Diseases that cause sleep loss or that wake people from sleep can impair cognition. For example, *obstructive sleep apnea* can severely fragment sleep, resulting in daytime sleepiness, inattention, and other cognitive impairments. Fragmented sleep is also common in Alzheimer disease. Alzheimer patients tend to have fewer neurons in the ventrolateral preoptic nucleus, and the extent of neuronal loss correlates with their degree of sleep fragmentation. Whether treating sleep fragmentation can improve cognition in Alzheimer patients remains to be determined.

Sleep Changes With Age

Sleep changes with age in striking and characteristic ways. As every new parent quickly learns, the lengthy sleep time of a newborn is distributed almost randomly throughout the day. Although the EEG rhythms in newborns are not as well formed as those of older children or adults, more than 50% (8–9 hours per day) of that sleep is spent in a state much like REM sleep.

Sleep recordings from a premature infant exhibit an even higher percentage of REM-like sleep, indicating that in utero the fetus spends a large fraction of the day in a brain-activated but movement-inhibited state. As neuronal activity influences the development of functional circuits in the brain (Chapters 48 and 49), it is reasonable to think that the spontaneous activity of the immature brain during sleep facilitates the development of neural circuits.

By approximately 4 months of age, the average baby begins to show diurnal rhythms that are synchronized with day and night, much to the relief of weary parents. The total duration of sleep gradually declines, and by 5 years of age, the child may sleep 11 hours each night plus a nap, and 10 hours of sleep is typical around age 10. At these early ages, sleep is deep; stage N3 is prominent, with an abundance of delta waves in the EEG. As a result, children are not easily wakened by environmental stimuli.

With age, sleep becomes lighter and more fragmented. The percentage of time spent in stage N3 sleep drops across adulthood, and by the age of 50 to 60, it is not unusual for N3 to fade entirely, especially in men. This shift toward lighter stages of non-REM sleep results in two to three times as many spontaneous awakenings and more easily disrupted sleep. Many sleep disorders, including insomnia and sleep apnea, become more prevalent with age, and insomnia is common, often due to waking in response to neural signals to empty the bladder or due to discomfort from menopausal symptoms or from arthritis and other diseases. Why this change occurs with age is unclear; homeostatic sleep pressure appears normal, but the neural mechanisms for producing deep non-REM sleep may be less effective.

Disruptions in Sleep Circuitry Contribute to Many Sleep Disorders

Insomnia May Be Caused by Incomplete Inhibition of the Arousal System

Insomnia is one of the most common problems in all of medicine, yet the underlying neurobiology remains a mystery. Insomnia is defined as difficulty falling asleep or trouble staying asleep, so that function the next day is impaired. Positron emission tomography studies in patients with chronic insomnia demonstrate unusual activation of brain arousal systems during sleep, and the EEG often shows persistence of high-frequency activity (15–30 Hz) that is usually seen only during wake.

In addition, rats exposed to acute stress show high-frequency EEG activity during sleep, as well as simultaneous activity in neurons of the ventrolateral preoptic nucleus and components of the arousal system, such as the locus ceruleus and histamine neurons. This simultaneous activation can produce a unique state in which the EEG shows slow waves consistent with sleep along with high-frequency activity consistent with the awake state; this may explain why some patients appear asleep on the polysomnogram recording but they may feel awake.

Clinically, insomnia is often treated with cognitive behavioral therapy that is aimed at reducing the hyperarousal and improving sleep habits. Some patients may be treated with benzodiazepines and

related drugs that potentiate GABA transmission and, therefore, may help reduce activity in arousal-promoting brain regions. Other patients derive benefit from drugs that block the arousal system more directly, such as antihistamines.

Sleep Apnea Fragments Sleep and Impairs Cognition

Sleep apnea is one of the most common sleep disorders, affecting about 5% of adults and children. Patients with *obstructive sleep apnea* have repeated episodes of airway obstruction that force the individual to briefly awaken from sleep to resume breathing. During sleep, muscle tone falls, and in people with small airways, relaxation of airway dilator muscles such as the genioglossus (which normally acts to pull the tongue forward) results in collapse of the airway. This causes a brief period of no air flow, and consequently, blood levels of carbon dioxide rise while oxygen levels fall, activating chemosensory systems in the medulla that increase respiratory effort.

These chemosensory systems also activate neurons in the parabrachial nucleus that promote awakening, which results in a further increase in muscle tone that reopens the airway. These airway obstructions can occur hundreds of times per night, but the arousals are usually so brief that the individual may not remember them in the morning. Many people with obstructive sleep apnea do not feel rested in the morning; they feel sleepy all day and they have difficulty with a wide variety of cognitive tasks, especially those that require vigilance or learning.

Clinicians often treat sleep apnea with a *continuous positive airway pressure (CPAP) device* that delivers mildly pressurized air via the nose to inflate and open the airway during sleep. Sleep apnea can also be treated with upper airway surgery to remove obstructions such as large tonsils, a dental device to move the tongue forward, or weight loss to reduce adipose tissue in the neck. Treated patients often feel more alert and have better cognitive function, although there may be some residual cognitive impairment, possibly due to neuronal injury from repeated episodes of low oxygen saturation or hypoxia (Figure 44–8).

Narcolepsy Is Caused by a Loss of Orexinergic Neurons

Narcolepsy was first described in the late 1800s, but the underlying cause, a deficiency in a single

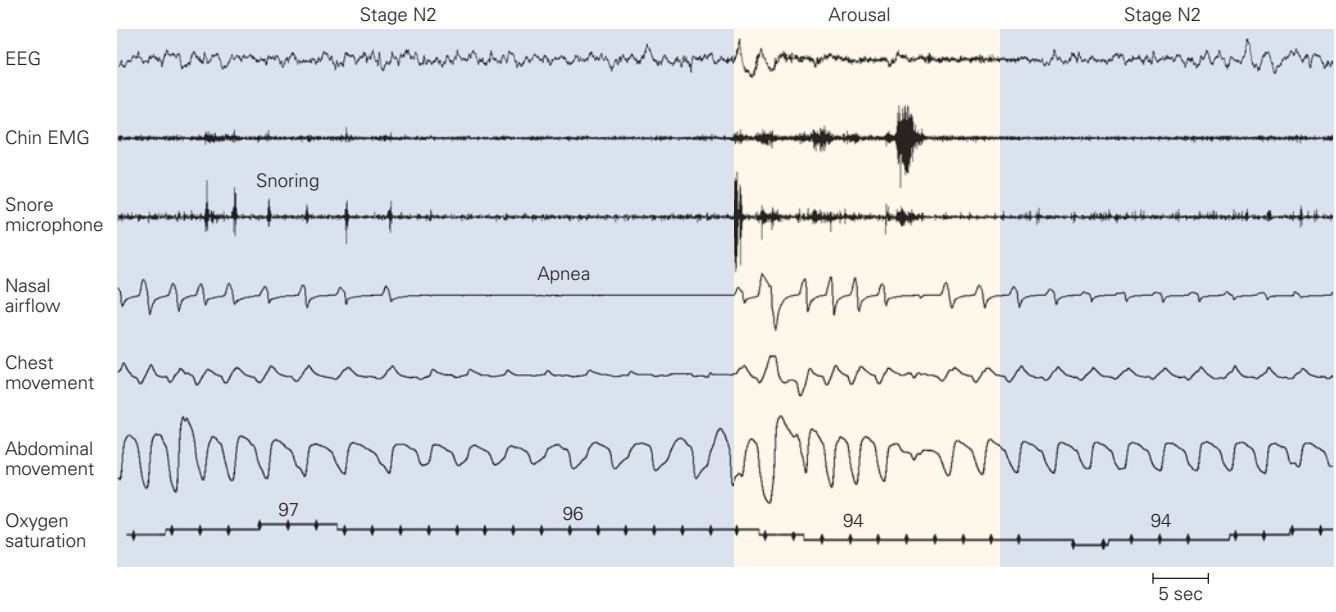

Figure 44–8 An episode of sleep apnea. At the start of this polysomnogram, an individual is in stage N2 sleep. Some snoring is detected, but nasal airflow is good and oxygen saturation is normal. The individual then experiences an obstructive apnea with no nasal airflow; nevertheless, respiratory effort persists (shown by the abdominal movement). The apnea is terminated by a brief awakening (low-voltage fast electroencephalogram [EEG]), accompanied by a loud snore, increased electromyographic activity, intensified respiratory effort, and opening of the airway. Oxygen saturation drops by about 3%, reaching its nadir about 15 seconds after the apnea finishes, as it takes time for blood to get from the lungs to the fingertip where oxygen saturation is measured.

neurotransmitter, has become clear only in the last two decades. Narcolepsy typically begins in the teen years as moderate to severe sleepiness every day, even with ample amounts of sleep at night. People with narcolepsy can easily fall asleep in class, while driving, or during other activities when sleep might be embarrassing or dangerous. Unlike sleep apnea, their sleep is restorative, and they often feel much more alert after a 15- to 20-minute nap.

In addition, in people with narcolepsy, elements of REM sleep often occur during wakefulness. For example, at night, while falling asleep or waking up, an individual with narcolepsy might find himself unable to move (*sleep paralysis*) or may have vivid dream-like hallucinations (*hypnagogic or hypnopompic hallucinations*) superimposed on wakefulness. Even more mysteriously, during the day, when surprised with a good joke or by unexpectedly seeing a friend, a person with narcolepsy can develop *cataplexy*, emotionally triggered muscle weakness that is similar to the paralysis of REM sleep. Mild cataplexy can cause weakness of the face and neck, but when severe, the individual can lose all muscle control, collapse to the ground, and be unable to move for 1 to 2 minutes.

Narcolepsy remained mysterious until the late 1990s when a new family of peptide neurotransmitters, orexins (also known as hypocretins), was discovered. There are two orexin peptides, derived from the same mRNA precursor, and they are found only in cells in the posterior lateral hypothalamus. It was soon found that loss of orexin signaling in animals or humans could reproduce the entire narcolepsy phenotype. People with narcolepsy show a highly selective loss of more than 90% of their orexin neurons, while other types of hypothalamic neurons are spared. This cell loss is probably due to an autoimmune attack as it is linked to genes that affect immune function and has been triggered by seasonal influenza epidemics and use of a certain influenza vaccine. Recently, researchers discovered that people with narcolepsy have immune cells (T lymphocytes) that target the orexin neuropeptides (Figure 44–9).

Orexinergic neurons promote wakefulness and suppress REM sleep, in part by activating monoaminergic neurons in the locus ceruleus and dorsal raphe as well as REM-off GABAergic neurons in the periaqueductal gray matter, all of which inhibit the REM sleep generating neurons in the pons. Thus, people and animals with loss of orexinergic neurons have great difficulty remaining awake for long periods, and REM sleep is disinhibited, such that REM sleep (or components of REM sleep, such as motor atonia during

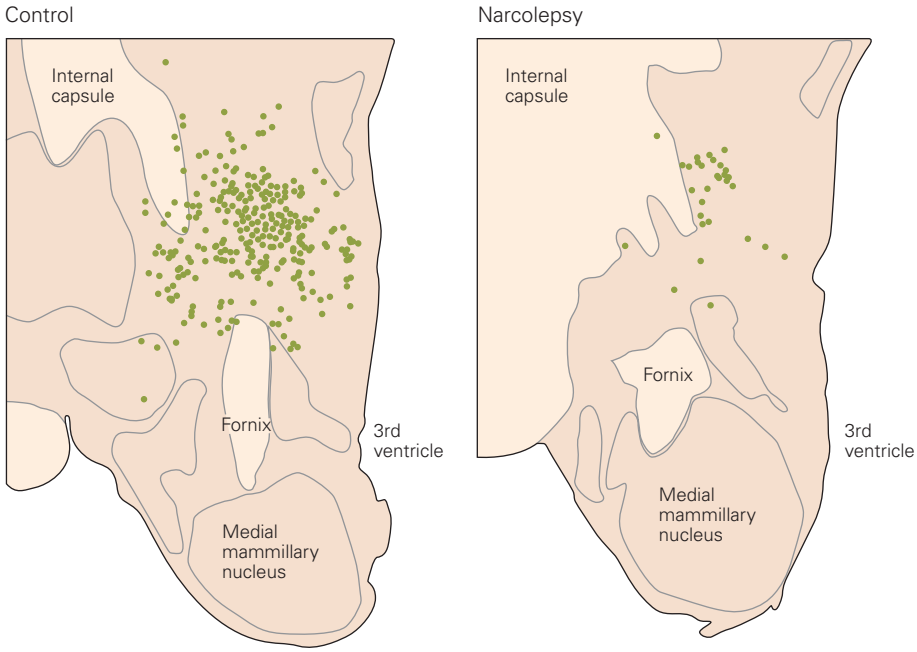

Figure 44–9 Narcolepsy is associated with a loss of hypothalamic neurons that produce the orexin neuropeptides. A dramatic loss of orexinergic neurons (**green dots**) is evident in these drawings of sections through the brain at the level of the mammillary bodies in an individual with narcolepsy (*right*) compared to a normal brain (*left*). (Reproduced, with permission, from Crocker et al. 2005. Copyright © 2005 American Academy of Neurology.)

wakefulness, or cataplexy) breaks through at inappropriate times during the day.

In terms of sleep circuitry, loss of orexinergic neurons can be considered to destabilize both the wake–sleep and the REM/non-REM switches in the brain. Thus, patients with narcolepsy can easily doze off during the day but also spontaneously wake from sleep more frequently at night. The dysregulation of REM sleep is also apparent on the Multiple Sleep Latency Test; healthy individuals almost never experience REM sleep during the day as it is under tight circadian control, but patients with narcolepsy often experience REM sleep during daytime naps.

The absence of orexin signaling also explains the mysterious symptom of cataplexy. Evidence from mice lacking orexins suggests that pleasant experiences turn on neurons in the prefrontal cortex and amygdala that can activate the brain stem pathways that trigger REM sleep paralysis. This influence is normally opposed by the orexin system, so that one may feel slightly "weak with laughter." When orexin signaling is absent, full-blown paralysis can occur.

Narcolepsy is treated with medications and behavioral approaches. Sleepiness can be substantially attenuated with wake-promoting medications such as amphetamine and modafinil. One to two strategically timed naps during the day are often helpful and can improve alertness for a couple of hours. Cataplexy often responds well to antidepressants such as serotonin or norepinephrine reuptake inhibitors, as these drugs strongly suppress REM sleep. Sodium oxybate taken during the night enhances deep sleep, and through an unknown mechanism, it helps consolidate wakefulness and reduce cataplexy during the day.

REM Sleep Behavior Disorder Is Caused by Failure of REM Sleep Paralysis Circuits

REM sleep behavior disorder—the loss of paralysis during REM sleep in some older adults—is the direct opposite of cataplexy. The lack of paralytic inhibition permits the patients to act out their dreams. The individual often calls out and may grab or violently punch or kick; injuries from hitting nearby furniture or the bed partner are not unusual. These dramatic movements typically awaken the patient, who can then recall a dream about fighting off an attacker in a way that closely matches the actual movements.

REM sleep behavior disorder was first identified in 1986 by Mahowald and Schenck. Ten years later, they reported that 40% of their original cohort of 19 patients had developed Parkinson disease or a related neurodegenerative disorder with deposition of alpha-synuclein, such as Lewy body dementia or multiple system atrophy. Subsequent studies have shown that about half of patients with REM sleep behavior disorder develop a synucleinopathy by 12 to 14 years after onset, and nearly all by 25 years. It is now thought that the synucleinopathy begins in the brain stem and early on damages the subceruleus neurons that normally drive REM sleep paralysis. If this relationship is confirmed, the diagnosis of REM sleep behavior disorder may identify individuals with nascent synucleinopathies who could be treated with drugs, not yet developed, that slow the neurodegeneration.

Restless Legs Syndrome and Periodic Limb Movement Disorder Disrupt Sleep

Restless legs syndrome occurs in about 10% of the population and is characterized by an irresistible urge to move the legs, usually accompanied by an annoying internal discomfort like "ants in the pants." This restless sensation typically occurs in the evening and first half of the night and often makes it hard to fall asleep. The sensation is much worse with rest and improves by moving the legs in bed or walking about.

Many people suffering from restless legs syndrome also experience *periodic limb movement disorder*, in which the legs and sometimes arms flex in a stereotyped way every 20 to 40 seconds during non-REM sleep. These leg movements fragment sleep and can produce daytime sleepiness. Iron deficiency is a common cause of restless legs, and treatment with iron can be very helpful. Genome-wide association studies have found genes common to both conditions, but the underlying pathophysiology is not yet understood. Patients with both disorders often improve with low doses of a D_2 dopamine agonist, the antiepileptic drug pregabalin, or an opiate drug.

Non-REM Parasomnias Include Sleepwalking, Sleep Talking, and Night Terrors

Parasomnias are unusual behaviors that occur during either REM or non-REM sleep. Non-REM parasomnias are common in children and include sleepwalking, sleep talking, confusional arousals, bed-wetting, and night terrors. About 15% of young adolescents have some sleepwalking, but this usually fades over time, so only about 1% of adults regularly sleepwalk.

The non-REM parasomnias typically begin with a sudden arousal from stage N3 sleep, which can occur spontaneously or be triggered by a noise or airway obstruction from sleep apnea. These are not full arousals, as for the first minute or two, the EEG still shows

the slow EEG delta waves typical of stage N3 sleep even as the child walks, dresses, or eats. Over time, the EEG changes to the pattern typical of wakefulness and eventually the individual wakes up. Sleepwalkers or talkers often have no memory of these events, so that reports from the family are necessary to make the diagnosis. Bed-wetting (enuresis) may also occur during deep non-REM sleep in some children.

Night terrors also occur in stage N3 sleep and are common in children age 2 to 5. The child often sits up and cries as if in great fear, sometimes with dilated pupils and a fast heart rate. During the episode, the child is inconsolable; attempts to calm or wake the child may only cause the screams and fearful behavior to worsen. Like sleep walking, but in contrast to ordinary nightmares, the child usually does not remember the night terror, and the events are typically much more difficult for the parent than the child.

The underlying cause of non-REM parasomnias is unknown. They are usually managed by ensuring adequate sleep to reduce pressure for deep non-REM sleep, reducing stress, and treating underlying sleep disorders such as sleep apnea that might trigger arousals from sleep. Fluid restriction in the evening may help with enuresis. Most children outgrow non-REM parasomnias as their N3 sleep decreases in late adolescence. Drugs that reduce the amount of N3 sleep, such as tricyclic antidepressants, are sometimes used as well. As with REM sleep behavior disorder, people can be seriously hurt sleepwalking if they fall down stairs or trip over furniture, and it is important to make the bedroom layout safe. The amount of time spent in stage N3 sleep is high in individuals with high homeostatic sleep pressure, so getting adequate sleep is also helpful.

Sleep Has Many Functions

Although there has been remarkable progress in our understanding of the brain circuitry that regulates sleep and wakefulness, we still understand relatively little about the actual functions of sleep. For an activity that occupies one-third of the life of humans, and much more in some other species, we have very little understanding of sleep's purposes. Allan Rechtschaffen, who first systematized the stages of sleep (and was an author of this chapter in earlier editions of this book), once said that if sleep did not have a vital function it would be the biggest mistake that evolution ever made. He found that rats would die of overwhelming infection and hypothermia if chronically deprived of sleep. However, the methods for keeping animals continuously awake were stressful, and it is unclear whether the consequences observed were due to loss of sleep or continuous stress. Indeed, it is not clear if prolonged sleep loss and stress can be dissociated.

One proposed function of sleep suggests that a period of brain inactivity is needed to permit metabolic recovery of the brain. The role of adenosine as a sleep-promoting humoral factor is based on the rundown of adenosine triphosphate (ATP) stores to adenosine during the awake period. Another idea is that sleep may permit the body to reconstitute injured tissue and replenish energy stores, but there is little evidence that sleep deprivation impairs any of these processes.

A recent hypothesis has been raised by the observation that during sleep the extracellular space in the brain expands, thus permitting the cerebrospinal fluid to "clean out" undesirable molecules that should not be allowed to build up extracellularly. The waking brain has very little extracellular space, largely due to ion fluxes to and from neurons during synaptic communication. These fluxes establish an osmotic gradient that drives most fluid in the brain into cells. During sleep, neurons and glia may shrink as that fluid moves back into the extracellular space. Among the molecules that may be washed out from the extracellular space during sleep are beta-amyloid peptides. In mice engineered to produce high levels of human beta-amyloid, sleep deprivation reduces the clearance of beta-amyloid from the extracellular space in the brain, thus accelerating its deposition in the plaques that are characteristic of Alzheimer disease (Chapter 64). Because buildup of beta-amyloid peptide in the brain is thought to be an early step in Alzheimer disease, work is now underway to determine whether poor sleep may predispose people to this disease.

In addition to these biochemical functions, sleep also promotes memory formation. As described earlier, the synaptic homeostasis model suggests that synapses are rebalanced during sleep, although it is not clear why this process would require sleep. A more basic need may be to provide a time for synapses to consolidate new memory traces. During the waking state, experience can modify synaptic strength on the fly by such processes as protein phosphorylation, insertion of premade receptors into the postsynaptic membrane, or translation of mRNA in the dendrites into new protein. But some portion of the synaptic remodeling that underlies memory formation requires nuclear-dependent transcription of new mRNA. Because synaptic sites on dendrites may be a millimeter from the nucleus or even more in some neurons, time is required for messenger molecules that are produced at the synapse to reach the nucleus and alter transcription and then for

the resulting mRNA to be transported back to the dendrite where it can result in new protein synthesis. This process may require a time when these messengers are not competing with new incoming signals to complete their work in stabilizing memories.

One thing about sleep is certain: It is required for normal brain function, and inadequate sleep, as defined by an increased tendency to fall asleep during the day, is associated with impaired cognitive function. Medical training programs are now being redesigned to reduce the risk of interns and residents making critical medical decisions while sleep deprived. Similar approaches to school start times, drowsy driving, and other aspects of our society could potentially improve productivity and save many lives.

Highlights

1. Sleep involves distinct changes in the electroencephalogram (EEG), electromyogram (EMG), and electro-oculogram (EOG) that are recorded on a polysomnogram. These changes can be used to divide sleep into rapid eye movement (REM) sleep—during which the EEG is similar to wake, but the body has such low muscle tone that it is essentially paralyzed—and three stages of non-REM sleep (N1–N3), with low to high amounts of slow waves in the EEG.
2. During the night, sleep alternates between periods of non-REM sleep followed by bouts of REM sleep, with the entire cycle taking about 90 minutes. Over the course of a night, non-REM sleep becomes progressively lighter, while REM sleep bouts become longer.
3. The waking state is actively produced by an ascending arousal network. The key neurons required to drive wakefulness are glutamatergic neurons in the parabrachial and pedunculopontine tegmental nuclei, dopaminergic neurons in the midbrain, glutamatergic neurons in the supramammillary nucleus, and GABAergic and cholinergic neurons in the basal forebrain that directly innervate the cerebral cortex. Modulatory cell groups, using mainly monoamines such as norepinephrine, serotonin, and histamine as neurotransmitters, can drive arousal under appropriate conditions, but unlike the main pathways, lesions of these cell groups do not impair baseline wakefulness.
4. During sleep, the ascending arousal system is inhibited by GABAergic neurons in the ventrolateral preoptic nuclei and the parafacial zone. Conversely, during wake, the ventrolateral preoptic neurons are inhibited by neurons in the ascending arousal system. These mutually antagonistic pathways produce a neural circuit resembling an electrical flip-flop switch, which favors rapid and complete transitions between sleep and wakefulness. Similarly, populations of mutually inhibitory neurons in the caudal midbrain and pons govern transitions between REM and non-REM sleep. Monoamine neurotransmitters, such as serotonin and norepinephrine, also act on these switching neurons and prevent transitions into REM sleep during wakefulness. Orexin neurons in the lateral hypothalamus activate REM sleep-suppressing neurons, preventing transitions from wake into REM sleep.
5. Sleep is regulated by a homeostatic drive to sleep, so that the longer one is awake, the more intense the drive, and the more sleep is required to satisfy the need to sleep. There is also a circadian influence on sleep that inhibits sleep during the day but promotes it at night, especially during the latter part of the night, when homeostatic sleep drive wanes. The circadian cycle is synchronized with the outside world by light signals from the retina to the brain's master circadian clock in the suprachiasmatic nucleus. The suprachiasmatic nucleus then activates hypothalamic pathways that regulate wake–sleep states, as well as many other behaviors, hormonal cycles, and physiological adjustments.
6. Sleep needs change throughout development, from about 16 hours per day in a newborn to about 8 hours per day in a healthy young adult. However, sleep-promoting mechanisms weaken with aging, and so individuals over 70 years old have more fragmented sleep and sleep about an hour less per day.
7. Sleep apnea is a condition in which the airway collapses due to reduced muscle tone during sleep. This impaired breathing causes frequent awakenings and can impair cognition. Restoring airway patency with continuous positive airway pressure (CPAP) can overcome this problem.
8. Insomnia may be caused by hyperactivation of the arousal system, and it is best treated with cognitive behavioral therapy.
9. Narcolepsy is caused by selective loss of the orexin (also called hypocretin) neurons in the hypothalamus. The orexin neuropeptides normally promote wake and regulate REM sleep, and loss of orexin signaling results in chronic daytime sleepiness and poor control of REM sleep.

