert Stickgold and colleagues found that if the training is in the morning, and the subjects are tested 12 hours later in the evening (without intervening sleep), they perform at about the same level as when they stopped their training. However, if they are tested the next morning after a night of sleep, they usually perform better than on the day of training. Subjects who are trained in the evening still perform better 12 hours later if they have had a chance to sleep overnight but not if they remained awake. Improvement of certain types of memory consolidation (eg, memory for a visual perception task) is correlated with the amount of REM sleep, while other types (eg, memory for a finger-tapping sequence task) correlate with stage N2 non-REM sleep.

These studies suggest that in each stage of sleep the cerebral cortex undergoes synaptic reorganization to consolidate the memory of specific types of salient information. Conversely, this memory consolidation is lost when subjects are deprived of sleep or have fragmented sleep. A related theory, proposed by Giulio Tononi and Chiara Cirelli, is that rebalancing of synaptic strengths based on recent experience (synaptic homeostasis) occurs during sleep. The size of many excitatory synapses is increased during learning, requiring that some excitatory inputs be reduced to avoid overexciting the target neuron. Tononi and Cirelli found that the size of smaller synapses in motor and sensory cortex is reduced during sleep, resulting in strong inputs being strengthened while competing weaker ones are removed.