Specifically, people with narcolepsy may quickly transition into REM sleep after dozing off, and they can have fragments of REM sleep, such as cataplexy and hypnogogic hallucinations, during wake. Narcolepsy is usually treated with medications that promote wake and suppress REM sleep.

10. REM sleep behavior disorder is due to loss of atonia during REM sleep, causing patients to act out their dreams. REM sleep behavior disorder is usually an early manifestation of either Parkinson disease or Lewy body dementia.
11. Restless legs syndrome is a genetically influenced disorder in which people feel that they have to move their legs. This makes them very uncomfortable when awake, and they can have periodic leg movements during sleep that disrupt sleep.
12. Sleepwalking and related parasomnias usually occur in young children during deep (stage N3) non-REM sleep. They are best managed by ensuring adequate, good-quality sleep.
13. Sleep loss impairs the ability to maintain sustained attention and clouds judgment. The reasons for this are not understood. Theories about the brain requiring down time to recharge its metabolic status or to allow it to flush out unwanted products from the extracellular space have received attention, but it is unclear whether this accounts for the penalty paid due to lack of sleep. One attractive theory for the function of sleep is that it may be required for synaptic remodeling that is necessary for certain types of learning.

VII Development and the Emergence of Behavior

THE INNUMERABLE BEHAVIORS controlled by the mature nervous system—our thoughts, perceptions, decisions, emotions, and actions—depend on precise patterns of synaptic connectivity among the billions of neurons in our brain and spinal cord. These connections form during embryonic and early postnatal life but can then be remodeled throughout life. In this section, we describe how the nervous system develops and matures.

The history of developmental neurobiology is long and illustrious. Nearly 150 years ago, Santiago Ramón y Cajal undertook a comprehensive series of anatomical studies on the structure and organization of the nervous system and then set out to probe its development. The only method available to him was light microscopic analysis of fixed tissue, but from his observations, he deduced many developmental principles that are still recognized as correct. During the first half of the 20th century, other anatomists followed in his footsteps. Progress then accelerated as new methods became available—first electrophysiology and electron microscopy and, more recently, molecular biology, genetics, and live imaging. We now know a great deal about molecules that determine how nerve cells acquire their identities, how they extend axons to target cells, and how these axons choose appropriate synaptic partners once they have arrived at their destinations.

It is useful to divide the numerous steps that compose neural development into three epochs, which are conceptually distinct even though they overlap temporally to some extent. The first, beginning at the earliest stages of embryogenesis, leads to the generation and differentiation of neurons and glia. One can think of this epoch as devoted to producing the components from which neural circuits will be assembled: the hardware. These steps depend on the expression of particular genes at particular times and places. Some of the molecules that control these spatial and temporal patterns are transcription factors that act at the level of DNA to regulate gene expression. They act within the differentiating cells and are therefore called cell-autonomous factors. Other factors, called cell non-autonomous, include cell surface and secreted molecules that arise from other cells.

They act by binding to receptors on the differentiating cells and generating signals that regulate the activity of the cell-autonomous transcriptional programs. The interaction of these intrinsic and extrinsic factors is critical for the proper differentiation of each nerve cell.

A second epoch encompasses the steps by which neurons wire up: the migration of their somata to appropriate places, the guidance of axons to their targets, and the formation of synaptic connections. The complexity of the wiring problem is staggering—axons of many neuronal types must navigate, often over long distances, and then choose among a hundred or more potential synaptic partners. Nonetheless, progress has been encouraging. A major factor has been the ability to address the problem through the analysis of simple and genetically accessible organisms such as the fruit fly *Drosophila* and the nematode worm *Caenorhabditis elegans*. It turns out that many of the key molecules that control the formation of the nervous system are conserved in organisms separated by millions of years of evolution. Thus, despite the great diversity of animal forms, the developmental programs that govern body plan and neural connectivity are conserved throughout phylogeny.

In the third epoch, the genetically determined patterns of connectivity (the hardware) are molded by activity and experience (the software). Unfortunately for investigators, these steps in mammals are shared to a very limited degree with invertebrates and lower vertebrates. A newly hatched bird or fly is not remarkably different in its behavioral repertoire from its adult self, but no one could say that about a person. This is largely because our nervous system is something of a rough draft at birth. The hardwired circuits that lay out its basic plan are modified over a prolonged postnatal period by experience, acting via neural activity. In this way, the experience of each individual can leave indelible imprints on his or her nervous system and the cognitive abilities of the brain can be enhanced by learning. These processes act in all mammals, and neuroscientists now use mice to probe the mechanisms that underlie them—but they are especially prominent and prolonged in humans. It may be that the prolonged period during which experience can sculpt the human nervous system is the most important single factor in making its capabilities unique among all species.

As our understanding of development increases, it is increasingly informing neurology and psychiatry. Many genes that regulate the first two epochs have now been implicated as susceptibility factors for, or even causes of, some neurodegenerative and behavioral disorders. Thus, studies of neural development are beginning to provide insights into the etiology of neurological diseases and to suggest rational strategies for restoring neural connections and function after disease or traumatic injury. More recently, as we learn about the cellular and molecular changes that underlie experience-dependent remodeling, we can hope to understand how, for example, the plasticity that is so evident during early life can be recruited in adults to

improve rehabilitative therapy after injury, stroke, or neurodegenerative disease. Moreover, there is increasing reason to believe that some behavioral disorders, such as autism or schizophrenia, may result in part from defects in the experience-dependent tuning of neural circuits during early postnatal life.

Part VII summarizes these epochs in a sequential manner. Beginning with the early stages of neural development, we concentrate on the factors that control the diversity and survival of nerve cells, guide axons, and regulate the formation of synapses. We then explain how interactions with the environment, both social and physical, modify or consolidate the neural connections formed during early development. Finally, we examine ways in which developmental processes can be harnessed in adults and how factors such as steroid hormones mold the brain, affecting sexual and gender identity. The last steps—changes that occur as the brain ages—are covered in Section IX (Chapter 64).

Patterning the Nervous System

A vast array of neurons and glial cells is produced during development of the vertebrate nervous system. Different types of neurons develop in discrete anatomical positions, acquire varied morphological forms, and establish connections with specific populations of target cells. Their diversity is far greater than that of cells in any other organ of the body. The retina, for example, has dozens of types of interneurons, and the spinal cord has more than a hundred types of motor neurons. At present, the true number of neuronal types in the mammalian central nervous system remains unknown, but it is surely more than a thousand. The number of glial types is even less clear; unexpected heterogeneity is being discovered in what was thought, until recently, to be rather homogeneous classes of astrocytes and oligodendrocytes.

The diversity of neuronal types underlies the impressive computational properties of the mammalian nervous system. Yet, as we describe in this chapter and those that follow, the developmental principles that drive the differentiation of the nervous system are begged and borrowed from those used to direct the development in other tissues. In one sense, the development of the nervous system merely represents an elaborate example of the basic challenge that pervades

all of developmental biology: how to convert a single cell, the fertilized egg, into the highly differentiated cell types that characterize the mature organism. Only at later stages, as the neurons form complex circuits and experience modifies their connections, do principles of neural development diverge from those in other organs.

Early developmental principles are conserved not only among tissues but also across species and phyla. Indeed, much of what we know about the cellular and molecular bases of neural development in vertebrates comes from genetic studies of so-called simple organisms, most notably the fruit fly *Drosophila melanogaster* and the worm *Caenorhabditis elegans.* Nevertheless, because a main goal of studying neural development is to explain how the assembly of the nervous system underlies both human behavior and brain disorders, our description of the rules and principles of nervous system development focus primarily on vertebrate organisms.

The Neural Tube Arises From the Ectoderm

The vertebrate embryo arises from the fertilized egg. Cell divisions initially form a ball of cells, called the morula, which then hollows out to form the blastula. Next, infoldings and growth generate the gastrula, a structure with polarity (dorsal-ventral and anterior-posterior) and three layers of cells—the endoderm, mesoderm, and ectoderm (Figure 45–1A).

The *endoderm* is the innermost germ layer that later gives rise to the gut, as well as to the lungs, pancreas, and liver. The *mesoderm* is the middle germ layer that gives rise to muscle, connective tissues, and much of the vascular system. The *ectoderm* is the outermost layer. Most of the ectoderm gives rise to the skin, but a narrow central strip flattens out to become the *neural plate* (Figure 45–1B). It is from the neural plate that the central and peripheral nervous systems arise.

Soon after the neural plate forms, it begins to invaginate, forming the *neural groove.* The folds then deepen and eventually separate from the rest of the ectoderm to form the *neural tube*, through a process called neurulation (Figure 45–1C,D). The caudal region of the neural tube gives rise to the spinal cord, whereas the rostral region becomes the brain. As the neural tube closes, cells at its junction with the overlying ectoderm are set aside to become the neural crest, which eventually gives rise to the autonomic and sensory nervous systems, as well as several non-neural cell types (Figure 45–1E).

Secreted Signals Promote Neural Cell Fate

As with other organs, the emergence of the nervous system is the culmination of a complex molecular program that involves the tightly orchestrated expression of specific genes. For the nervous system, the first step is the formation of the neural plate from a restricted region of the ectoderm. This step reflects the outcome of an early choice that ectodermal cells have to make: whether to become neural or epidermal cells. This decision has been the subject of intense study for nearly 100 years.

Much of this work has focused on a search for signals that control the fate of ectodermal cells. We now know that two major classes of proteins work together to promote the differentiation of an ectodermal cell into a neural cell. The first are *inductive factors,* signaling molecules that are secreted by nearby cells. Some of these factors are freely diffusible and exert their actions at a distance, but others are tethered to the cell surface and act locally. The second are surface receptors that enable cells to respond to inductive factors. Activation of these receptors triggers the expression of genes encoding intracellular proteins—transcription factors, enzymes, and cytoskeletal proteins—that push ectodermal cells along the pathway to becoming neural cells.

The ability of a cell to respond to inductive signals, termed its *competence,* depends on the exact repertoire of receptors, transduction molecules, and transcription factors that it expresses. Thus, a cell's fate is determined not only by the signals to which it is exposed—a consequence of when and where it finds itself in the embryo—but also by the profile of genes it expresses as a consequence of its prior developmental history. We will see in subsequent chapters that the interaction of localized inductive signals and intrinsic cell responsiveness is evident at virtually every step throughout neural development.

Development of the Neural Plate Is Induced by Signals From the Organizer Region

The discovery that specific signals are responsible for triggering the formation of the neural plate was the first major advance in understanding the mechanisms that pattern the nervous system. In 1924, Hans Spemann and Hilde Mangold made the remarkable observation that the differentiation of the neural plate from uncommitted ectoderm depends on signals secreted by a specialized group of cells they called the *organizer region.*

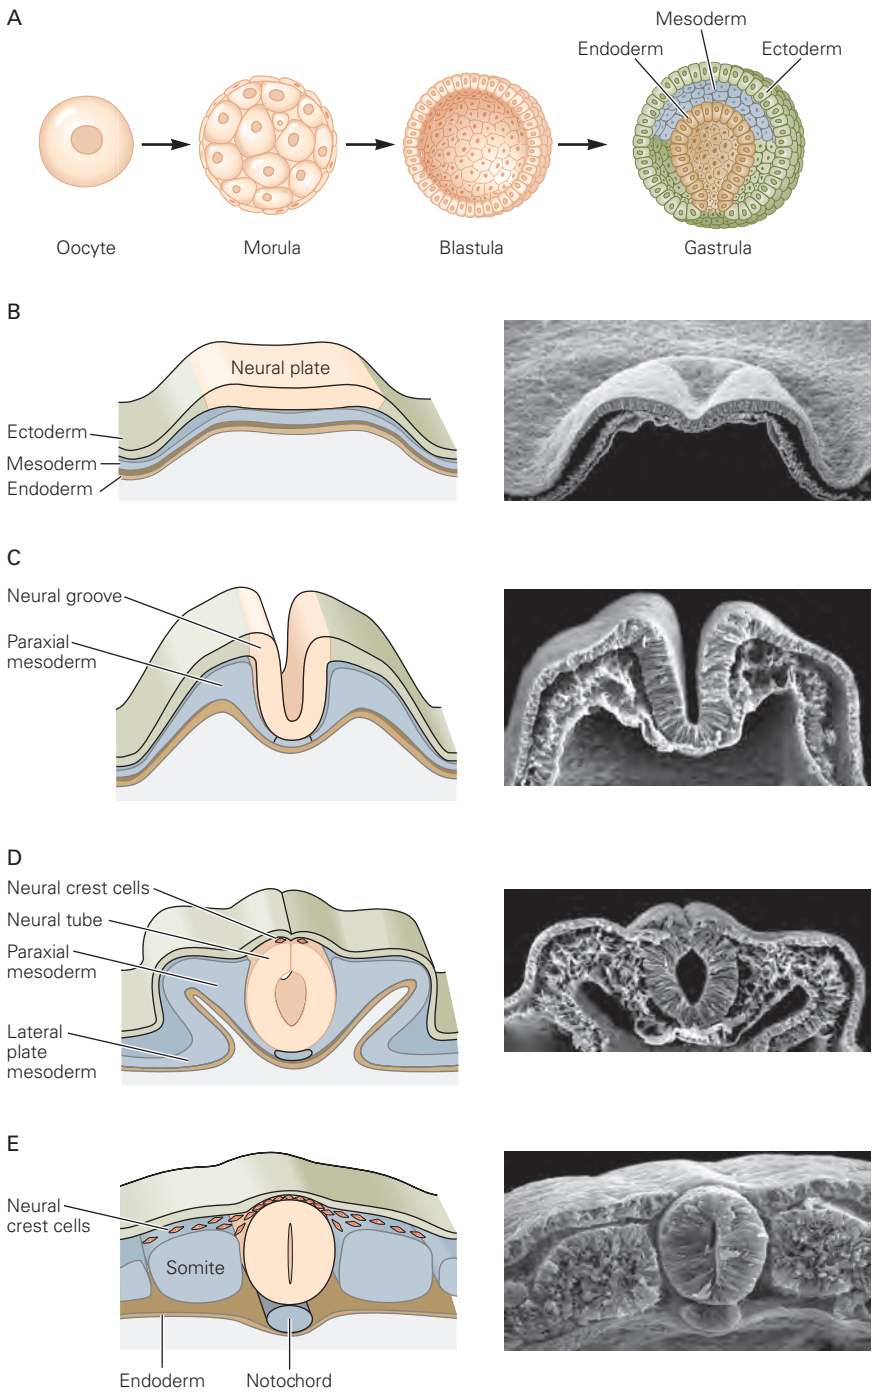

Figure 45–1 The neural plate folds to form the neural tube. (Scanning electron micrographs of chick neural tube reproduced, with permission, from G. Schoenwolf.)

A. Following fertilization of the egg by sperm, cell divisions give rise successively to the morula, blastula, and gastrula. Three germ cell layers—the ectoderm, mesoderm, and endoderm—form during gastrulation.

B. A strip of ectoderm becomes the neural plate, the precursor of the central and peripheral nervous systems.

C. The neural plate buckles at its midline to form the neural groove.

D. Closure of the dorsal neural folds forms the neural tube.

E. The neural tube lies over the notochord and is flanked by somites, an ovoid group of mesodermal cells that give rise to muscle and cartilage. Cells at the junction between the neural tube and overlying ectoderm are set aside to become the neural crest.

Their experiments involved transplanting small pieces of tissue from one amphibian embryo to another. Most telling were transplantations of the dorsal lip of the blastopore, which is destined to form the dorsal mesoderm, from its normal dorsal position to the ventral side of a host embryo. The dorsal lip lies underneath the dorsal ectoderm, a region that normally gives rise to dorsal epidermis, including the neural plate (Figure 45–2). They grafted the tissue from a pigmented embryo into unpigmented host, allowing them to distinguish the position and fate of donor and host cells.

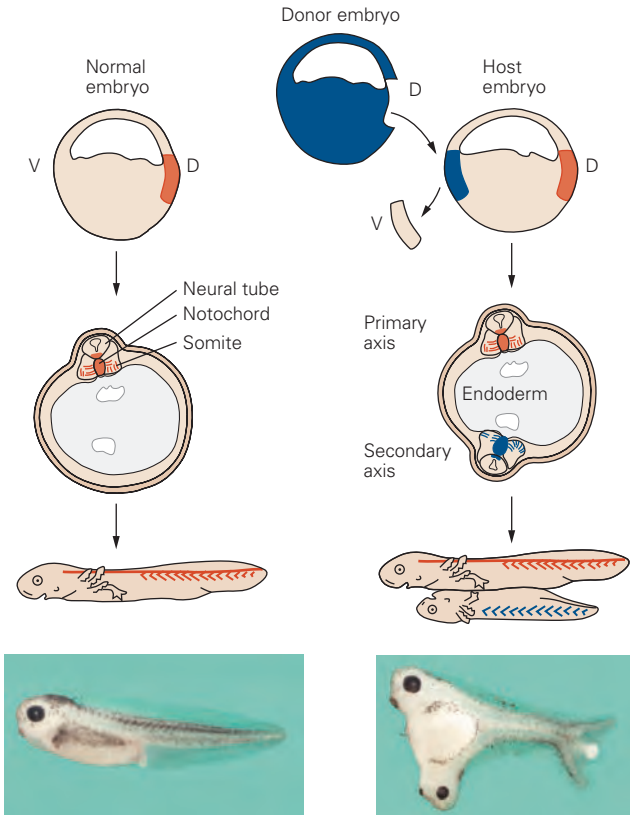

Figure 45–2 Signals from the organizer region induce a second neural tube. (Micrographs reproduced, with permission, from Eduardo de Robertis.)

Left: In the normal frog, embryo cells from the organizer region (the dorsal blastopore lip) populate the notochord, floor plate, and somites. *Right:* Spemann and Mangold grafted the dorsal blastopore lip from an early gastrula stage embryo into a region of a host embryo that normally gives rise to the ventral epidermis. Signals from grafted cells induce a second embryonic axis, which includes a virtually complete neural tube. The donor tissue was from a pigmented embryo, whereas the host tissue was unpigmented, permitting the fate of grafted cells to be monitored by their color. Grafted cells themselves contribute only to the notochord, floor plate, and somites of the host embryo. As the embryo matures, the secondary neural tube develops into a complete nervous system. In the *Xenopus* embryo shown in the micrograph, the second neural axis was induced by injection of an antagonist of bone morphogenetic protein (BMP), in effect substituting for the organizer signal (Figure 45–3). The primary neural axis is also apparent. (Abbreviations: **D**, dorsal; **V**, ventral.)

Spemann and Mangold found that transplanted cells from the dorsal lip of the blastopore followed their normal developmental program, generating midline mesoderm tissue such as the somites and notochord. But the transplanted cells also caused a striking change in the fate of the neighboring ventral ectodermal cells of the host embryo. Host ectodermal cells were induced to form a virtually complete copy of the nervous system (Figure 45–2). They therefore called the donor tissue the *organizer*. Spemann and Mangold went on to show that the dorsal lip of the blastopore was the only tissue that possessed this "organizing" effect.

These pioneering studies also demonstrated that "induction" plays a critical role in neural development. Induction is a process by which cells of one tissue direct the development of neighboring cells at a region where the two come into proximity. The importance is that it provides a mechanism by which signals from one tissue can lead to subdivision of a second tissue. In this case, the mesoderm induces one part of the ectoderm to become the neural plate, and eventually the nervous system, while the remainder goes on to become epithelium, and eventually skin. The new juxtaposition thereby formed could, in principle, set the stage for a cascade of subsequent inductions and subdivisions. Indeed, we will see that many aspects of neural tube patterning are now known to depend on signals secreted by local organizing centers through actions similar in principle to that of the classical organizer region.

Neural Induction Is Mediated by Peptide Growth Factors and Their Inhibitors

For decades after Spemann and Mangold's pioneering studies, identification of the neural inducer constituted a Holy Grail of developmental biology. The search was marked by little success until the 1980s, when the advent of molecular biology and the availability of better markers of early neural tissue led to breakthroughs in our understanding of neural induction and its chemical mediators.

The first advance came from a simple finding: When the early ectoderm is dissociated into single isolated cells, effectively preventing cell-to-cell signaling, the cells readily acquire neural properties in the absence of added factors (Figure 45–3A). The surprising implication of this finding was that the "default" fate of ectodermal cells is neural differentiation and that this fate is prevented by signaling among ectodermal cells. In this model, the long sought-after "inducer" is actually a "de-repressor": It prevents ectoderm from repressing neural fate.

These ideas immediately raised two further questions. What ectodermal signal represses neural differentiation, and what does organizer tissue provide to overcome the effects of the repressor? Studies of neural induction in frogs and chicks have now provided answers to these questions.

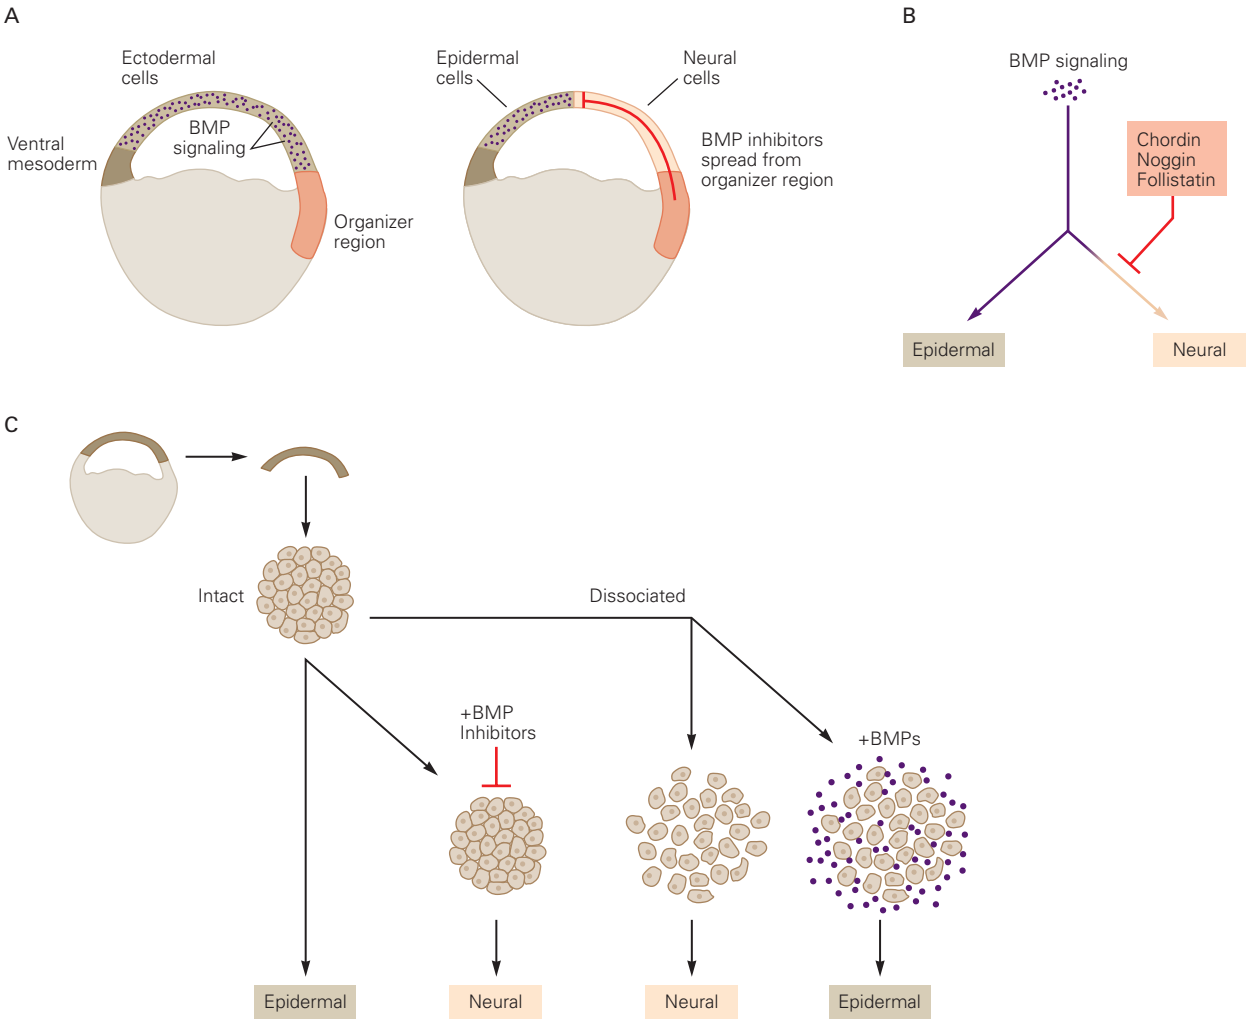

Figure 45–3 Inhibition of bone morphogenetic protein (BMP) signaling initiates neural induction.

A. In *Xenopus* frog embryos, signals from the organizer region (**red line**) spread through the ectoderm to induce neural tissue. Ectodermal tissue that is beyond the range of organizer signals gives rise to epidermis.

B. BMP inhibitors secreted from the organizer region (including noggin, follistatin, and chordin) bind to BMPs and block the ability of ectodermal cells to acquire an epidermal fate, thus promoting neural character.

C. Ectodermal cells acquire neural or epidermal character depending on the presence or absence of BMP signaling. When ectodermal cell aggregates are exposed to BMP signaling, they differentiate into epidermal tissue. When BMP signaling is blocked, either by dissociating ectodermal tissue into single cells or by addition of BMP inhibitors to ectodermal cell aggregates, the cells differentiate into neural tissue.

In the absence of signals from the organizer, ectodermal cells synthesize and secrete *bone morphogenetic proteins* (BMPs), members of a large family of transforming growth factor β (TGFβ)-related proteins. The BMPs, acting through serine/threonine kinase class receptors on ectodermal cells, suppress the potential for neural differentiation and promote epidermal differentiation (Figure 43–3B). Key evidence for the role of BMPs as neural repressors came from experiments in which a truncated version of a BMP receptor, which blocks BMP signaling, was found to trigger the differentiation of neural tissue in the *Xenopus* frog embryo. Conversely, exposure of ectodermal cells to BMP signaling promoted differentiation as epidermal cells (Figure 45–3C).

The identification of BMPs as suppressors of neuronal differentiation in turn suggested that the

organizer might induce neural differentiation in ectodermal cells by secreting factors that antagonize BMP signaling. Direct support for this idea came from the finding that cells of the organizer region express many secreted proteins that act as BMP antagonists. These proteins include noggin, chordin, follistatin, and even some variant BMP proteins. Each of these proteins has the ability to induce ectodermal cells to differentiate into neural tissue (Figure 45–3B). Thus, there is no single neural inducer. In fact, multiple classes of proteins are required for induction, as shown by the later finding that the exposure of ectodermal cells to fibroblast growth factors (FGFs) is also a necessary step in neural differentiation.

Together, these studies provided a molecular explanation of the cellular phenomenon of neural induction. Although many details of the pathway remain to be clarified and some mechanistic differences among species remain perplexing, a key chapter in neural development has now been brought to a satisfying conclusion nearly a century after the organizer was discovered by Spemann and Mangold.

Rostrocaudal Patterning of the Neural Tube Involves Signaling Gradients and Secondary Organizing Centers

As soon as cells of the neural plate have been induced, they begin to acquire regional characteristics that mark the first steps in dividing the nervous system into regions such as forebrain, midbrain, hindbrain, and spinal cord. The subdivision is directed by a series of secreted inductive factors and follows the same basic principles of neural induction. Neural plate cells in different regions of the neural tube respond to these inductive signals by expressing distinct transcription factors that gradually constrain the developmental potential of cells in each local domain. In this way, neurons in different positions acquire functional differences. Signaling occurs along both the rostrocaudal and the dorsoventral axes of the neural tube. We begin by describing rostrocaudal patterning and then return to dorsoventral patterning.

The Neural Tube Becomes Regionalized Early in Development

After the neural tube forms, cells divide rapidly, but rates of proliferation are not uniform. Individual regions of the neural epithelium expand at different rates and begin to form the specialized parts of the mature central nervous system. Differences in the rate of proliferation of cells in rostral regions of the neural tube result in the formation of three brain vesicles: the forebrain (or prosencephalic) vesicle, the midbrain (or mesencephalic) vesicle, and the hindbrain (or rhombencephalic) vesicle (Figure 45–4A).

At this early three-vesicle stage, the neural tube flexes twice: once at the *cervical flexure,* at the junction of the spinal cord and hindbrain, and once at the *cephalic flexure,* at the junction of the hindbrain and midbrain. A third flexure, the *pontine flexure,* forms later, and later still, the cervical flexure straightens out and becomes indistinct (Figure 45–4D). The cephalic flexure remains prominent throughout development, and its persistence is the reason why the orientation of the longitudinal axis of the forebrain deviates from that of the brain stem and spinal cord.

As the neural tube develops, two of the primary embryonic vesicles divide further, thus forming five vesicles (Figure 45–4B,C). The forebrain vesicle divides to form the telencephalon, which will give rise to the cortex, hippocampus, and basal ganglia, and the diencephalon, which will give rise to the thalamus, hypothalamus, and retina. The mesencephalon, which does not divide further, gives rise to the inferior and superior colliculi and other midbrain structures. The hindbrain vesicle divides to form the metencephalon, which will give rise to the pons and cerebellum, and the myelencephalon, which will give rise to the medulla. Together with the spinal cord, these divisions make up the major functional regions of the mature central nervous system (see Chapter 4). The progressive subdivision of the neural tube into these functional domains is regulated by a variety of secreted signals.

Signals From the Mesoderm and Endoderm Define the Rostrocaudal Pattern of the Neural Plate

It was originally believed that the organizer, as defined by Spemann and Mangold, was uniform in character, and therefore induced an initially uniform neural plate. Subsequent studies showed, however, that the organizer is regionally specialized and secretes factors that initiate the rostrocaudal patterning of the neural plate almost as soon as induction commences. One important class of factors comprises the Wnt proteins (an acronym based on their founding family members, the *Drosophila W*ingless protein and the mammalian Int1 proto-oncogene protein). Others include retinoic acid and FGFs. They are produced by mesodermal cells of the organizer as well as nearby paraxial mesoderm.

The net level of Wnt signaling activity is low at rostral levels of the neural plate and increases

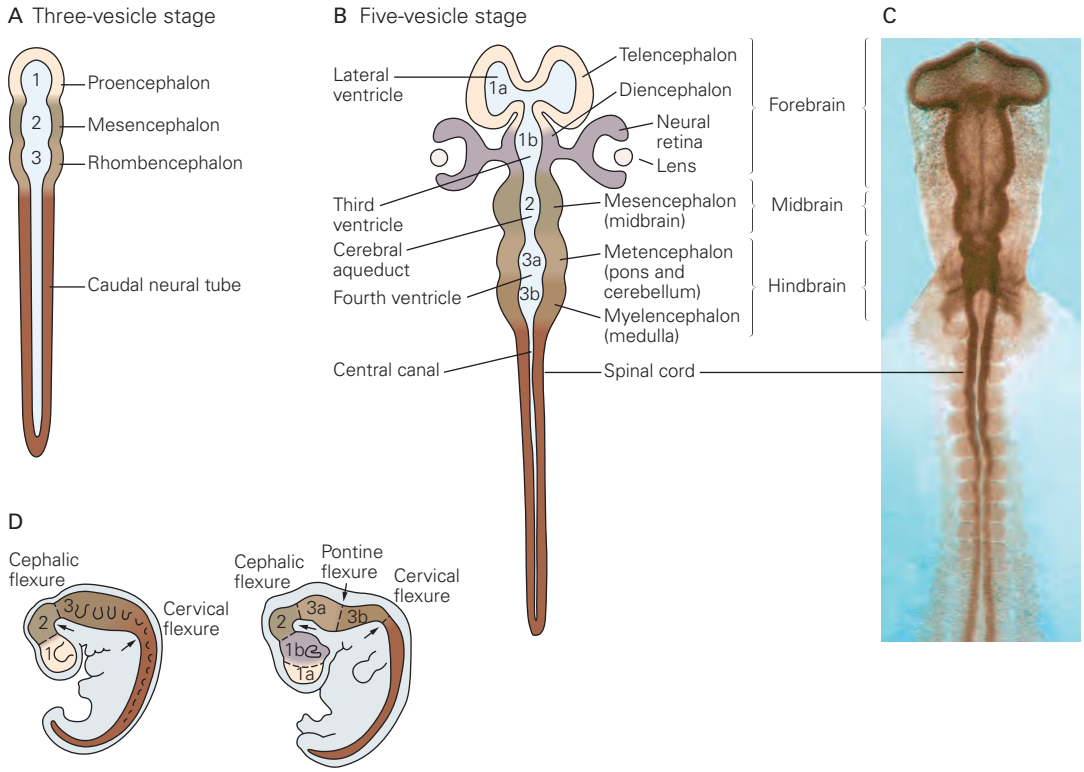

Figure 45–4 Sequential stages of neural tube development.

A. At early stages of neural tube development, there are three brain vesicles, which will form the prosencephalon (forebrain), mesencephalon (midbrain), and rhombencephalon (hindbrain).

B. Further division within the prosencephalon and rhombencephalon generate additional vesicles. The prosencephalon splits to form the telencephalon and diencephalon, and the rhombencephalon splits to form the metencephalon and the myelencephalon.

C. Top-down view of the neural tube of a chick embryo at the five-vesicle stage. (Reproduced, with permission, from G. Schoenwolf.)

D. The neural tube bends at borders between vesicles, forming the cephalic, pontine, and cervical flexures.

progressively in the caudal direction. This activity gradient arises because the mesoderm adjacent to the caudal region of the neural plate expresses high levels of Wnt. Sharpening this gradient, tissue that underlies the rostral region of the neural plate is a source of secreted proteins that inhibit Wnt signaling, much as BMP inhibitors attenuate BMP signaling at an earlier stage. Thus, cells at progressively more caudal positions along the neural plate are exposed to increasing levels of Wnt activity and acquire a more caudal regional character, spanning the entire range from forebrain to midbrain to hindbrain and finally to spinal cord (Figure 45–5A). These results suggest that an anterior character is the "default" state for neural tissue, with signals such as Wnt imposing a posterior character. Indeed, when ectodermal cells are induced to become neural by application of BMP inhibitors, they differentiate into cells characteristic of anterior structures.

Signals From Organizing Centers Within the Neural Tube Pattern the Forebrain, Midbrain, and Hindbrain

The early influence of mesodermal and endodermal tissues on rostrocaudal neural pattern is further refined by signals from specialized cell groups in the neural tube itself. One that has been studied in particular detail is called the *isthmic organizer*, which forms at the boundary of the hindbrain and midbrain (Figure 45–5B). The isthmic organizer serves a key role in patterning these two domains of the neural tube as well as in specifying the neuronal types within them. Dopaminergic neurons of the substantia nigra and ventral tegmental area are generated in the midbrain, just rostral to the isthmic organizer, whereas serotonergic neurons of the raphe nuclei are generated just caudal to the isthmic organizer, within the hindbrain. As an illustration of how these secondary neural signaling

centers impose neural pattern, we describe the origin and signaling activities of the isthmic organizer.

The rostrocaudal positional character of the neural plate stems from the expression of homeodomain transcription factors, the homeodomain being a section of the protein that binds to a specific DNA sequence in regulatory regions of genes, leading to changes in the gene's transcription. Cells in forebrain and midbrain domains of the neural plate express Otx2, whereas cells in the hindbrain domain express Gbx2, both of which are homeodomain transcription factors. The point of transition between Otx2 and Gbx2 expression is located at the midbrain–hindbrain boundary (Figure 45–5B) and marks the position at which the isthmic organizer will emerge after neural tube closure. At this boundary, other transcription factors are expressed, notably En1 (an Engrailed class transcription factor).

These transcription factors in turn control the expression of two signaling factors, Wnt1 and FGF8, by cells of the isthmic organizer. Wnt1 is involved in the proliferation of cells in the midbrain–hindbrain domain and in the maintenance of FGF8 expression. The spread of FGF8 from the isthmic organizer into the midbrain domain marked by Otx2 expression induces differentiation of dopaminergic neurons, whereas its spread into the hindbrain domain marked by Gbx2 expression triggers the differentiation of serotonergic neurons (Figure 45–5C).

The roles of FGF8 and Wnt1 in signaling from the *isthmic organizer* illustrate an important economy in early neural patterning. The early actions of inductive signals impose discrete domains of transcription factor expression, and these transcriptional domains then allow cells to interpret the actions of the same secreted factor in different ways, producing different neuronal subtypes. In this way, a relatively small number of secreted factors—FGFs, BMPs, hedgehog proteins, Wnt proteins, and retinoic acid—are used in different regions and at different times to program the vast diversity of neuronal cell types generated within the central and peripheral nervous systems.

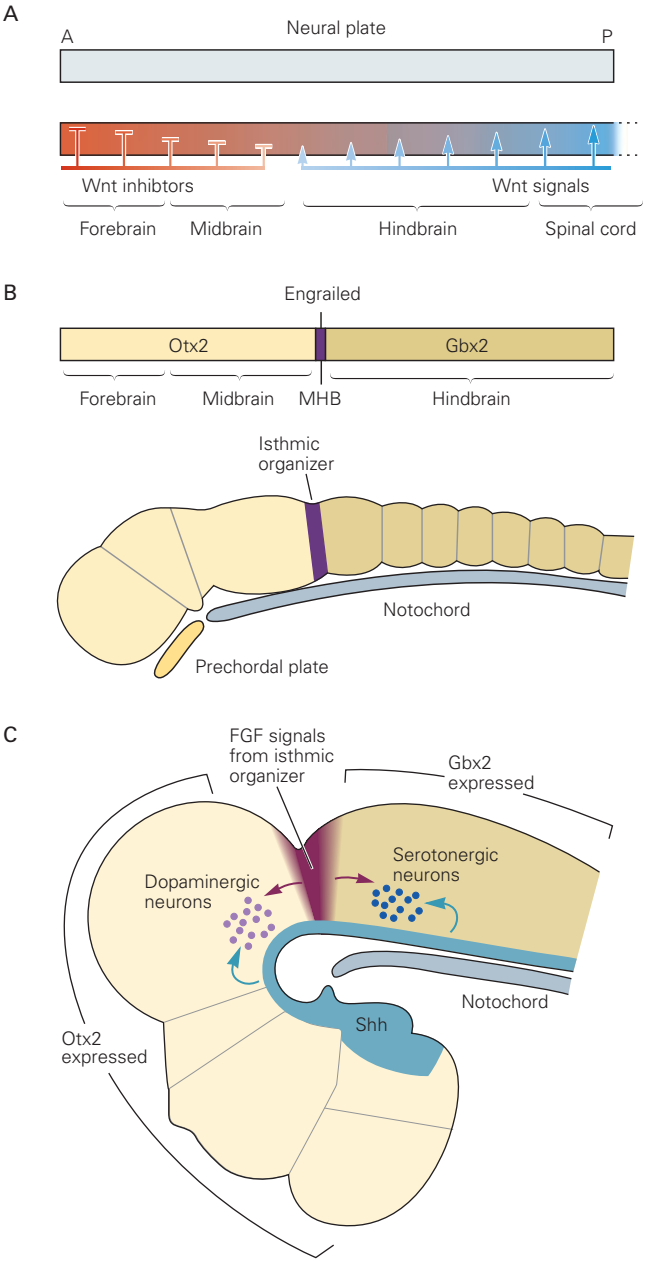

Figure 45–5 (Left) Early anteroposterior patterning signals establish distinct transcription factor domains and define the position of the midbrain–hindbrain boundary region.

A. The anteroposterior pattern of the neural plate is established by exposure of neural cells to a gradient of Wnt signals. Anterior (**A**) regions of the neural plate are exposed to Wnt inhibitors secreted from the endoderm and thus perceive only low levels of Wnt activity. Progressively more posterior (**P**) regions of the neural plate are exposed to high levels of Wnt signaling from the paraxial mesoderm and to lower levels of Wnt inhibitors.

B. In response to this Wnt signaling gradient and other signals, cells in anterior and posterior regions of the neural plate begin to express different transcription factors: Otx2 at anterior levels and Gbx2 at more posterior levels. The intersection of these two transcription factor domains marks the region of the midbrain–hindbrain boundary (**MHB**), where Engrailed transcription factors are expressed. The neural tube then forms segments anterior and posterior to the MHB.

C. Fibroblast growth factor (**FGF**) signals from the isthmic organizer act in concert with sonic hedgehog (**Shh**) signals from the ventral midline to specify the identity and position of dopaminergic and serotonergic neurons. The distinct fates of these two classes of neurons result from the expression of Otx2 in the midbrain and Gbx2 in the hindbrain.

(Adapted, with permission, from Wurst and Bally-Cuif 2001. Copyright © 2001 Springer Nature.)

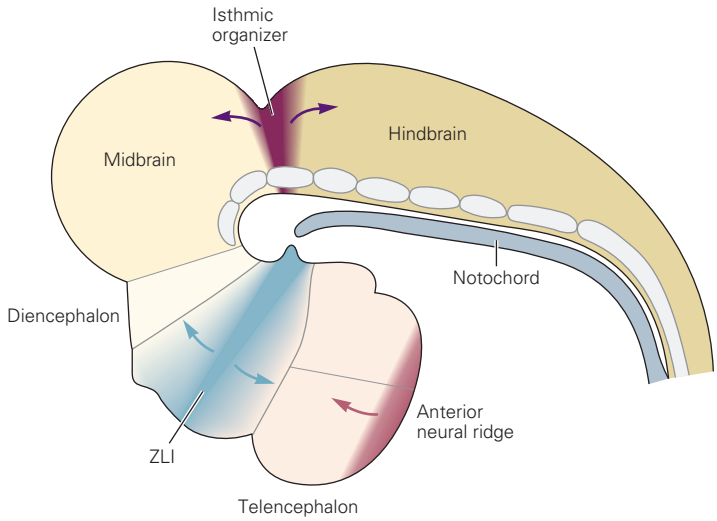

Figure 45–6 Local signaling centers in the developing neural tube. This side view of the neural tube at a later stage shows the positions of three key signaling centers that pattern the neural tube along the anterior-posterior axis: the anterior neural ridge, the zona limitans intrathalamica (**ZLI**) at the boundary between the rostral and caudal forebrain (diencephalon), and the isthmic organizer, the boundary of the midbrain and hindbrain. The ZLI is a source of sonic hedgehog, and the isthmic organizer and anterior neural ridge are sources of fibroblast growth factor (see Figure 45–5).

Other cell groups serve similar roles in subdividing the neural tube into domains. For example, at the very rostral margin of the neural tube, a specialized group of cells, called the *anterior neural ridge*, secretes FGF that patterns the telencephalon (Figure 45–6). More caudally is a restricted region called the *zona limitans intrathalamica*, which appears as a pair of horn-like spurs within the diencephalon. Zona limitans intrathalamica cells secrete the protein sonic hedgehog (Shh), which patterns nearby cells that give rise to the nuclei of the thalamus. FGFs and Shh are described in detail below in the context of their prominent role in patterning the cortex and spinal cord, respectively.

Repressive Interactions Divide the Hindbrain Into Segments

An important next step in patterning the neural tube along the rostrocaudal axis is the subdivision of the forebrain and hindbrain into segments, compartmental units that are arrayed along the rostrocaudal axis. These units are called *prosomeres* in the forebrain and *rhombomeres* in the hindbrain.

We use the formation of rhombomeres 3 and 4 (of 7 total) to illustrate the mechanisms leading to segmentation (Figure 45–7). An initial morphogen gradient leads to expression of two distinct transcription factors in this region—*krox20* in what will become rhombomere 3, endowing these cells with a rhombomere 3 identity, and *hoxb1* in what will become rhombomere 4, endowing these cells with a rhombomere 4 identity. Cells near the border express both factors and therefore have an uncertain identity. However, these two factors inhibit each other's expression, so eventually the identity of each cell is fixed.

The problem is that some cells are trapped within the wrong rhombomere. This intermingling is rectified in several ways, one of which is a second inhibitory interaction, this one of a markedly different type. Krox20 and Hoxb1 induce the expression of cell surface recognition and signaling molecules called EphA4 and ephrinB3, respectively. These two proteins bind to each other, leading to transmission of a repulsive signal that separates the cells. We will see below that this repulsion is also key to later decisions that axons make as they grow to their targets. In the hindbrain, before neurons form, it sharpens the borders between rhombomeres. More broadly, rhombomere segregation provides another example of a general theme in neural development: that inductive or adhesive interactions combine with repressive or inhibitory ones to pattern the nervous system.

Dorsoventral Patterning of the Neural Tube Involves Similar Mechanisms at Different Rostrocaudal Levels

As the neural epithelium acquires its rostrocaudal character, cells located at different positions along its dorsoventral axis also begin to acquire distinct identities. Together, patterning along the rostrocaudal and dorsoventral axes divides the neural tube into a three-dimensional grid of molecularly distinct cell types, leading eventually to generation of the various neuronal and glial cell types that distinguish one part of the nervous system from another.

In contrast to the diversity of signals and organizing centers responsible for rostrocaudal patterning of developing neurons, there is a striking consistency in

the strategies and principles that establish dorsoventral pattern. We focus initially on the mechanisms of dorsoventral patterning at caudal levels of the neural tube that give rise to the spinal cord and then describe how similar strategies are used to pattern the forebrain.

Neurons in the spinal cord serve two major functions. They relay cutaneous sensory input to higher centers in the brain, and they transform sensory input into motor output. The neuronal circuits that mediate these functions are segregated anatomically. Circuits involved in the processing of cutaneous sensory information are located in the dorsal half of the spinal cord, whereas those involved in the control of motor output are mainly located in the ventral half of the spinal cord.

The neurons that form these circuits are generated at different positions along the dorsoventral axis of the spinal cord in a patterning process that begins with the establishment of distinct progenitor cell types. Motor neurons are generated close to the ventral midline, and most of the interneuron classes that control motor output are generated just dorsal to the position at which motor neurons appear (Figure 45–8). The dorsal half of the neural tube generates projection neurons and local circuit interneurons that process incoming sensory information.

How are the position and identity of spinal neurons established? The dorsoventral patterning of the neural tube is initiated by signals from mesodermal and ectodermal cells that lie close to the ventral and dorsal poles of the neural tube and is perpetuated by signals from two midline neural organizing centers. Ventral patterning signals are initially provided by the notochord, a mesodermal cell group that lies immediately under the ventral neural tube (Figure 45–1). This signaling activity is transferred to the floor plate, a specialized glial cell group that sits at the ventral midline of the neural tube itself. Similarly, dorsal signals are provided initially by cells of the epidermal ectoderm that span the dorsal midline of the neural tube, and subsequently by the roof plate, a glial cell group embedded at the dorsal midline of the neural tube (Figure 45–8).

Thus, neural patterning is initiated through a process of *homogenetic* induction, in which like begets like: Notochord signals induce the floor plate, which

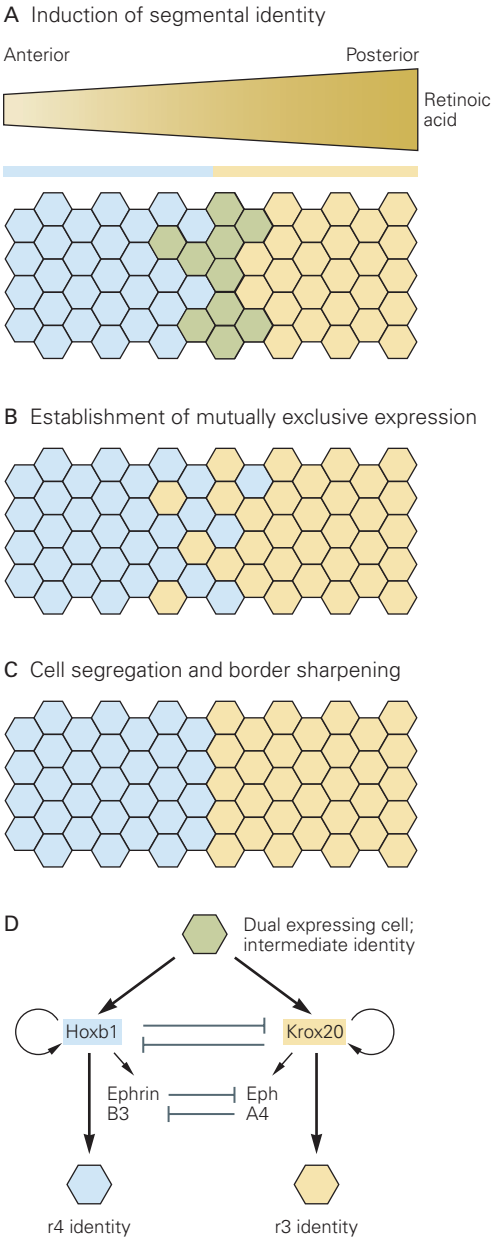

Figure 45–7 (Left) **Repressive interactions divide the hindbrain into rhombomeres.** The sharp border between hindbrain rhombomeres 3 and 4 forms in several steps. (Adapted, with permission, from Addison and Wilkinson 2016. Copyright © 2016 Elsevier Inc.)

A. A gradient of retinoic acid upregulates expression of *hoxb1* in anterior cells (**blue**) and *krox20* in posterior cells (**yellow**), with some cells at the prospective border expressing both genes (**green**).

B. Hoxb1 expression and Krox20 expression become mutually exclusive, thus endowing each cell with a unique molecular identity.

C. Cells trapped in the wrong domain migrate to sharpen the border.

D. Inhibitory interactions underlying border formation. Hoxb1 and Krox20 repress each other's expression in individual cells, so a modest imbalance in level leads to exclusive expression of one factor. Krox20 then upregulates EphA4 in r3 cells, whereas ephrinB3 is upregulated in r4 cells. EphA4 and ephrinB3 repel each other, driving migration of isolated cells and sharpening the segment border.

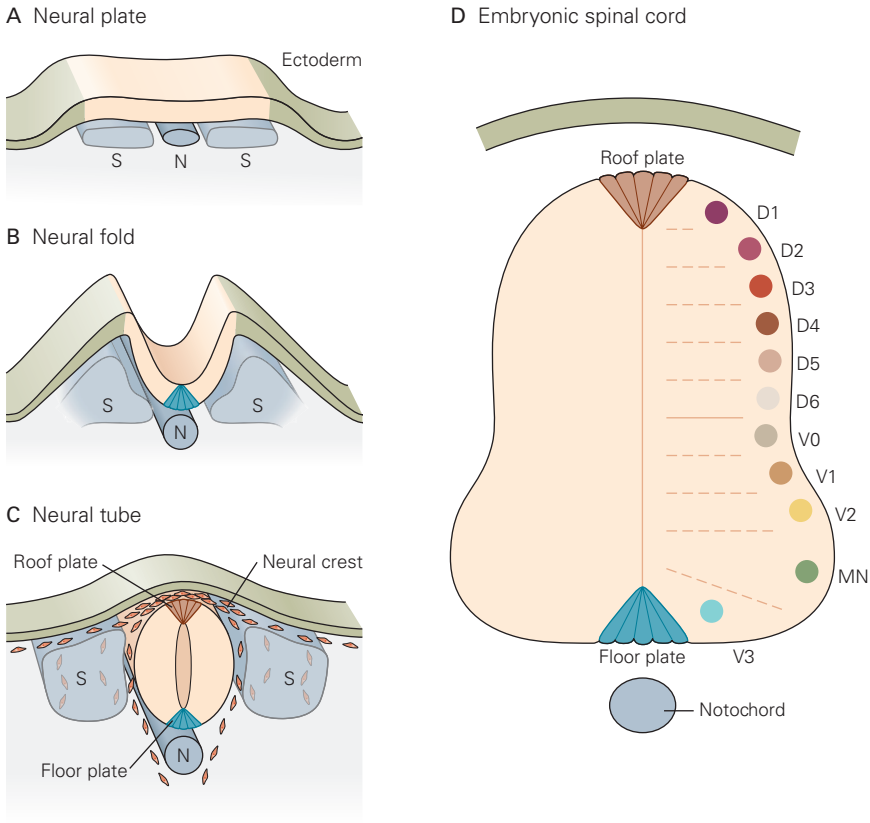

Figure 45–8 Distinct precursor populations form along the dorsoventral axis of the developing spinal cord.

A. The neural plate is generated from ectodermal cells that overlie the notochord (**N**) and the future somites (**S**). It is flanked by the epidermal ectoderm. (See also Figure 45–1)

B. The neural plate folds dorsally at its midline to form the neural fold. Floor plate cells (**blue**) differentiate at the ventral midline of the neural tube.

C. The neural tube forms by fusion of the dorsal tips of the neural folds. Roof plate cells form at the dorsal midline of the neural tube. Neural crest cells migrate from the neural tube into and past the somites before populating the sensory and sympathetic ganglia.

D. Distinct classes of neurons are generated at different dorsoventral positions in the embryonic spinal cord. Ventral interneurons (**V0–V3**) and motor neurons (**MN**) differentiate from progenitor domains in the ventral spinal cord. Six classes of early dorsal interneurons (**D1–D6**) develop in the dorsal half of the spinal cord. (Adapted from Goulding et al. 2002.)

induces ventral neurons, and signals from ectoderm induce the roof plate, which induces dorsal neurons. This strategy ensures that inductive signals are positioned appropriately to control neural cell fate and pattern over a prolonged period of development, as tissues grow and cells move.

The Ventral Neural Tube Is Patterned by Sonic Hedgehog Protein Secreted from the Notochord and Floor Plate

Within the ventral half of the neural tube, the identity and position of developing motor neurons and local interneurons depend on the inductive activity of the Shh protein, which is secreted by the notochord and subsequently by the floor plate. Shh is a member of a family of secreted proteins related to the *Drosophila* hedgehog protein, which had been discovered earlier and shown to control many aspects of embryonic development.

Shh signaling is necessary for the induction of each of the neuronal classes generated in the ventral half of the spinal cord. How can a single inductive signal specify the fate of at least half a dozen neuronal classes? The answer lies in the ability of Shh to act as a morphogen—a signal that can direct different cell fates at different concentration thresholds. The secretion of Shh from the notochord and floor plate establishes a ventral-to-dorsal gradient of Shh protein activity in the ventral neural tube, such that progenitor cells occupying different dorsoventral positions within the neural epithelium are exposed to small (two- to three-fold) differences in ambient Shh signaling activity. Different levels of Shh signaling activity direct progenitor cells in different ventral domains to differentiation as motor neurons and interneurons (Figure 45–9A).

These findings raise two additional questions. How is the spread of Shh protein within the ventral neural epithelium controlled in such a precise manner? And how are small differences in Shh signaling activity converted into all-or-none decisions about the identity of progenitor cells in the ventral neural tube?

Active Shh protein is synthesized from a larger precursor protein, cleaved through an unusual autocatalytic process that involves a serine protease-like activity resident within the carboxy terminus of the precursor protein. Cleavage generates an amino

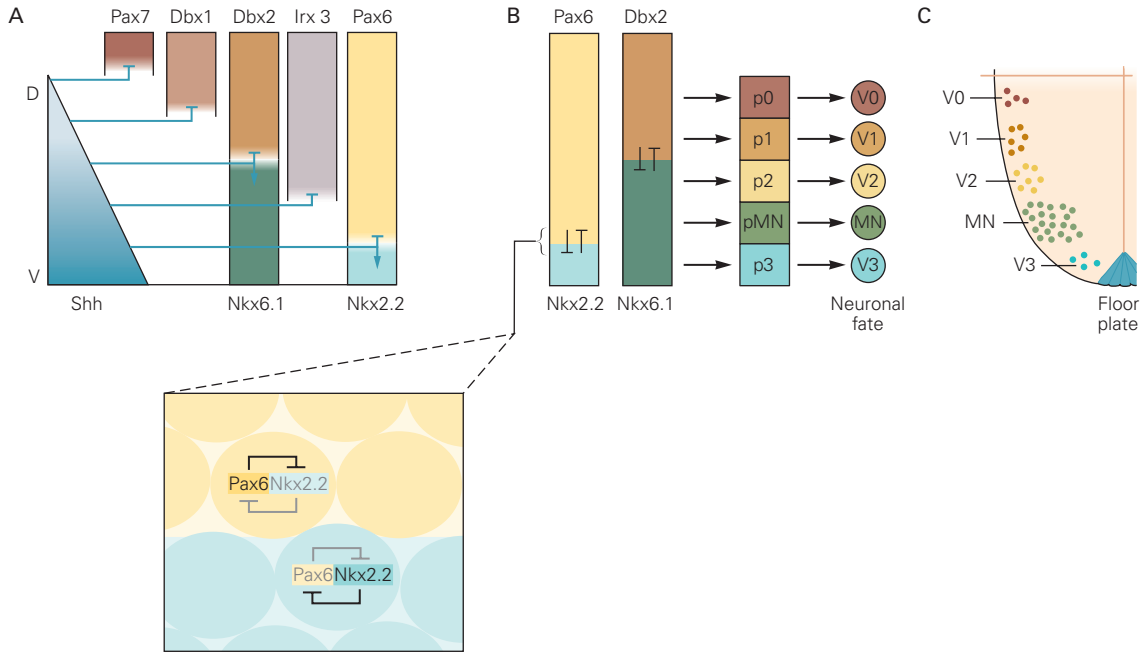

Figure 45–9 A sonic hedgehog signaling gradient controls neuronal identity and pattern in the ventral spinal cord.

A. A ventral-to-dorsal (**V–D**) gradient of sonic hedgehog (**Shh**) signaling establishes dorsoventral domains of homeodomain protein expression in progenitor cells within the ventral half of the neural tube. At each concentration, a different homeodomain transcription factor (Pax7, Dbx1, Dbx2, Irx3, or Pax6) is repressed, with Pax7 the most sensitive and Pax6 the least sensitive to repression. Other homeodomain transcription factors (Nkx6.1 and Nkx2.2) are induced at different Shh levels. The homeodomain proteins that abut a common progenitor domain boundary have similar Shh concentration thresholds for repression and activation. Graded Shh signaling generates a corresponding gradient of Gli transcription factor activity (not shown).

B. Cross-repression between transcription factors induced or repressed by Shh/Gli signaling specifies different neuronal classes. For example, Pax6 and Nkx2.2, and Dbx2 and Nkx6.1, act in a cell-autonomous manner to repress each other's expression (inset), conferring cell identity to progenitor cells in an unambiguous manner. The sequential influence of graded Shh and Gli signaling, together with homeodomain transcriptional cross-repression, establishes five cardinal progenitor domains.

C. The postmitotic neurons that emerge from these domains give rise to the five major classes of ventral neurons: the interneurons **V0–V3** and motor neurons (**MN**).

terminal protein fragment that possesses all of the signaling activity of Shh. During cleavage, the active amino terminal fragment is modified covalently by the addition of a cholesterol molecule. Following Shh secretion, this lipophilic anchor tethers most of the protein to the surface of notochord and floor plate cells. Nevertheless, a small fraction of the anchored protein is released from the cell surface and transferred from cell to cell within the ventral neural epithelium. In reality, the molecular machinery that ensures the formation of a long-distance gradient of extracellular Shh protein is more complex, involving specialized transmembrane proteins that promote the release of Shh from the floor plate, as well as proteins that regulate Shh protein transfer between cells.

How does the gradient of Shh protein within the ventral neural tube direct progenitor cells along different pathways of differentiation? Shh signaling is initiated by its interaction with a transmembrane receptor complex that consists of a ligand-binding subunit called *patched* and a signal-transducing subunit called *smoothened* (named for the corresponding *Drosophila* genes). The binding of Shh to patched relieves its inhibition of smoothened and so activates an intracellular signaling pathway that involves several protein kinase enzymes, transport proteins, and most important, the Gli proteins, a class of zinc finger transcription factors.

In the absence of Shh, the Gli proteins are proteolytically processed into transcriptional repressors that prevent the activation of Shh target genes. Activation of the Shh signaling pathway inhibits this proteolytic processing, with the result that transcriptional activator forms of Gli predominate, thus directing the expression of Shh target genes. In this way, an extracellular gradient of Shh protein is converted into a nuclear gradient of Gli activator proteins. The ratio of

Gli repressor and activator proteins at different dorsoventral positions determines which target genes are activated.

What genes are activated by Shh-Gli signaling, and how do they participate in the specification of ventral neuronal subtypes? The major Gli targets are genes encoding yet more transcription factors. One major class of Gli targets encodes homeodomain proteins, transcription factors that contain a conserved DNA-binding motif termed a *homeobox*. A second major class of target genes encodes proteins with a basic helix-loop-helix DNA-binding motif. Some homeodomain and basic helix-loop-helix proteins are repressed and others activated by Shh signaling, each at a particular concentration threshold. In this way, cells in the ventral neural tube are allocated to one of five cardinal progenitor domains, each marked by its own transcription factor profile (Figure 45–9B,C).

The transcription factors that define adjacent progenitor domains repress each other's expression. Thus, although a cell may initially express several transcription factors that could direct the cell along different pathways of differentiation, a minor imbalance in the starting concentration of the two factors is rapidly amplified through repression, and only one of these proteins is stably expressed. This winner-take-all strategy of transcriptional repression sharpens the boundaries of progenitor domains and ensures that an initial gradient of Shh and Gli activity will resolve itself into clear distinctions in transcription factor profile. The transcription factors that specify a ventral progenitor domain then direct the expression of downstream genes that commit progenitor cells to a particular postmitotic neuronal identity. Thus, studies of Shh signaling have not only revealed the logic of ventral neuronal patterning but also demonstrated that the fate of a neuron is determined in part by the actions of transcriptional repressors rather than activators. This principle operates in many other tissues and organisms.

Although originally studied in the context of neural development, defects in Shh signaling have now been implicated in a wide variety of human diseases. Mutations in human Shh pathway genes result in defects in the development of ventral forebrain structures (holoprosencephaly), as well as neurological defects such as spina bifida, limb deformities, and certain cancers.

The Dorsal Neural Tube Is Patterned by Bone Morphogenetic Proteins

A signaling strategy based on graded morphogen levels activating sets of transcriptional programs has also been found to determine the patterning of cell types in the dorsal spinal cord. The differentiation of roof plate cells at the dorsal midline of the neural tube is triggered by BMP signals from epidermal cells that initially border the neural plate and later flank the dorsal neural tube.

After the neural tube has closed, roof plate cells themselves begin to express BMP as well as Wnt proteins. Wnt proteins promote the proliferation of progenitor cells in the dorsal neural tube. BMP proteins induce the differentiation of neural crest cells at the very dorsal margin of the neural tube and later induce generation of diverse populations of sensory relay neurons that settle in the dorsal spinal cord.

Dorsoventral Patterning Mechanisms Are Conserved Along the Rostrocaudal Extent of the Neural Tube

The strategies used to establish dorsoventral pattern in the spinal cord also control cell identity and pattern along the dorsoventral axis of the hindbrain and midbrain, as well as throughout much of the forebrain.

In the mesencephalic region of the neural tube, Shh signals from the floor plate act in concert with the rostrocaudal patterning signals discussed earlier to specify dopaminergic neurons of the substantia nigra and ventral tegmental area as well as serotonergic neurons of the raphe nuclei (see Figure 45–5C). In the forebrain, Shh signals from the ventral midline and BMP signals from the dorsal midline act in combination to establish different regional domains. Shh signaling from the ventral midline sets up early progenitor domains that later produce neurons of the basal ganglia and some cortical interneurons, whereas BMP signaling from the dorsal midline is involved in establishing early neocortical character.

Local Signals Determine Functional Subclasses of Neurons

To this point, we have seen how a uniform group of neural precursor cells, the neural plate, is progressively partitioned into discrete rostrocaudal and dorsoventral domains within the neural tube, largely by morphogen-dependent differential expression of different sets of transcriptional regulators. The next question is how cells within these domains go on to generate the extraordinary diversity of neuronal types that characterize the vertebrate central nervous system. We address that question by focusing on development of the motor neuron.

Motor neurons can be distinguished from all other classes of neurons in the central nervous system by the simple fact that they have axons that extend into the periphery. Viewed in this light, motor neurons represent a coherent and distinct class. But motor neuron types can be distinguished by their position within the central nervous system as well as by the target cells they innervate. The primary job of most motor neurons is to innervate skeletal muscles, of which there are approximately 600 in a typical mammal. From this, it follows that there must be an equal number of motor neuron types.

In this section, we discuss the developmental mechanisms that direct the differentiation of these different functional subclasses. The details of motor neuron development are also important for understanding the basis of neurological disorders that affect these neurons, including spinal muscular atrophy and amyotrophic lateral sclerosis (Lou Gehrig disease). In both diseases, some motor neuron types are highly vulnerable whereas others are relatively resilient. Similar principles drive the diversification of other neuronal classes into distinct types.

Rostrocaudal Position Is a Major Determinant of Motor Neuron Subtype

Motor neurons are generated along much of the rostrocaudal axis of the neural tube, from the midbrain to the spinal cord. Distinct motor neuron types develop at each rostrocaudal level (Figure 45–10), suggesting that one goal of the patterning signals that establish rostrocaudal positional identity within the neural tube is to make motor neurons different.

One major class of genes involved in specifying motor neuron types is the *Hox* gene family. Their name reflects the fact that they were the first transcription factors found that contain a homeodomain, a DNA binding domain now known to be present in many transcription factors that regulate developmental processes in organisms as diverse as yeast, plants, and mammals. For example, the *Otx* and *Gbx* genes discussed above contain homeodomains. The mammalian *Hox* gene family is especially large, containing 39 genes organized in four chromosomal clusters. These genes derive from an ancestral *Hox* complex that also gave rise to the *HOM-C* gene complex in *Drosophila*, where they were initially discovered and analyzed (Figure 45–11).

Members of the vertebrate *Hox* gene family are expressed in overlapping domains along the rostrocaudal axis of the developing midbrain, hindbrain, and spinal cord. As in *Drosophila*, the position of an individual *Hox* gene within its cluster predicts its rostrocaudal domain of expression within the neural tube. In most but not all cases, *Hox* genes located at more 3′ positions within the chromosomal cluster are expressed in more rostral domains, within the midbrain and hindbrain, whereas genes at more 5′ positions are expressed in progressively more caudal positions within the spinal cord (Figures 45–10 and 45–11). This spatial array of *Hox* gene expression determines many aspects of neuronal diversity.

Genetic studies, mostly in mice, have revealed how *Hox* genes control motor neuron identity in the hindbrain and spinal cord. We saw above that Hox genes contribute to formation of the rhombomeres, the fundamental cellular building blocks of the hindbrain. Later, the same genes help to determine the identity of motor neurons within rhombomeres. For example, *Hoxb1* is expressed at high levels in rhombomere 4, the domain that gives rise to facial motor neurons, but is absent from rhombomere 2, the domain that gives rise to trigeminal motor neurons (Figure 45–10).

In the mouse, mutations that eliminate the activity of *Hoxb1* change the fate of cells in rhombomere 4; there is a switch in the identity and connectivity of the motor neurons that emerge from this domain. In the absence of *Hoxb1* function, cells in rhombomere 4 generate motor neurons that innervate trigeminal rather than facial targets, that is, the motor neuron subtype normally generated within rhombomere 2 (Figure 45–12). Many additional studies have confirmed the general principle that motor neuron identity in the hindbrain is controlled by the spatial distribution of *Hox* gene expression.

The control of spinal motor neuron identity is more complicated. Spinal motor neurons are clustered within longitudinal columns that occupy discrete segmental positions, in register with their peripheral targets. Motor neurons that innervate forelimb and hindlimb muscles are found in the lateral motor columns at cervical and lumbar levels of the spinal cord, respectively. In contrast, motor neurons that innervate sympathetic neuronal targets are found within the preganglionic motor column at thoracic levels of the spinal cord. Within the lateral motor columns, motor neurons that innervate a single limb muscle are clustered together into discrete groups, termed *motor pools*. Because each limb in higher vertebrates contains more than 50 different muscle groups, a corresponding number of motor pools are required.

The identity of motor neurons in the spinal cord is controlled by the coordinate activity of *Hox* genes found at more 5′ positions within the chromosomal *Hox* clusters. For example, the spatial domains of expression and activity of Hox6 and Hox9 proteins establish the identities of motor neurons in the

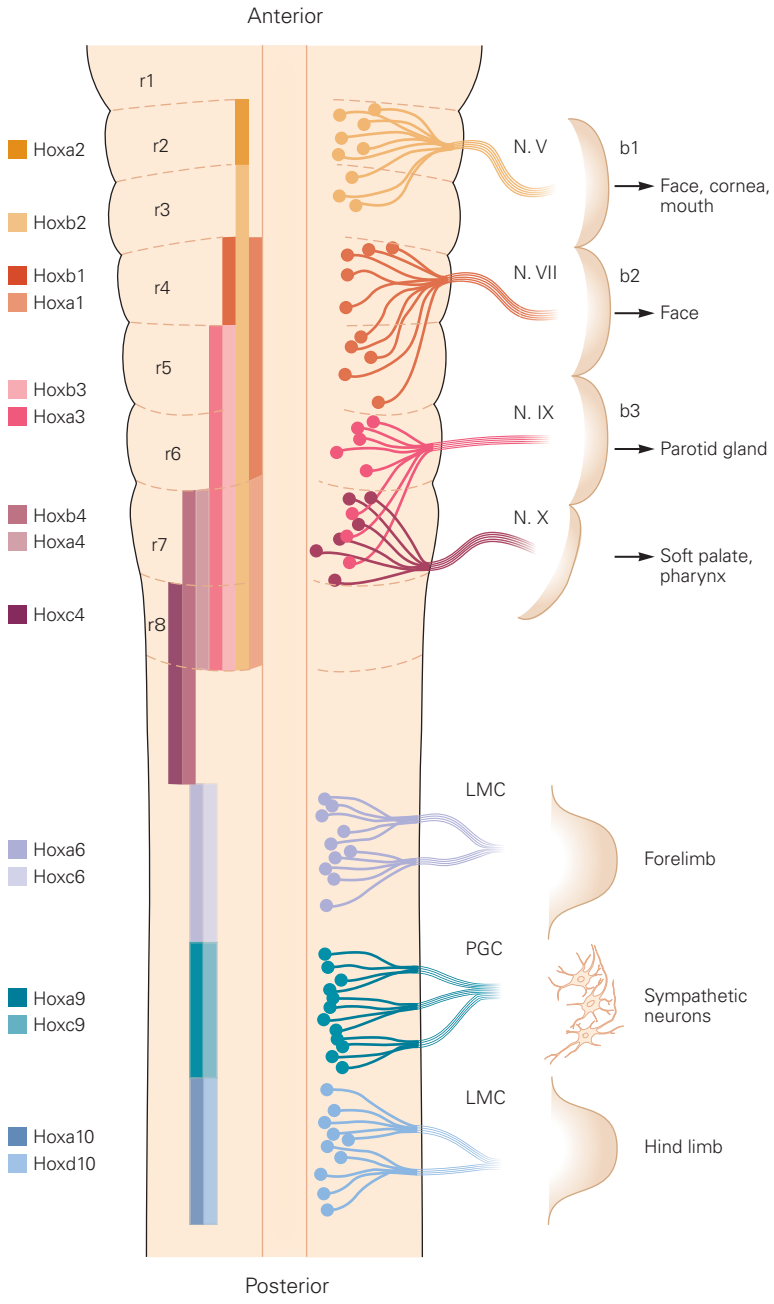

Figure 45–10 The anteroposterior profile of *Hox* gene expression determines the subtype of motor neurons in the hindbrain and spinal cord. Different Hox proteins are expressed in discrete but partially overlapping rostrocaudal domains of the hindbrain and spinal cord. The position of *Hox* genes on the four mammalian chromosomal clusters roughly corresponds to their domain of expression along the anteroposterior axis of the neural tube.

At hindbrain levels, motor neurons sending axons into cranial nerves V (trigeminal), VII (facial), IX (glossopharyngeal), and X (vagus) are depicted. These cranial motor nerves project to peripheral targets in the branchial arches **b1–b3**. The hindbrain rhombomeres (**r1–r8**) and Hox profiles are shown on the left.

At spinal levels, motor neurons that send axons to the forelimb and hind limb are contained within the lateral motor columns (**LMC**), located at brachial and lumbar levels of the spinal cord, respectively. Preganglionic autonomic motor neurons (**PGC**) destined to innervate sympathetic ganglion targets are generated at thoracic levels. (Adapted, with permission, from Kiecker and Lumsden 2005. Copyright © 2005 Springer Nature.)

brachial lateral motor column and the preganglionic motor column. Hox6 proteins specify brachial lateral motor column identity, whereas Hox9 proteins specify preganglionic motor column identity. Motor neurons at the boundary of the forelimb and thoracic regions acquire an unambiguous columnar identity because the Hox6 and Hox9 proteins are mutually repressive (Figure 45–13A), similar to the transcriptional cross-repression that occurs in the dorsoventral patterning of the spinal cord.

Local Signals and Transcriptional Circuits Further Diversify Motor Neuron Subtypes

How do motor neurons within the lateral motor columns develop more refined identities, directing their axons to specific limb muscles? Once again, *Hox* genes control this stage of motor neuron diversification. We illustrate this function of Hox proteins by considering the pathway that generates the distinct divisional and pool identities of neurons within the brachial lateral

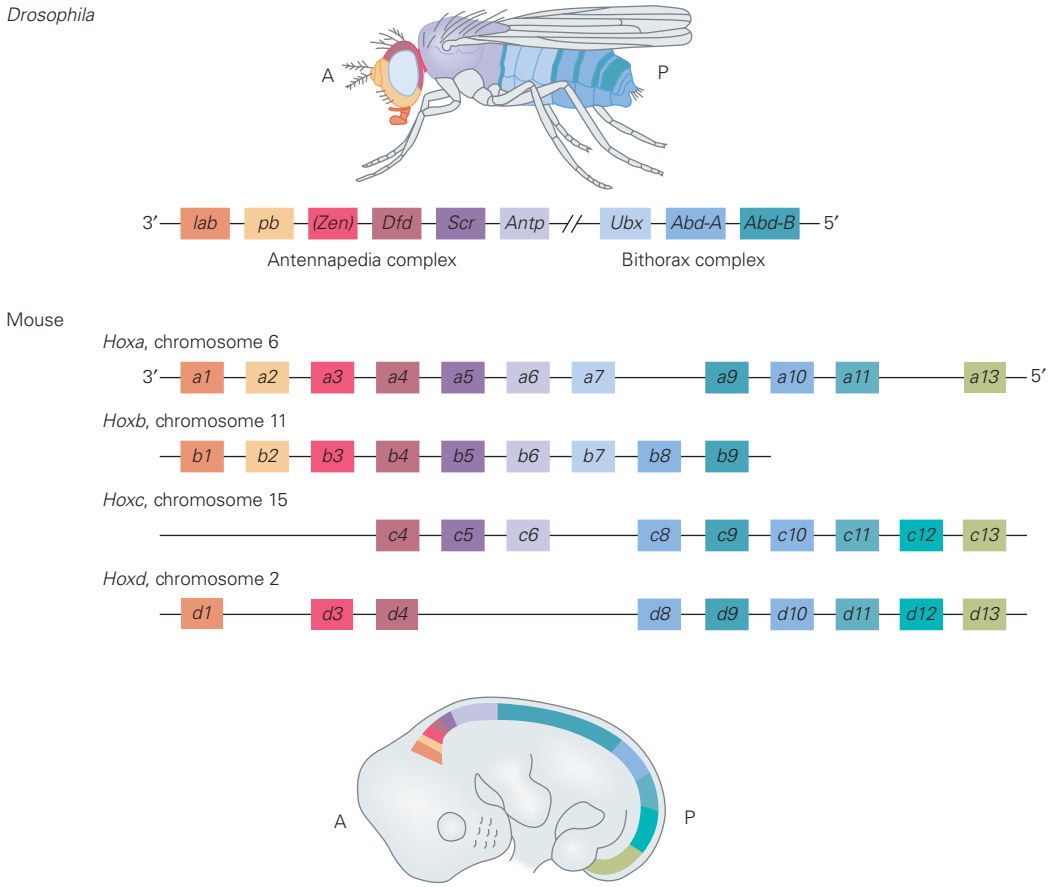

Figure 45–11 The clustered organization of *Hox* genes is conserved from flies to vertebrates. The diagram shows the chromosomal arrangement of *Hox* genes in the mouse and *HOM-C* genes in *Drosophila*. Insects have one ancestral *Hox* gene cluster, whereas higher vertebrates such as birds and mammals have four duplicate *Hox* gene clusters. The position of a given *Hox* or *HOM-C* gene on the chromosomal cluster is typically related to the position on the anteroposterior body axis where the gene is expressed. motor column that innervate the muscles of the forelimb (Figure 45–13A).

Repressive interactions between Hox proteins expressed by the neurons in different lateral motor columns ensure that neurons that populate different motor pools express distinct profiles of Hox protein expression. These Hox profiles direct the expression of downstream transcription factors as well as the axonal surface receptors that enable motor axons to respond to local cues within the limb that guide them to specific muscle targets. For example, the expression of Hox6 proteins activates a retinoic acid signaling pathway that directs the expression of two homeodomain transcription factors, Is11 and Lhx1. These factors in turn assign motor neurons to two divisional classes and determine the pattern of expression of the ephrin receptors that guide motor axons in the limb. The axons of motor neurons in these two divisions project into the ventral and dorsal halves of the limb mesenchyme under the control of ephrin signaling (Figure 45–14).

Not all motor neuron columns are determined by Hox protein activity, however. The median motor column is generated at all segmental levels of the spinal cord in register with axial muscles. Development of median motor column cells is controlled by Wnt4/5 signals secreted from the ventral midline of the spinal cord and by the expression of the homeodomain proteins Lhx3 and Lhx4, which render neurons in this column immune to the segmental patterning actions of Hox proteins.

Thus, in both the hindbrain and spinal cord, the point-to-point connectivity of motor neurons with specific muscles emerges through tightly orchestrated programs of homeodomain protein expression and activity. In vertebrates, these genes have evolved to

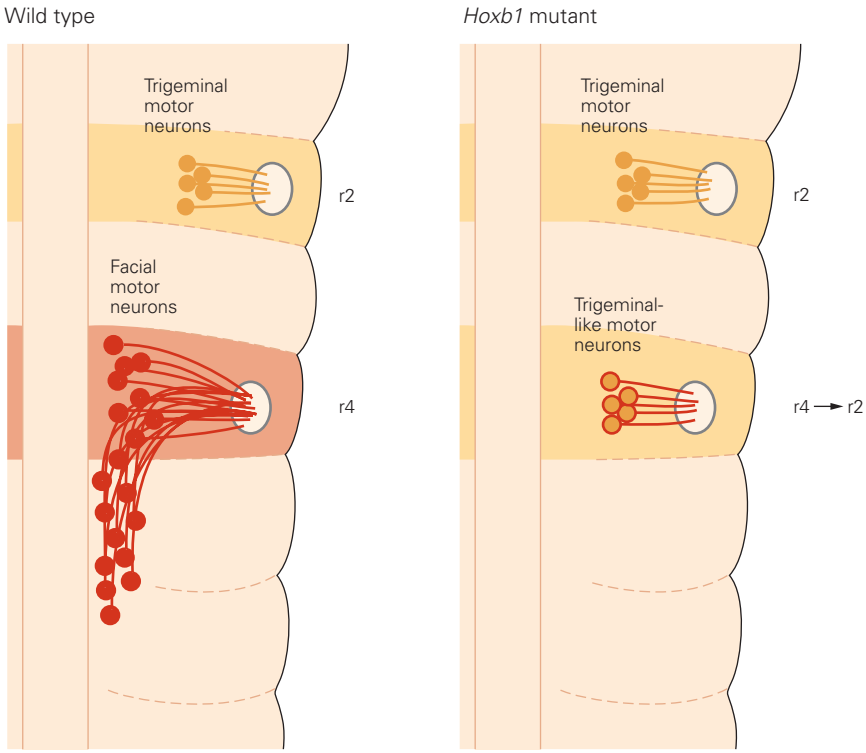

Figure 45–12 The mouse *Hoxb1* gene controls the identity and projection of hindbrain motor neurons. *Hoxb1* is normally expressed at highest levels by cells in rhombomere r4. In wild-type mice, trigeminal motor neurons are generated in rhombomere r2, and their cell bodies migrate laterally before projecting their axons out of the hindbrain at the r2 level. In contrast, the cell bodies of facial motor neurons generated in rhombomere r4 migrate caudally yet project their axons out of the hindbrain at the r4 level. In mouse *Hoxb1* mutants, motor neurons generated in rhombomere r4 migrate laterally instead of caudally, acquiring the features of r2 level trigeminal motor neurons. **Ellipses** indicate axonal exit points. direct neuron subtype and connectivity as well the basic body plan.

The Developing Forebrain Is Patterned by Intrinsic and Extrinsic Influences

Neurons in the mammalian forebrain form circuits that mediate emotional behaviors, perception, and cognition and participate in the storage and retrieval of memories. Much like the hindbrain, the embryonic forebrain is initially divided along its rostrocaudal axis into transversely organized domains called *prosomeres*. Prosomeres 1 to 3 develop into the caudal part of the diencephalon, from which the thalamus emerges. Prosomeres 4 to 6 give rise to the rostral diencephalon and telencephalon. The ventral region of the rostral diencephalon gives rise to the hypothalamus and basal ganglia, whereas the telencephalon gives rise to the neocortex and hippocampus.

Inductive Signals and Transcription Factor Gradients Establish Regional Differentiation

Finally, we turn to the patterning of the neocortex itself, asking whether the developmental mechanisms and principles that govern the development of other regions of the central nervous system also control the emergence of cortical areas specialized for particular sensory, motor, and cognitive functions.

From the time of Brodmann's classical anatomical description at the beginning of the 20th century, we have known that the cerebral cortex is subdivided into many different areas. Recent studies of cortical development have begun to provide insight into the signaling mechanisms that establish somatosensory, auditory, and visual areas.

There is now evidence for the existence of a cortical "protomap," a basic plan in which different cortical areas are established early in development before inputs from other brain regions can influence development. This view is supported by studies of transcription factor expression in the developing neocortex. Two homeodomain transcription factors, Pax6 and Emx2, are expressed in complementary anteroposterior gradients in the ventricular zone of the developing neocortex—high levels of Pax6 at anterior levels and high levels of Emx2 at posterior levels. These early patterns are established in part by a local rostral source of FGF signals, which promote Pax6 and repress Emx2 expression (Figure 45–15A). As is the case in the hindbrain, the distinct spatial domains of expression of Pax6 and Emx2 are sharpened by cross-repressive interactions between the two transcription factors.

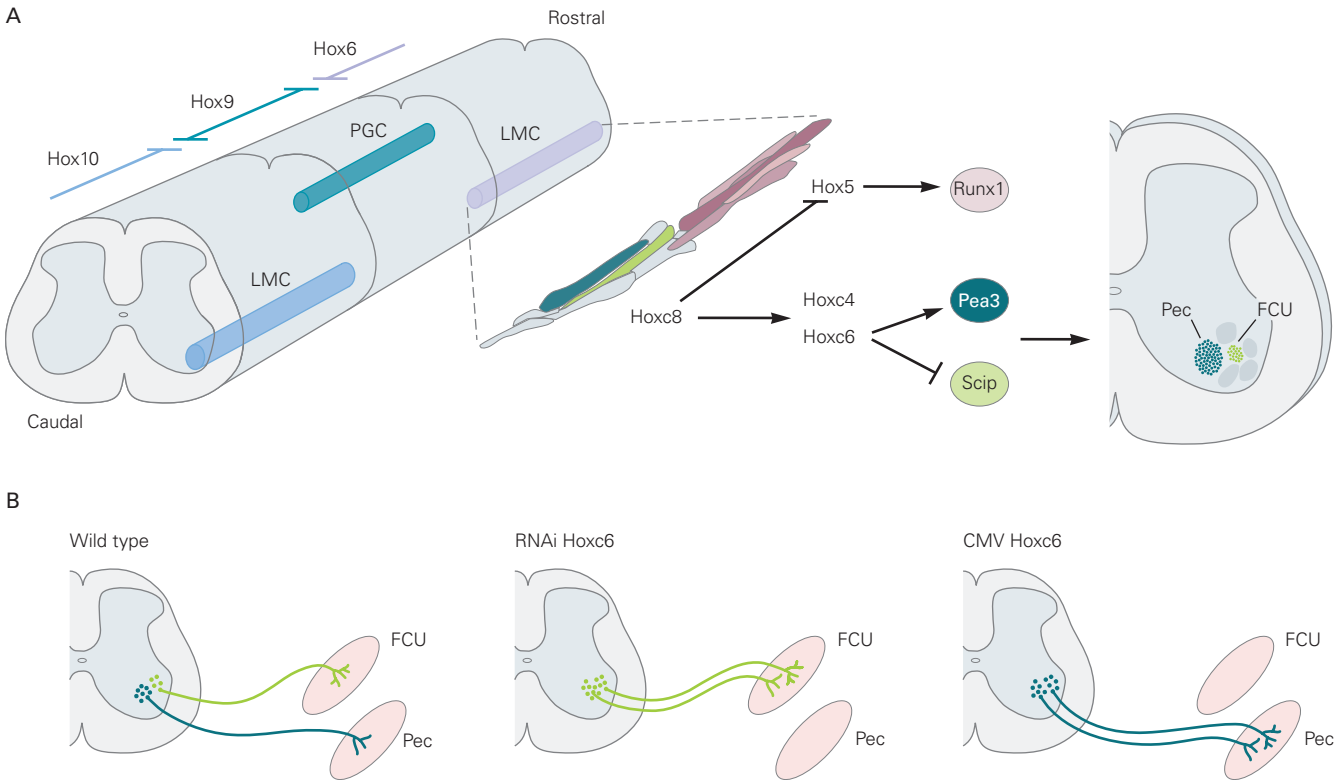

Figure 45–13 Hox proteins control the identity of neurons in motor columns and pools. (Adapted, with permission, from Dasen et al. 2005.)

A. Hox6, Hox9, and Hox10 proteins are expressed in motor neurons at distinct rostrocaudal levels of the spinal cord and direct motor neuron identity and peripheral target connectivity. Hox6 activities control the identity of cells in the brachial lateral motor column (**LMC**), Hox9 controls the identity of cells in the preganglionic column (**PGC**), and Hox10 controls the identity of cells in the lumbar column (**LMC**). Cross-repressive interactions between Hox6, Hox9, and Hox10 proteins refine Hox profiles, and Hox activator functions define LMC and PGC identities. A more complex Hox transcriptional network controls motor pool identity and connectivity. Hox genes determine the rostrocaudal position of motor pools within the LMC. Hoxc8 is required in caudal LMC neurons to generate the motor pools for the pectoralis (**Pec**) and flexor carpi ulnaris (**FCU**) muscles; these neurons express the transcription factors Pea3 and Scip, respectively. The patterns of Hox expression in the Pec and FCU pools are established through a transcriptional network that appears to be driven largely by Hox cross-repressive interactions.

B. Changing the Hox code within motor pools changes the pattern of muscle connectivity. Alterations in the profile of Hox6 expression determine the expression of Pea3 and Scip and control the projection of motor axons to the Pec or FCU muscles. RNA interference (**RNAi**) knock-down of Hox6 suppresses innervation of the Pec muscle so that motor axons innervate the FCU muscle only. Ectopic expression of Hoxc6 driven by a cytomegalovirus (**CMV**) promoter represses connectivity with FCU, so that motor axons innervate only the Pec muscle.

The spatial distribution of Pax6 and Emx2 helps to establish the initial regional pattern of the neocortex. In mice lacking Emx2 activity, there is an expansion of rostral neocortex—the motor and somatosensory areas—at the expense of the more caudal auditory and visual areas. Conversely, in mice lacking Pax6 activity, visual and auditory areas are expanded at the expense of motor and somatosensory areas (Figure 45–15B).

Thus, as in the spinal cord, hindbrain, and midbrain, early neocortical patterns are established through the interplay between local inductive signals and gradients of transcription factor expression. How these gradients specify discrete functional areas in the neocortex remains unclear. Unlike segmentation in the hindbrain, where transcription factors precisely specify rhombomeres, transcriptional markers of individual neocortical areas have not yet been identified.

Afferent Inputs Also Contribute to Regionalization

In the adult neocortex, different functional areas can be distinguished by differences in the layering pattern of neurons—the cytoarchitecture of the areas—and by their neuronal connections. One striking instance of

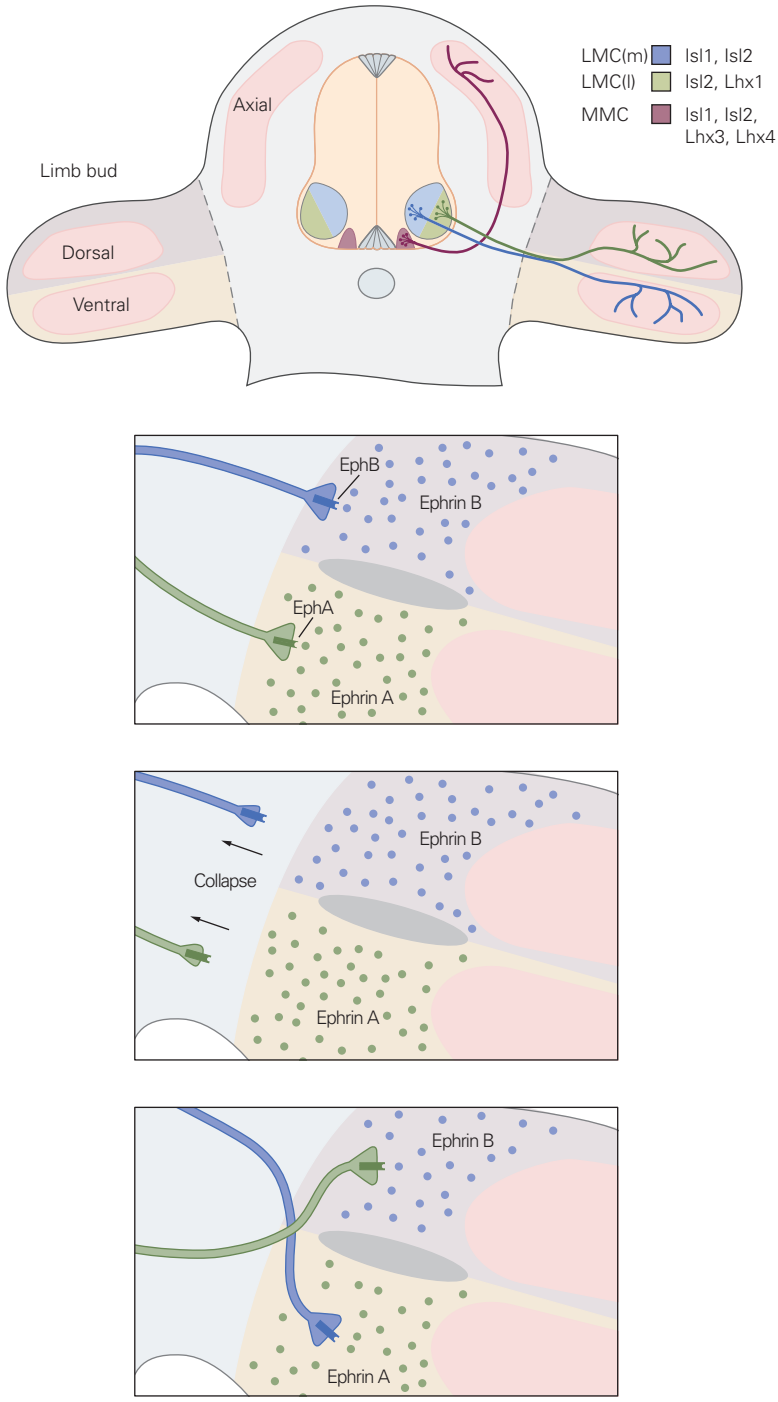

Figure 45–14 **The axons of lateral motor column neurons are guided into the limb by ephrin class tyrosine kinase receptors.** Motor neurons in the medial and lateral divisions of the lateral motor column (**LMC**) project axons into the ventral and dorsal halves of the limb mesenchyme, respectively. The profile of expression of LIM class homeodomain proteins regulates this dorsoventral projection. The LIM homeodomain protein Isl1 expressed by medial LMC neurons directs a high level of expression of EphB receptors, such that as the axons of these cells enter the limb, they are prevented from projecting dorsally by the high level of repellant ephrin B ligands expressed by cells of the dorsal limb mesenchyme. These axons therefore project into the ventral limb mesenchyme. Conversely, the LIM homeodomain protein Lhx1 expressed by lateral LMC neurons directs a high level of expression of EphA receptors, such that as the axons of these cells enter the limb, they are prevented from projecting ventrally by the high level of repellant ephrin A ligands expressed by cells of the ventral limb mesenchyme. These axons therefore project into the dorsal limb mesenchyme. Eph and ephrin signaling is discussed in greater detail in Chapter 47. (Abbreviation: **MMC**, medial motor column.)

regional distinctiveness in cell pattern is a grid-like array of neurons and glial cells termed "barrels" in the primary somatosensory cortex of rodents. Each cortical barrel receives somatosensory information from a single whisker on the snout, and the regular array of cortical barrels reflects the somatotopic organization of afferent information from the body surface, culminating in the projection of thalamic efferents to specific cortical barrels (Figure 45–16A).

Cortical barrels are evident soon after birth, and their development depends on a critical period of afferent input from the periphery; their formation is disrupted if the whisker field in the skin is eliminated during this critical period. Strikingly, if prospective

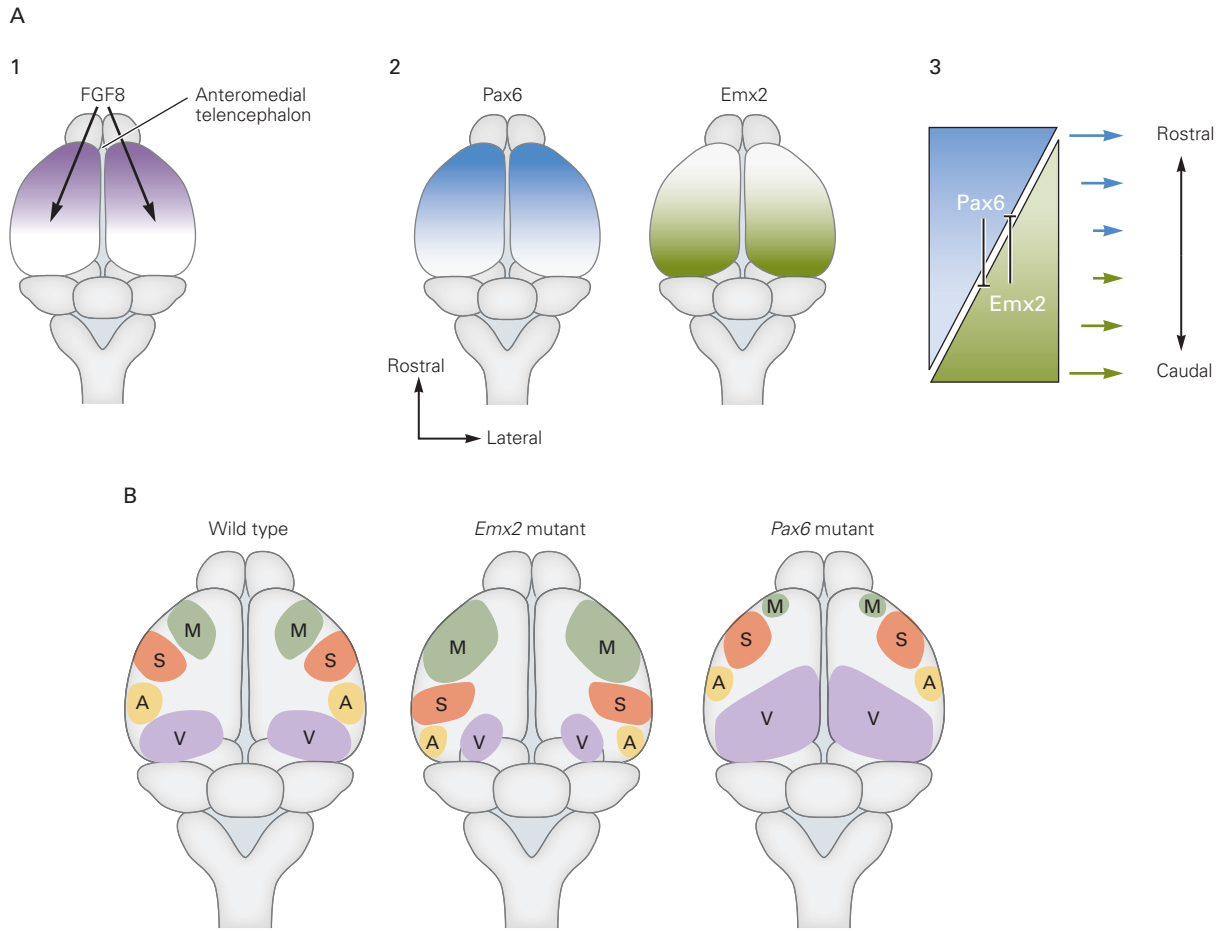

Figure 45–15 Anteroposterior gradients of expression of transcription factors establish discrete functional areas along the anteroposterior axis of the developing forebrain. (Adapted from Hamasaki et al. 2004.)

A. (**1**) FGF8 signals from the anteromedial telencephalon establish the rostrocaudal pattern of the cerebral cortex. (**2**) A top-down view of the developing cerebral cortex in the mouse shows inverse rostrocaudal gradients of the transcription factors Pax6 and Emx2. (**3**) These two transcription factors mutually repress each other's expression.

B. Different functional areas develop at different rostrocaudal positions. Motor areas develop in the anterior region (**M**) and visual areas in more posterior regions (**V**). Genetic elimination of Emx2 function results in expansion of the motor areas and contraction in auditory (**A**) and visual areas. Conversely, elimination of Pax6 function results in an expansion of the visual areas and a contraction of motor and auditory areas. (Abbreviation: **S**, somatosensory areas.)

visual cortical tissue is transplanted into the somatosensory cortex around the time of birth, barrels form in the transplanted tissue with a pattern that closely resembles that of the normal somatosensory barrel field (Figure 45–16B). Together, these findings demonstrate that afferent input superimposes aspects of neocortical patterning on the basic features of the protomap.

The nature of the input to different cortical areas influences neural function as well as cytoarchitecture. This can be shown by monitoring physiological and behavioral responses after rerouting afferent pathways of one sensory modality to a region of neocortex that normally processes a different modality. In animals in which retinal inputs are rerouted into the auditory pathway, the primary auditory cortex contains a systematic representation of visual space rather than of sound frequency (Figure 45–17). When these animals are trained to discriminate a visual from an auditory cue, they perceive a cue as visual when the rewired auditory cortex is activated by vision.

Thus, brain pathways and neocortical regions are established through genetic programs during early development but later depend on afferent inputs for their specialized anatomical, physiological, and behavioral functions.

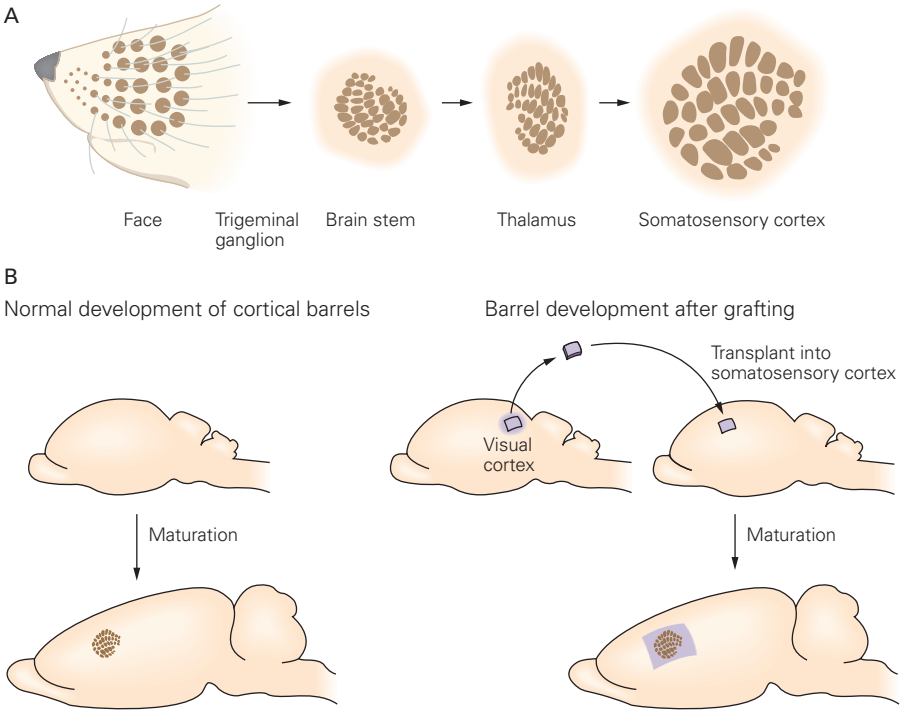

Figure 45–16 Sensory input regulates the organization of "barrels" in the developing somatosensory cortex in rodents. (Adapted from Schlaggar and O'Leary 1991.)

A. The barrel area of the rodent somatosensory cortex forms a somatotopic representation of the rows of whiskers on the animal's snout. Similar representations of the whisker field are present upstream—in the brain stem and in the thalamic nuclei that relay somatosensory inputs from the face to the cortex.

B. A barrel-like cellular organization is induced in developing visual cortex tissue that was grafted at an early postnatal stage into the somatosensory cortex.

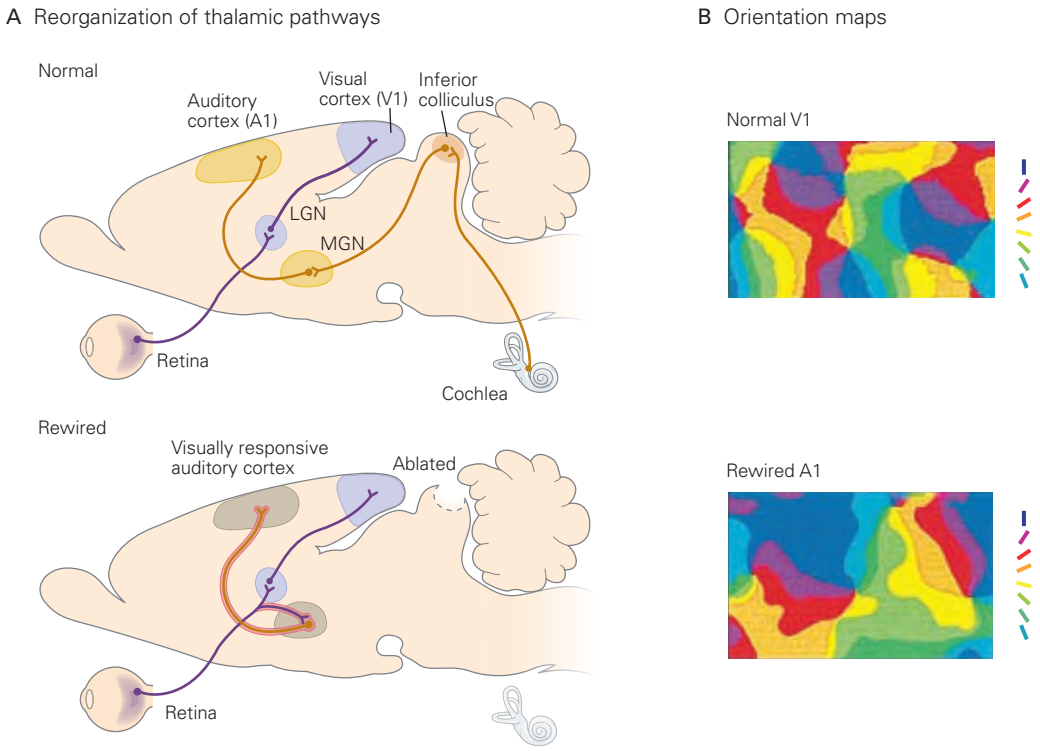

Figure 45–17 Rerouting thalamocortical input can recruit cortical areas for new sensory functions. (Adapted, with permission, from Sharma, Angelucci, and Sur 2000. Copyright © 2000 Springer Nature.)

A. The visual pathway consists of afferent fibers from the retina that innervate the lateral geniculate nucleus (**LGN**) and superior colliculus. Axons from the LGN project to the primary visual cortex (**V1**). The auditory pathway projects from the cochlear nucleus (not shown) to the inferior colliculus, and then to the medial geniculate nucleus (**MGN**) and on to the primary auditory cortex (**A1**). Ablating the inferior colliculus in neonatal ferrets causes retinal afferents to innervate the MGN. As a consequence, the auditory cortex is reprogrammed to process visual information.

B. Visual orientation maps similar to those seen in normal V1 cortex are observed in rewired A1 auditory cortex of ferrets using optical imaging of intrinsic signals. The different colors represent different receptor field orientations (see bars at right). The pattern of activity in rewired A1 resembles that of normal V1.

Highlights

1. The early vertebrate embryo consists of three layers of cells—ectoderm, mesoderm, and endoderm. The entire nervous system arises from the ectoderm, and more specifically from a central strip of ectoderm called the neural plate.
2. Formation of neural plate within the ectoderm occurs by a process called induction, in which underlying mesodermal cells secrete soluble factors that induce a neural program of gene expression in neighboring ectodermal cells. Induction involves a "de-repression" mechanism in which mesoderm-derived soluble factors prevent ectoderm-derived bone morphogenetic proteins (BMPs; members of the transforming growth factor β family) from suppressing the neural fate.
3. Following induction, the neural plate invaginates from the ectoderm to form a neural tube. The tube gives rise to the central nervous system, while cells at the border between neural tube and ectoderm form neural crest, which migrates through the embryo to form the sensory and autonomic ganglia of the peripheral nervous system.
4. As soon as the neural tube forms, it begins to become regionalized. Regionalization along the anterior-posterior axis leads to a series of subdivisions. The anterior region becomes the brain, and the posterior region becomes the spinal cord. Divisions of the prospective brain generate the forebrain, midbrain, and hindbrain. The forebrain divides further to form the telencephalon, from which cortex, hippocampus, and basal ganglia arise; and the diencephalon, which gives rise to thalamus, hypothalamus, and retina. The hindbrain divides to form the pons and cerebellum anteriorly and the medulla posteriorly.
5. Anterior-posterior patterning is established by gradients of Wnt signaling, which arise from selective production of Wnts posteriorly and selective production of Wnt inhibitors anteriorly.
6. Subdivisions along the anteroposterior axis are established by groups of cells called organizing centers at defined positions within the neural tube. The organizing centers secrete factors that pattern neighboring regions of the neural tube and specify neuronal types within them. For example, the isthmic organizer at the boundary of the hindbrain and midbrain secretes Wnts and fibroblast growth factors (FGFs). They act differentially in anterior and posterior regions because the earlier patterning events led to expression of different transcription factors by cells in these regions.
7. Still later, further subdivisions form segments called prosomeres in the forebrain and rhombomeres in the hindbrain, with differential expression of transcription factors leading to generation of distinct neural types in each.
8. In both the hindbrain and the spinal cord, motor neurons acquire distinct properties according to their anterior-posterior position, differentiating into the groups that innervate distinct muscles. Differential expression of transcription factors called Hox proteins is particularly important in diversification of motor neurons. They act with other transcription and soluble factors to divide motor neurons into columns and pools, with each pool destined to innervate a specific muscle.
9. The neural tube is also patterned along the dorsoventral axis. Similar to anterior-posterior regionalization, patterning results from gradients of morphogens. The most important are sonic hedgehog (Shh), which forms a ventral high–dorsal low gradient, and BMPs, which form a dorsal high–ventral low gradient. Different levels of Shh and BMPs induce different transcription factors, which in turn lead to generation of different cell types.
10. Regionalization of the cerebral cortex into motor, sensory, and association areas also begins with gradients of morphogens that induce differential expression of transcription factors, leading to establishment of a "protomap" of area identity. Interactions among areas along with input from subcortical regions refine the protomap to form definitive cortical areas.
11. Several general principles explain many aspects of early neural development: (a) Inductive interactions lead to subdivision of a uniform set of cells into discrete areas. (b) A small set of soluble factors such as FGFs, BMPs, and Wnts are used multiple times at multiple stages to regionalize the nervous system. (c) Varying levels of these factors lead to expression of different transcription factors, which in turn generate different neural cell types. (d) Repressive interactions between cells expressing different transcription factors sharpen boundaries along both anteroposterior and dorsoventral axes.
12. Until recently, studies on early stages of neural development have been restricted to experimental animals. Recent advances now enable neuroscientists to recapitulate some of these processes using cultured human cells. It should therefore

soon be possible to learn whether there are critical early differences between humans and other species that contribute to the complexity of the human brain and to human brain disorders.

Differentiation and Survival of Nerve Cells

In the preceding chapter, we described how local inductive signals pattern the neural tube and establish the early regional subdivisions of the nervous system—the spinal cord, hindbrain, midbrain, and forebrain. Here, we turn to the issue of how progenitor cells within these regions differentiate into neurons and glial cells, the two major cell types of the nervous system. The mature brain comprises billions of nerve cells and a similar number of glial cells arranged in complex patterns, yet its precursor, the neural plate, initially contains only a few hundred cells arranged in a simple columnar epithelium. From this observation alone, it should be apparent that the generation of neural cells and their delivery to appropriate sites must be carefully regulated.

We begin by discussing some of the molecules that specify neuronal and glial cell fates. The basic mechanisms of neurogenesis endow cells with common neuronal properties, features that are largely independent of the region of the nervous system in which they are generated or the specific functions they perform. We also describe mechanisms by which developing neurons become specialized, for example by acquiring the machinery to synthesize specific neurotransmitters.

We next discuss how neurons are delivered from their sites of origin to their final destinations. A common theme is that neurons are frequently "born"—that is, become postmitotic—far from where they end up, for example, in the layers of the cerebral cortex or the ganglia of the peripheral nervous system. Such distances necessitate elaborate migratory mechanisms, which differ among neuronal types.

After the identity and functional properties of the neuron have begun to emerge, additional

developmental processes determine whether the neuron will live or die. Remarkably, approximately half of the neurons generated in the mammalian nervous system are lost through programmed cell death. We examine the factors that regulate the survival of neurons and the possible benefits of widespread neuronal loss. Finally, we describe a core biochemical pathway in nerve cells destined for elimination.

The Proliferation of Neural Progenitor Cells Involves Symmetric and Asymmetric Cell Divisions

Histologists in the late 19th century showed that neural epithelial cells close to the ventricular lumen of the embryonic brain exhibit features of mitosis. We now know that the proliferative zones surrounding the ventricles are the major sites for the production of neural cells in the central nervous system. Moreover, newborn cells in the proliferative zones often become committed to neuronal or glial fates before migrating from these zones.

At early stages of embryonic development, most progenitor cells in the ventricular zone of the neural tube proliferate rapidly. Many of these early neural progenitors have the properties of stem cells: They can generate additional copies of themselves, a process called *self-renewal*, and also give rise to differentiated neurons and glial cells. In a later chapter, we will describe the more recent discovery that stem cells resembling those of embryos also exist in the adult brain and may be harnessed for therapeutic purposes (Chapter 50).

As with other types of stem cells, neural progenitor cells undergo stereotyped programs of cell division. One mode of cell division is symmetric: Neural stem cells divide to produce two stem cells, and in this way expand the population of proliferative progenitor cells. This mode predominates at the earliest times, as the neuroepithelium expands. A second mode is asymmetric: The progenitor produces one differentiated daughter and another daughter that retains its stem cell–like properties. This mode retains but does not amplify the stem cell population. A third mode leads to production of two differentiated daughters. In this symmetric mode, the stem cell population is depleted. All three modes have been found in the embryonic cerebral cortex in vivo and in cortical cells grown in tissue culture (Figure 46–1).

The incidence of symmetric and asymmetric cell division is influenced by signals in the local environment of the dividing cell, making it possible to control the probability of self-renewal or differentiation. Environmental factors can influence the outcome of progenitor cell divisions in two fundamental ways. They can act in an "instructive" manner, biasing the outcome of the division process and causing the stem cell to adopt one fate at the expense of others. Or they can act in a "selective" manner, permitting the survival and maturation of only certain cell progeny.

Radial Glial Cells Serve as Neural Progenitors and Structural Scaffolds

Radial glial cells are the earliest morphologically distinguishable cell type to appear within the primitive neural epithelium. Their cell bodies are located in the ventricular zone, and their long process extends to the pial surface. As the brain thickens, the processes of radial glial cells remain attached to the ventricular and pial surfaces. After the generation of neurons is complete, many radial glial cells differentiate into astrocytes. The elongated shape of the radial glial cell places it in a favorable position to serve as a scaffold for the migration of neurons that emerge from the ventricular zone (Figure 46–2).

The ventricular zone was once thought to contain two major cell types: radial glial cells and a set of neuroepithelial progenitors that serve as the primary source of neurons. More recently, this classical view has changed dramatically. Once symmetric divisions of stem cells have expanded the neuroepithelium, these cells give rise to radial glial cells. The radial glial cells serve as progenitor cells that generate both neurons and astrocytes in addition to their role in neuronal migration (Figure 46–2). Labeling of radial glial cells with fluorescent dyes or viruses shows that their clonal progeny include both neuronal and radial glial cells. These findings indicate that radial glial cells are able to undergo both asymmetric and self-renewing cell division and serve as a major source of postmitotic neurons as well as astrocytes.

The Generation of Neurons and Glial Cells Is Regulated by Delta-Notch Signaling and Basic Helix-Loop-Helix Transcription Factors

How do radial glial cells make the decision to self-renew, generate neurons, or give rise to mature astrocytes? The answer to this question involves an evolutionarily conserved signaling system.

In flies and vertebrates, neural fate is regulated by a cell-surface signaling system, comprised of the

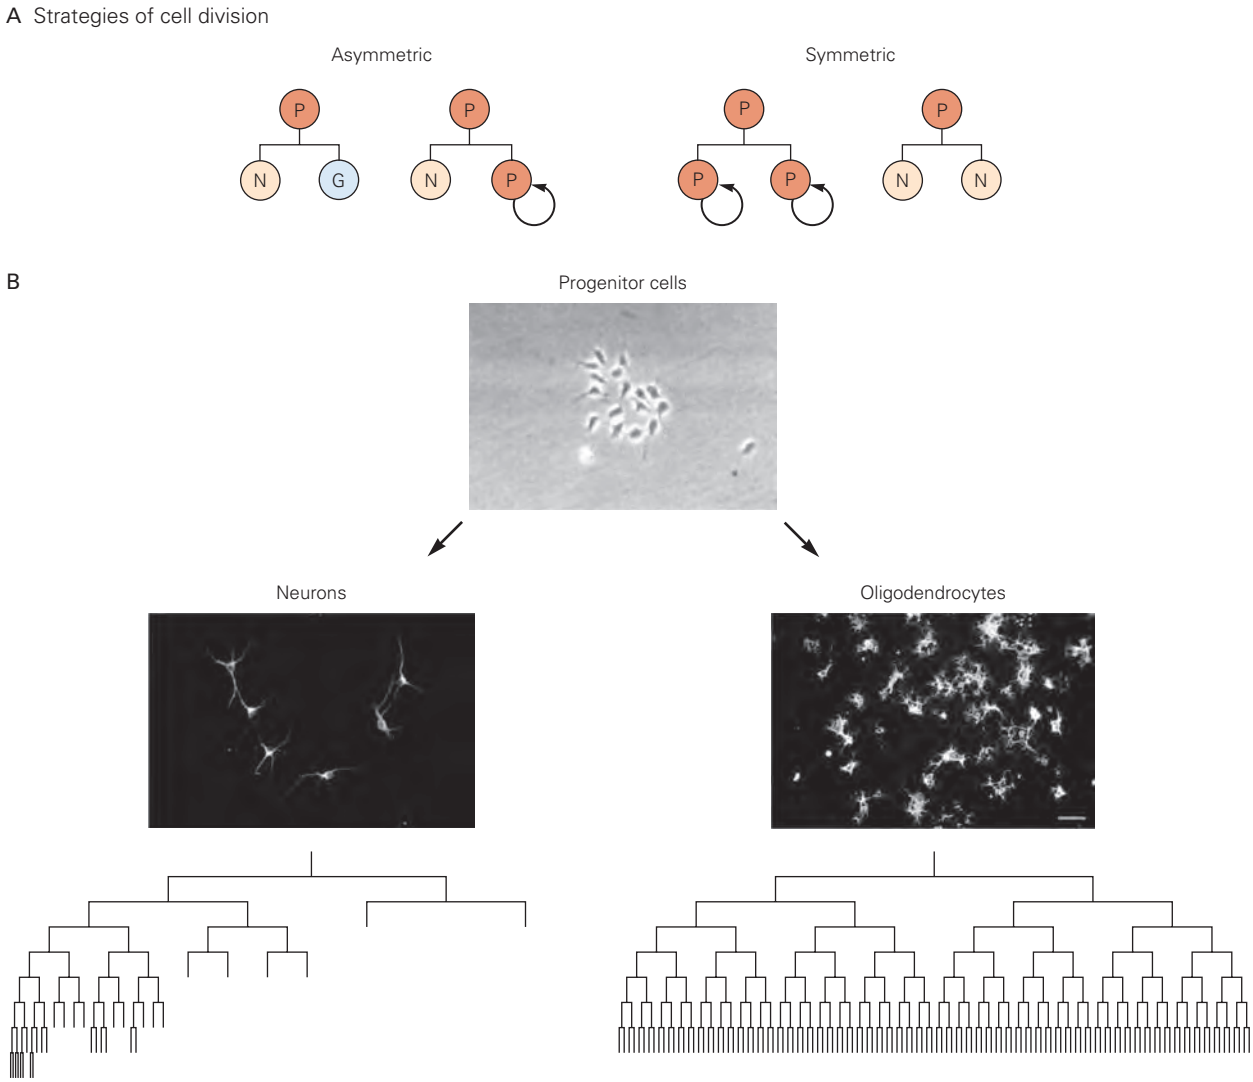

Figure 46–1 Neural progenitor cells have different modes of division.

A. Asymmetric and symmetric modes of cell division. A progenitor cell (P) can undergo asymmetric division to generate a neuron (N) and a glial cell (G), or a neuron and another progenitor. This mode of division contributes to the generation of neurons at early stages of development and of glial cells at later stages, typical of many regions of the central nervous system. Progenitor cells can also undergo symmetric division to generate two additional progenitor cells or two postmitotic neurons.

B. Time-lapse cinematography captures the divisions and differentiation of isolated cortical progenitor cells in the rodent. Lineage diagrams illustrate cells that undergo predominantly asymmetric division, giving rise to neurons, or symmetric division, giving rise to oligodendrocytes. (Adapted, with permission, from Qian et al. 1998. Permission conveyed through Copyright Clearance Center, Inc.)

transmembrane ligand Delta and its receptor Notch. This signaling system was revealed in genetic studies in *Drosophila*. Neurons emerge from within a larger cluster of ectodermal cells, called a *proneural region*, all of which have the potential to generate neurons. Yet within the proneural region, only certain cells form neurons; the others become epidermal support cells.

Delta and Notch are initially expressed at similar levels by all proneural cells (Figure 46–3A). With time, however, Notch activity is enhanced in one cell and suppressed in its neighbor. The cell in which Notch activity is highest loses the potential to form a neuron and acquires an alternative fate. The binding of Delta to Notch results in proteolytic cleavage of the Notch cytoplasmic domain, which then enters the nucleus.

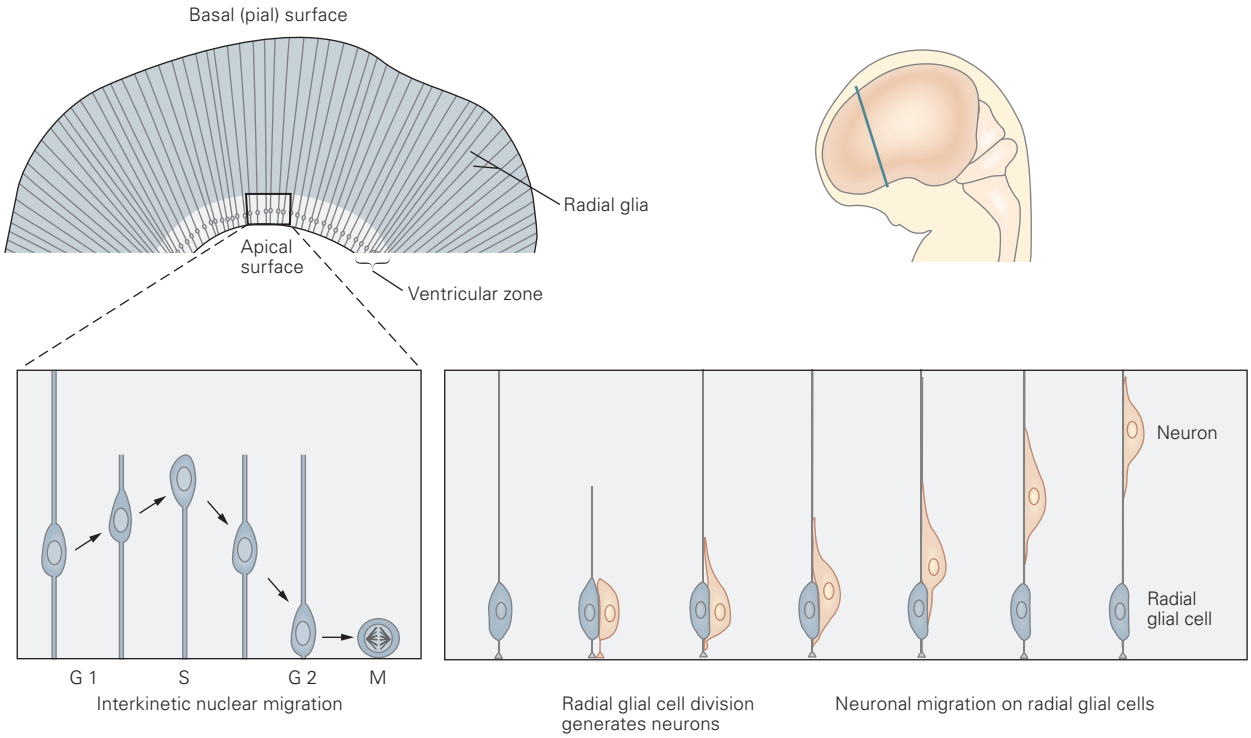

Figure 46–2 **Radial glial cells serve as precursors to neurons in the central nervous system and also provide a scaffold for radial neuronal migration.** The nuclei of progenitor cells in the ventricular zone of the developing cerebral cortex migrate along the apical-basal axis as they progress through the cell cycle. *Left*: During the G1 phase, the nuclei rise from the inner (apical) surface of the ventricular zone. During the S phase, they reside in the outer (basal) third of the ventricular zone. During the G2 phase, they migrate apically, and mitosis (**M**) occurs when the nuclei reach the ventricular surface. *Right*: During cell division, radial glial cells give rise to postmitotic neurons that migrate away from the ventricular zone using radial glial cells as a guide.

There, it functions as a transcription factor, regulating the activity of a cascade of other transcription factors of the basic helix-loop-helix (bHLH) family. The bHLH transcription factors suppress the ability of the cell to become a neuron and reduce the level of expression of the ligand Delta (Figure 46–3B,C).

The initial difference in Notch levels between cells may be small and in some cases stochastic (random). Through this feedback pathway, however, these initial minor differences are amplified to generate all-or-none differences in the status of Notch activation and, consequently, the fates of the two cells. This basic logic of Delta-Notch and bHLH signaling has been conserved in vertebrate and invertebrate neural tissues.

How does Notch signaling regulate neuronal and glial production in mammals? At early stages in the development of the mammalian cortex, Notch signaling promotes the generation of radial glial cells by activating members of the Hes family of bHLH transcriptional repressors. Two of these proteins, Hes1 and Hes5, appear to maintain radial glial cell character by activating the expression of an ErbB class tyrosine kinase receptor for neuregulin, a secreted signal that promotes radial glial cell identity. The Notch ligand Delta1 as well as neuregulin are expressed by newly generated cortical neurons; thus, the radial glial cells depend on feedback signals from their neuronal progeny for continued production.

At later stages of cortical development, Notch signaling continues to activate Hes proteins, but a change in the intracellular response pathway results in astrocyte differentiation. At this stage, the Hes proteins work by activating a transcription factor, STAT3, which recruits the serine-threonine kinase JAK2, a potent inducer of astrocyte differentiation. STAT3 also activates expression of astrocyte-specific genes such as the glial-fibrillary acidic protein (GFAP).

The generation of oligodendrocytes, the second major class of glial cells in the central nervous system, follows many of the principles that control neuron

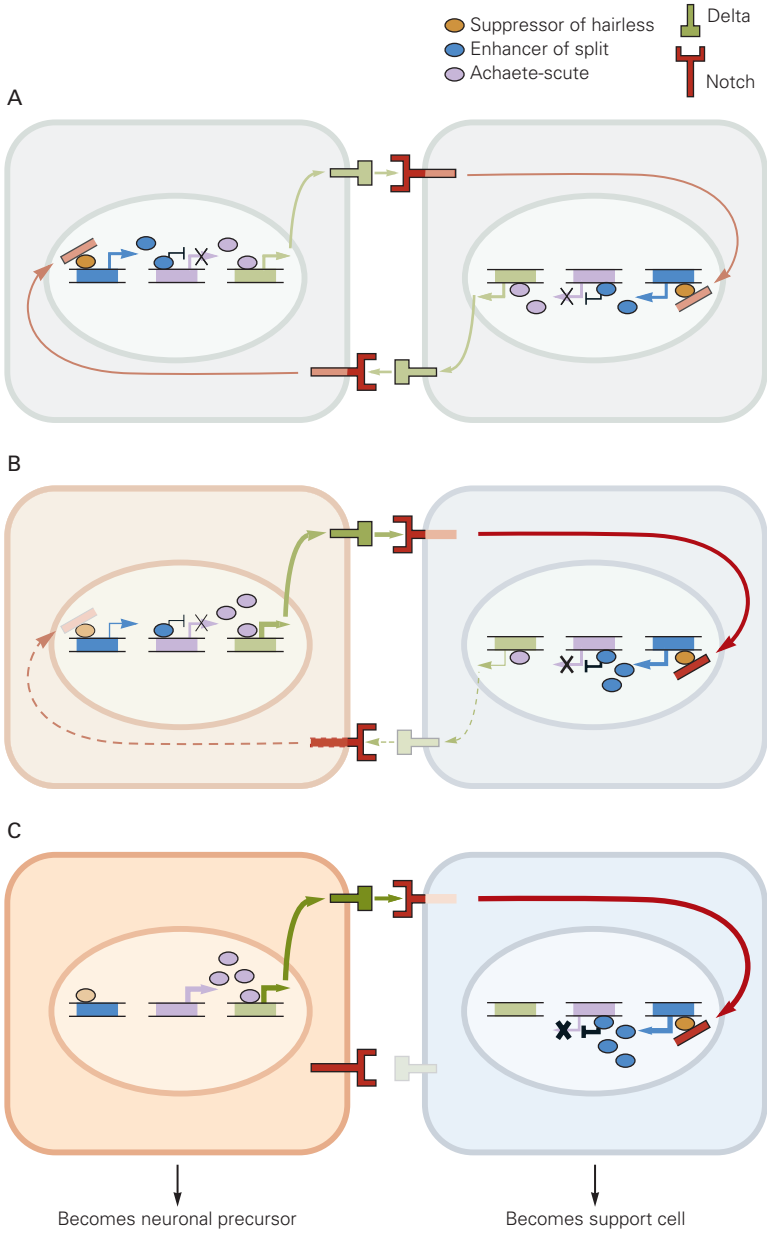

Figure 46–3 Delta binds the receptor Notch and determines neuronal fate.

A. At the onset of the interaction between two cells, Delta engages the receptor Notch. Delta and Notch are expressed at similar levels in each cell, and thus their initial signaling strength is equal.

B. A small imbalance in the strength of Delta-Notch signaling breaks the symmetry of the interaction. In this example, the left cell provides a slightly greater Delta signal, thus activating Notch signaling in the right cell to a greater extent. On binding by Delta, the cytoplasmic domain of Notch is cleaved to form a proteolytic fragment called Notch-Intra, which enters the nucleus of the cell and initiates a basic helix-loop-helix (bHLH) transcriptional cascade that regulates the level of Delta expression. Notch-Intra forms a transcriptional complex with a bHLH protein, suppressor of hairless, which binds to and activates the gene encoding a second bHLH protein, enhancer of split. Once activated, enhancer of split binds to and represses expression of the gene encoding a third bHLH protein, achaete-scute. Achaete-scute activity promotes expression of Delta. Thus, by repressing achaete-scute, enhancer of split decreases transcriptional activation of the Delta gene and production of Delta protein. This diminishes the ability of the cell on the right to activate Notch signaling in the left cell.

C. Once the level of Notch signaling in the left cell has been reduced, suppressor of hairless no longer activates enhancer of split, and the level of expression of achaete-scute increases, resulting in enhanced expression of Delta and further activation of Notch signaling in the right cell. In this way, a small initial imbalance in Delta-Notch signaling is rapidly amplified into a marked asymmetry in the level of Notch activation in the two cells. In the mammalian central nervous system, cells with high levels of Notch activation are diverted from neuronal fates, whereas cells with low levels of Notch activation become neurons.

and astrocyte production (Figure 46–4). Notch signaling regulates the expression of two bHLH transcription factors, Olig1 and Olig2, which have essential roles in the production of embryonic and postnatal oligodendrocytes.

Additional mechanisms exist to ensure that the effects of Notch signals are avoided in cells destined to become neurons. One involves a cytoplasmic protein called Numb. The key role of Numb in neurogenesis was first shown in *Drosophila*, where it determines the neuronal fate of daughter cells of asymmetrically dividing progenitors. In the mammalian cortex, Numb is preferentially localized in neuronal daughters and antagonizes Notch signaling. Loss of Numb activity causes progenitor cells to proliferate extensively. The inhibition of Notch signaling results in the expression of several proneural bHLH transcription factors, notably Mash1, neurogenin-1, and neurogenin-2. Neurogenins promote neuronal production by activating downstream

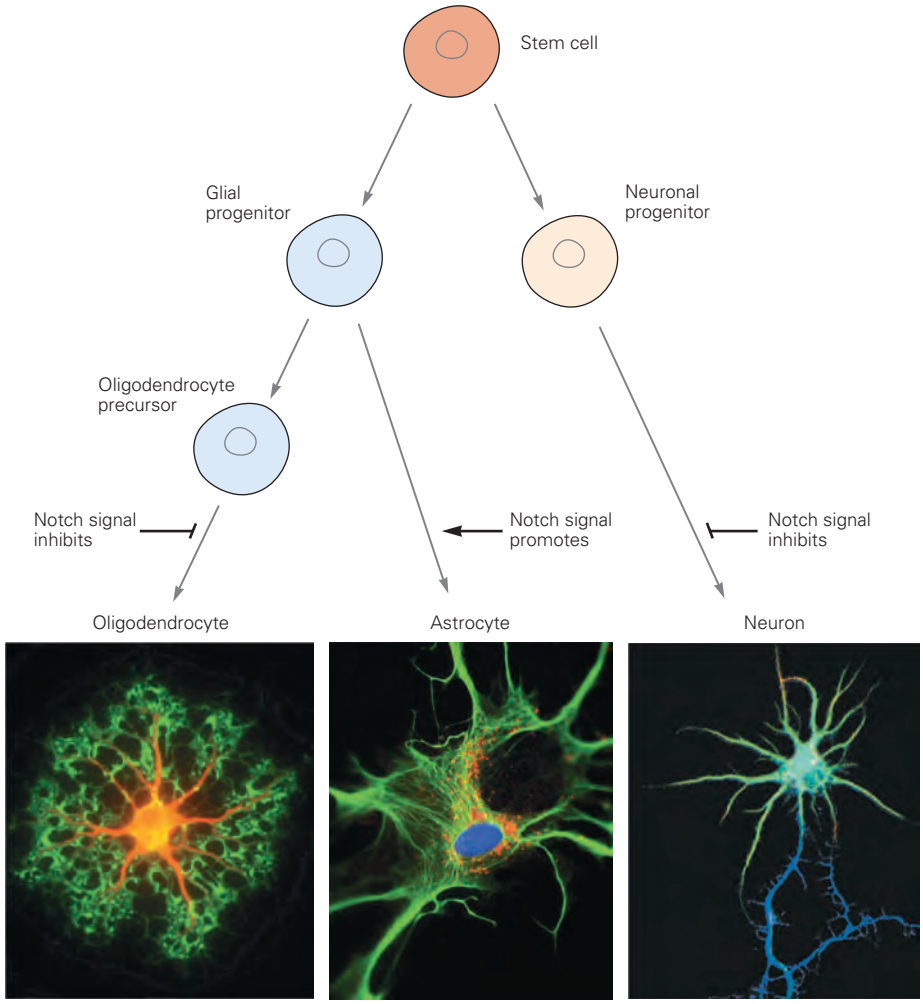

Figure 46–4 Notch signaling regulates the fate of cells in the developing cerebral cortex. Notch signaling has several roles in cell differentiation in the developing cerebral cortex. Activation of Notch signaling in glial progenitor cells results in differentiation of the cells as astrocytes and inhibits differentiation as oligodendrocytes (left pathway). Notch signaling also inhibits progenitor cells from differentiating into neurons (right pathway). (Photo of oligodendrocyte reproduced, with permission, from David H. Rowitch; photo of astrocyte reproduced, with permission, from SAASTA on behalf of photographers Edward Nyatia and Dirk Michael Lang; photo of neuron reproduced, with permission, from Masatoshi Takeichi.)

bHLH proteins such as neuroD, and they block the formation of astrocytes by inhibiting JAK and STAT signaling.

Although Delta-Notch signaling and bHLH transcription factor activators lie at the heart of the decision to produce neurons or glial cells, several additional transcriptional pathways augment this core molecular program. One important transcription factor, REST/NRSF, represses the expression of neuronal genes in neural progenitors and glial cells. REST/NRSF is rapidly degraded as neurons differentiate, permitting the expression of neurogenic bHLH factors and other neuronal genes. Homeodomain transcription factors of the SoxB class also play an important role in maintaining neural progenitors by blocking neurogenic bHLH protein activity. The differentiation of neurons therefore requires the avoidance of REST/NRSF and SoxB protein activity.

The Layers of the Cerebral Cortex Are Established by Sequential Addition of Newborn Neurons

The ventricular zone in the most anterior portion of the mammalian neural tube gives rise to the cerebral cortex in a series of steps. Cells from the ventricular zone, which is on the apical edge of the neuroepithelium, initially migrate basally to form a subventricular zone, which houses a set of progenitor cells with a more restricted set of fates. Next to form is an intermediate zone, through which newly formed neurons migrate, and a preplate, which houses the earliest-born neurons. Additional neurons migrate to form a layer called the cortical plate, which lies within the preplate. The cortical plate thereby divides the preplate into an apical subplate and a basal marginal zone (Figure 46–5A).

Once within the cortical plate, neurons become organized into well-defined layers. The layer in which a neuron settles is correlated precisely with the neuron's *birthday*, a term that refers to the time at which a dividing precursor cell undergoes its final round of cell division and gives rise to a postmitotic neuron. Cells that migrate from the ventricular and subventricular zones and leave the cell cycle at early stages give rise to neurons that settle in the deepest layers of the cortex. Cells that exit the cell cycle at progressively later stages migrate over longer distances and pass earlier-born neurons before settling in more superficial layers of the cortex. Thus, the layering of neurons in the cerebral cortex follows an inside-first, outside-last rule (Figure 46–5B).

Neurons Migrate Long Distances From Their Site of Origin to Their Final Position

The migration of neurons from the cortical ventricular zone to the cortical plate follows a process termed *radial migration.* In this mode, the neurons move along the long unbranched processes of radial glial cells to reach their destinations. In contrast, interneurons enter the cortex from subcortical sites by a process called *tangential migration*. We discuss these modes in turn and then describe a third migratory strategy, *free migration*, which predominates in the peripheral nervous system.

Excitatory Cortical Neurons Migrate Radially Along Glial Guides

Classical anatomical studies of cortical development in the 1970s provided evidence that neurons generated in the ventricular zone migrate to their settling position along a pathway of radial glial fibers. Radial glial cells serve as the primary scaffold for radial neuronal migration. Their cell bodies are located close to the ventricular surface and give rise to elongated fibers that span the width of the developing cerebral wall. Each radial glial cell has one basal end-foot at the apical surface of the ventricular zone and processes that terminate in multiple end-feet at the pial surface (Figure 46–6). Radial glial scaffolds are especially important in the development of the primate cortex, where neurons are required to migrate over long distances as the cortex expands. A single radial glial cell scaffold can support the migration of up to 30 generations of cortical neurons before eventually differentiating into an astrocyte.

What forces and molecules power neuronal migration on radial glial cells? After a neuron leaves the cell cycle, its leading process wraps around the shaft of the radial glial cell and its nucleus translocates within the cytoplasm of the leading process. Although the leading process of the migrating neuron extends slowly and steadily, the nucleus moves in an intermittent, stepwise manner because of complex rearrangements of the cytoskeleton. A microtubular lattice forms a cage around the nucleus; movement of the nucleus depends on a centrosome-like structure, termed a *basal body*, from which a system of microtubules projects into the leading process, providing tracks along which the nucleus moves (Figure 46–7A).

Neuronal migration along radial glia also involves adhesive interactions between cells. Adhesive receptors such as integrins promote neuronal extension on radial glial cells. The migration of neurons along glial fibers is nevertheless different from the extension of axons driven by growth cones (Chapter 47). In neuronal migration, the leading process is devoid of the structured actin filaments that typify growth cones and more closely resembles an extending dendrite, an inference made first by Santiago Ramón y Cajal.

Disruption in the migratory and settling programs of cortical neurons underlies much human cortical pathology (Figure 46–5C). For example, in lissencephaly

Figure 46–5 (Opposite) **The migration of neurons within the embryonic cerebral cortex leads to layered cortical organization.** (Adapted from Olsen and Walsh 2002.)

A. This temporal sequence of neurogenesis is for the mouse cerebral cortex. Neurons begin to accumulate in the cortical plate during the last 5 days of embryonic development. Within the cortical plate, neurons populate the deep layers before settling in the superficial layers. (Abbreviations: **IZ**, intermediate zone; **MZ**, marginal zone; **PP**, preplate; **SP**, subplate; **SVZ**, subventricular zone; **VZ**, ventricular zone; **WM**, white matter.)

B. During normal cortical development, neurons use radial glial cells as migratory scaffolds as they enter the cortical plate. As they approach the pial surface, neurons stop migrating and detach from radial glial cells. This orderly inside-out pattern of neuronal migration results in the formation of six neuronal layers in the mature cerebral cortex, arranged between the white matter and subplate. (Abbreviation: **CP**, cortical plate.)

C. In the mouse mutant *reeler,* which lacks functional reelin protein, the layering of neurons in the cortical plate is severely disrupted and partially inverted. In addition, the entire cortical plate develops beneath the subplate. In *doublecortin* mutants, the cortex is thickened, neurons lose their characteristic layered identity, and some layers contain fewer neurons. A similar disruption is observed in *Lis1* mutants, which underlies certain forms of human lissencephaly.

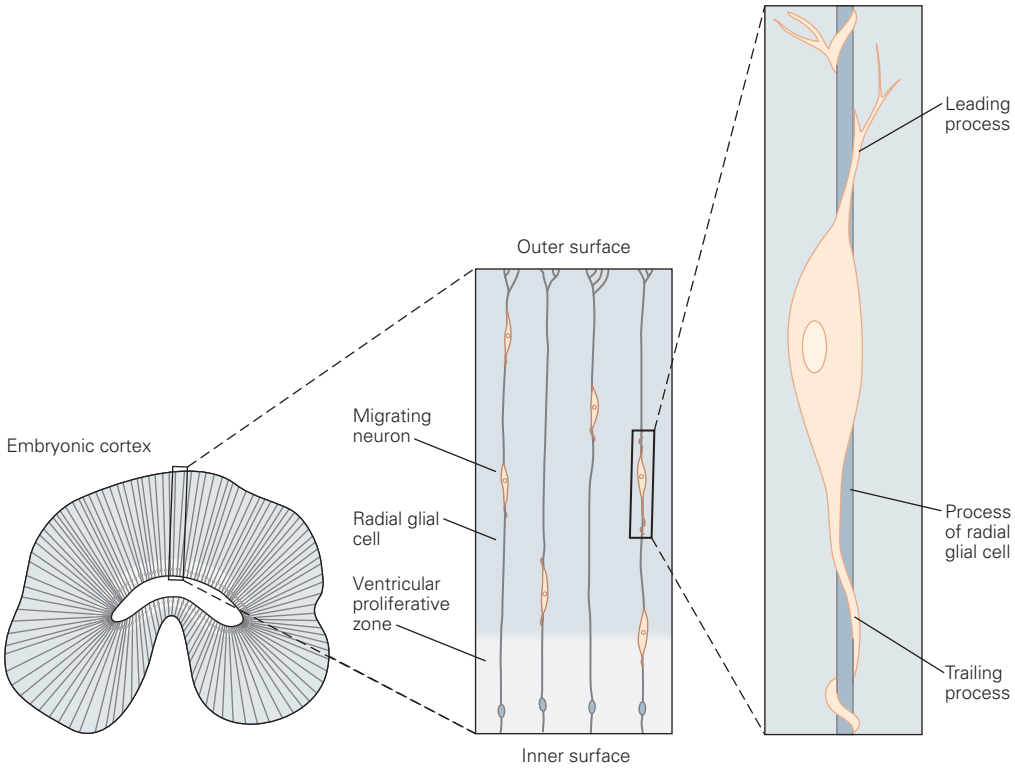

Figure 46–6 Neurons migrate along radial glial cells. After their generation from radial glial cells, newly generated neurons in the embryonic cerebral cortex extend a leading process that wraps around the shaft of the radial glial cell, thus using the radial glial cells as scaffolds during their migration from the ventricular zone to the pial surface of cortex.

(Greek, smooth brain, referring to the characteristic smoothing of the cortical surface in patients with the disorder), neurons leave the ventricular zone but fail to complete their migration into the cortical plate. As a result, the mature cortex is typically reduced from six to four neuronal layers, and the arrangement of neurons in each remaining layer is disordered. Occasionally, lissencephaly is accompanied by the presence of an additional group of neurons in the subcortical white matter. Patients with lissencephalies from mutations in the *Lis1* and *doublecortin* genes often suffer severe intellectual disability and intractable epilepsy. The Lis1 and doublecortin proteins have been localized to microtubules, suggesting that they are involved in microtubule-dependent nuclear movement, although their precise functions in neuronal migration remain unclear.

Mutations that disrupt the reelin signaling pathway disrupt the final stage of neuronal migration through the cortical subplate. The reelin protein is secreted from the Cajal-Retzius cells, a class of neurons found in the preplate and marginal zone. Signals from these cells are crucial for the migration of cortical neurons. In mice lacking functional reelin, neurons fail to detach from their radial glial scaffolds and pile up underneath the cortical plate, disobeying the inside-out migratory rule. As a consequence, the normal layering of cell types is partially inverted and the marginal zone is lost. Reelin acts through cell-surface receptors that include the ApoE receptor 2 and the very-low-density lipoprotein receptor. The binding of reelin to these receptors activates an intracellular protein, Dab1, which transduces reelin signals. Not surprisingly, the loss of proteins that transduce reelin signals produces similar migratory phenotypes.

Cortical Interneurons Arise Subcortically and Migrate Tangentially to Cortex

Progenitor cells in the cortical ventricular zone were initially believed to give rise to all cortical neurons. However, as better molecular labels for distinct neuronal types became available, it was found that interneurons arise in the ventricular zone of subcortical structures. Most of them originate in regions of the ventral telencephalon called the ganglionic eminences (Figure 46–8).

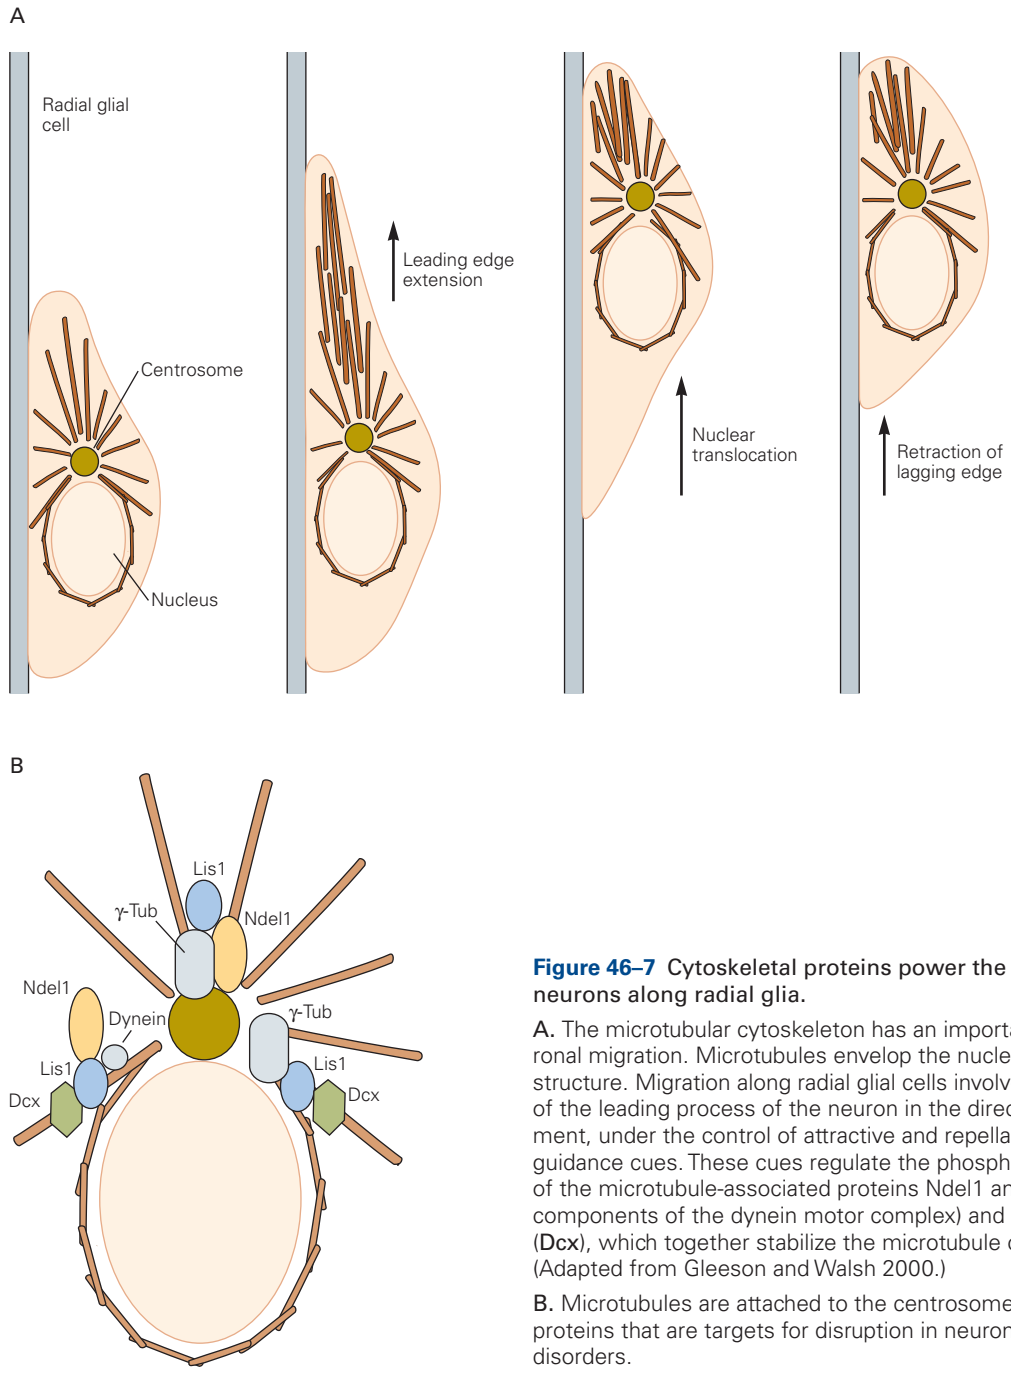

Figure 46–7 Cytoskeletal proteins power the migration of neurons along radial glia.

A. The microtubular cytoskeleton has an important role in neuronal migration. Microtubules envelop the nucleus in a cage-like structure. Migration along radial glial cells involves elongation of the leading process of the neuron in the direction of movement, under the control of attractive and repellant extracellular guidance cues. These cues regulate the phosphorylation status of the microtubule-associated proteins Ndel1 and Lis1 (two components of the dynein motor complex) and of doublecortin (**Dcx**), which together stabilize the microtubule cytoskeleton. (Adapted from Gleeson and Walsh 2000.)

B. Microtubules are attached to the centrosome by a series of proteins that are targets for disruption in neuronal migration disorders.

The medial and central eminences generate most cortical interneurons, which migrate dorsally from their sites of origin to enter the cortex. Some enter through the intermediate zone, while others enter through the marginal zone (Figure 46–5A). Once they reach particular anterior-posterior and mediolateral positions, they switch to a radial mode of migration to travel the final distance to appropriate layers. Distinct populations of neurons generated in the ganglionic eminences migrate at different times and through different routes, contributing to the diversity of the interneuronal population. Precise relationships between time and place of origin, migratory route, and ultimate fate remain to be determined.

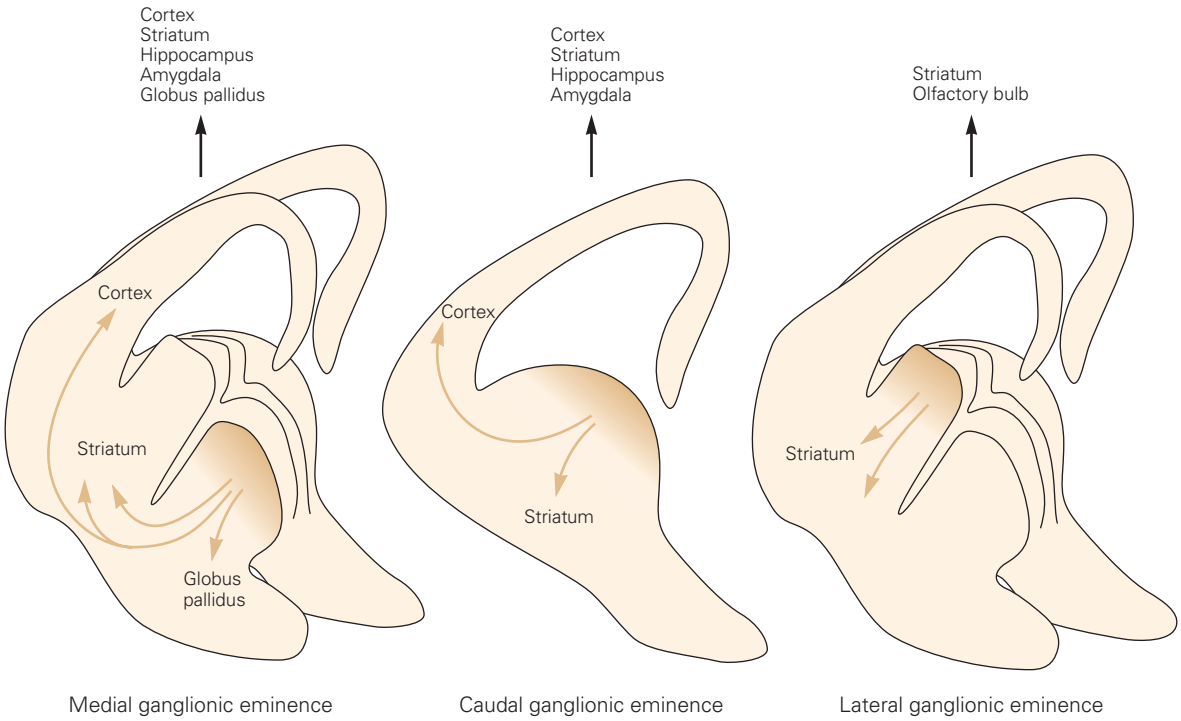

Figure 46–8 Forebrain interneurons are generated in the ventral telencephalon and migrate tangentially to the cerebral cortex. Neurons generated in the ganglionic eminences migrate to and settle in many regions of the forebrain, where they differentiate into interneurons. Cortical interneurons arise from medial and caudal ganglionic eminences. Other cells generated in these regions migrate in other directions, populating the hippocampus, striatum, globus pallidus, and amygdala with interneurons. The lateral ganglionic eminence generates cells that migrate to the striatum and the olfactory bulb. Cells migrating to the bulb use neighboring migrating cells as substrates for migration, a process called chain migration. (Adapted, with permission, from Bandler, Mayer, and Fishell 2017. Copyright © 2017 Elsevier Ltd.)

Nonetheless, it is now clear that cortical neurons originate from two sources: excitatory neurons from the cortical ventricular zone and interneurons from the ganglionic eminences.

Interneurons in other forebrain structures also arise from the ganglionic eminences, as well as a few other subcortical sites such as the preoptic area. Cells migrating caudally from the medial and caudal eminences populate the hippocampus, while cells migrating ventrolaterally from these regions populate the basal ganglia. In contrast, neurons generated in the lateral ganglionic eminence migrate rostrally and contribute the periglomerular and granule interneurons of the olfactory bulb. In this rostral migratory stream, neurons use neighboring neurons as substrates for migration (chain migration). In the adult brain, neurons that follow the rostral migratory stream originate instead in the subventricular zone of the striatum.

Transcription factors control the character of ganglionic eminence neurons. The homeodomain proteins Dlx1 and Dlx2 are expressed by cells in the ganglionic eminences. In mice lacking Dlx1 and Dlx2 activity, the resultant perturbation of neuronal migration leads to a profound reduction in the number of GABAergic interneurons in the cortex. Other transcription factors are responsible for differences among ganglionic eminences. For example, Nkx2.1 is selectively expressed by cells in the medial ganglionic eminence. In its absence, interneurons generated in this region take on characteristics of those normally generated in the lateral and caudal ganglionic eminences. Yet other transcription factors specify the distinct characteristics of subpopulations of neurons within each ganglionic eminence.

One of the main features that these transcription factors specify is the migratory path that the newborn interneurons take. A host of soluble and cell surface factors produced by cells in and near the ganglionic eminences provide repulsive cues that lead to expulsion of cells from the ventricular zone, so-called motogenic (movement-promoting) cues that speed their migration and attractive cues that direct them to their targets. These factors include slits, semaphorins, and ephrins, all of which we will encounter in Chapter 47 as molecules that guide axons to their targets.

Neural Crest Cell Migration in the Peripheral Nervous System Does Not Rely on Scaffolding

The peripheral nervous system derives from neural crest stem cells, a small group of neuroepithelial cells at the boundary of the neural tube and epidermal ectoderm. Soon after their induction, neural crest cells are transformed from epithelial to mesenchymal cells and begin to detach from the neural tube. They then migrate to many sites throughout the body (Figure 46–9). Neural crest cell migration does not rely on scaffolding (ie, radial glial cells or preexisting axon tracts) and thus is called free migration. This form of neuronal migration requires significant cytoarchitectural and cell adhesive changes and differs from most of the migratory events in the central nervous system.

Neural crest migration is promoted and guided by several families of secreted factors. For example, bone morphogenetic proteins (BMPs), which are critical for neural crest induction at an earlier stage (Chapter 45), are required for neural crest migration at later stages. Exposure of neural epithelial cells to BMPs triggers molecular changes that convert epithelial cells to a mesenchymal state, causing them to delaminate from the neural tube and migrate into the periphery. BMPs trigger changes in neural crest cells by inducing expression of transcription factors, notably the zinc finger proteins snail, slug, and twist, which have a conserved role in promoting epithelial-to-mesenchymal transitions. These transcription factors direct expression of proteins that regulate the properties of the cytoskeleton as well as enzymes that degrade extracellular matrix proteins. These enzymes give neural crest cells the ability to break down the basement membrane surrounding the epithelium of the neural tube, permitting them to embark on their migratory journey into the periphery.

As neural crest cells begin to delaminate, their expression of cell adhesion molecules changes. Alterations in expression of adhesive proteins, notably cadherins, permit neural crest cells to loosen their adhesive contacts with neural tube cells and begin the delamination process. Neural crest cells also begin to express integrins, receptors for extracellular matrix proteins such as laminins and collagens that are found along peripheral migratory paths.

The first structures encountered by migrating neural crest cells are somites, epithelial cells that later give rise to muscle and cartilage. Neural crest cells pass through the anterior half of each somite but avoid the posterior half (Figure 46–9A). The rostral channeling of migratory neural crest cells is imposed by ephrin B proteins, which are concentrated in the posterior half of each somite. Ephrins provide a repellant signal that interacts with EphB class tyrosine kinase receptors on neural crest cells to prevent their invasion. Neural crest cells that remain within the anterior sclerotome of the somite differentiate into sensory neurons of the dorsal root ganglia; those that migrate around the dorsal region of the somite approach the skin and give rise to melanocytes.

Differentiation of the neural crest into its various derivatives depends on complex interactions between the distinct cues that cells receive along their journey and intrinsic predispositions that vary along the rostrocaudal axis. Development of sensory neurons is initiated at the time the cells emigrate from the neural tube. The cells are exposed to signals from the dorsal neural tube and somites that induce expression of neurogenin, a transcription factor of the bHLH family, which in turn promotes a sensory fate. Subsequent influences diversify the neurons into multiple sensory types, such as nociceptive and proprioceptive neurons (Figure 46–10). In contrast, those neural crest cells that follow a more medial and ventral migratory path are exposed to BMPs secreted from the dorsal aorta. They express the bHLH factor Mash1, which leads to their differentiation into sympathetic neurons.

Structural and Molecular Innovations Underlie the Expansion of the Human Cerebral Cortex

No mice or monkeys are reading this book. This is in large part because the human brain is different from that of even our closest relatives, both qualitatively and quantitatively. Yet most studies of mammalian neural development have been carried out on mice, whose brain contains approximately 1,000-fold fewer neurons than those of the human brain and 100-fold fewer than the best-studied nonhuman primate, the rhesus macaque. Recently, however, new methods are making it possible to elucidate some of the molecular and structural features that lead to the expansion of the human brain and particularly the human cerebral cortex.

Classical anatomical studies made clear that the primate cortex has not only a far larger size and thickness than that of rodents but also more discrete areas and more layers (Figure 46–11A). In addition, the packing density of neurons is higher in primates than in mice, so the difference in neuronal number is greater than would be expected from size alone. One main contributor to the expansion in primates is a large pool of neuronal progenitors. Many of these progenitors are a second type of radial glial cell, called the outer radial

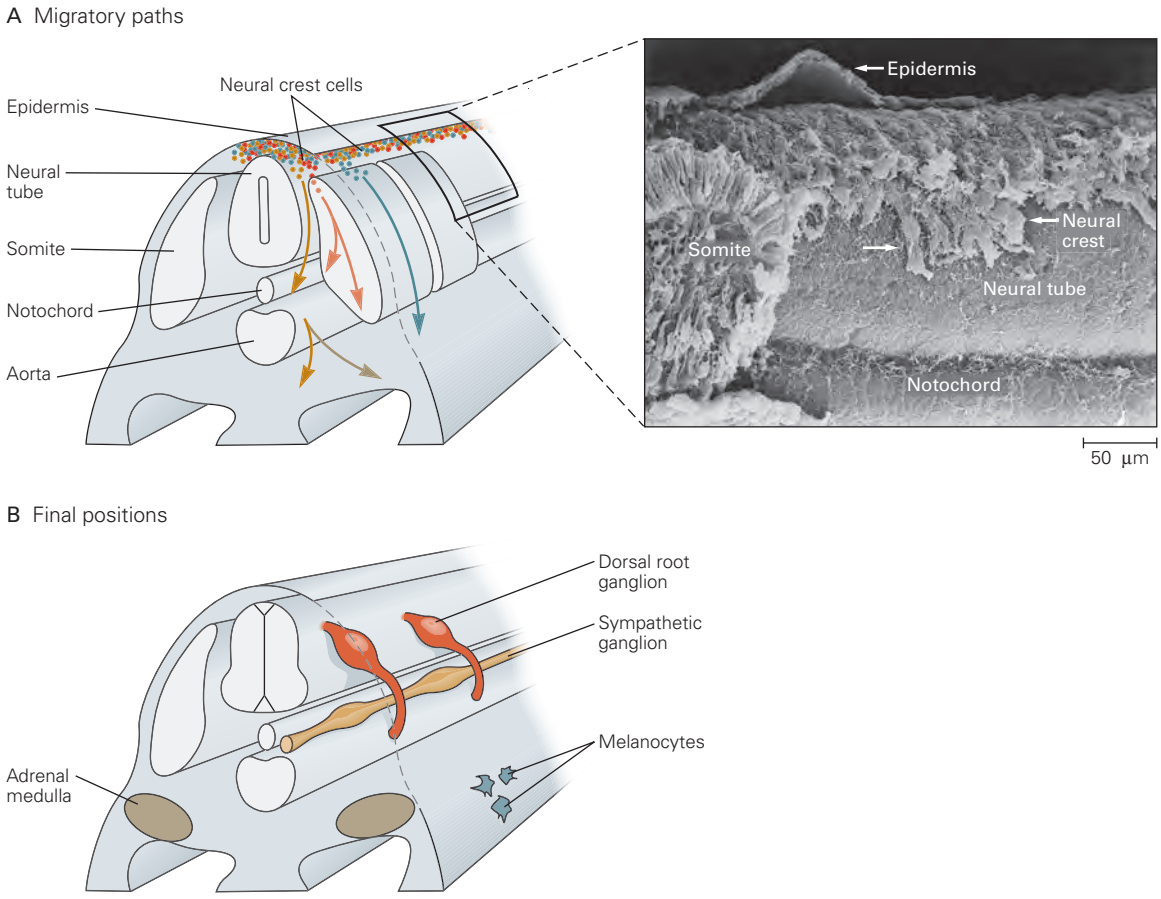

Figure 46–9 Neural crest cell migration in the peripheral nervous system.

A. A cross section through the middle part of the trunk of a chick embryo shows the main pathways of neural crest cells. Some cells migrate along a superficial pathway, just beneath the ectoderm, and differentiate into pigment cells of the skin. Others migrate along a deeper pathway that takes them through the somites, where they coalesce to form dorsal root sensory ganglia. Still others migrate between the neural tube and somites, past the dorsal aorta. These cells differentiate into sympathetic ganglia and adrenal medulla. The scanning electron micrograph shows neural crest cells migrating away from the dorsal surface of the neural tube of a chick embryo. (Micrograph reproduced, with permission, from K. Tosney.)

B. Neural crest cells reach their final settling positions where they complete differentiation.

glial cell to distinguish it from the canonical or inner radial glia described above. Outer radial glia, unlike inner radial glia, lack contact with the ventricular surface and exhibit molecular differences from inner radial glia. However, they are capable of generating neurons and serving as a migratory guide. The massive increase in their number in primates, and particularly humans, provides a partial explanation for the increase in the number of neurons in the human cerebral cortex.

How can human-specific developmental features be analyzed experimentally? New methods of molecular analysis are making it possible to compare the proteins, transcripts, and genes of humans with those of our close relatives, resulting in the discovery of intriguing specializations. However, hypotheses derived from these findings are difficult to test: Most of the developmental studies we describe in these chapters cannot be performed on humans, and even nonhuman primates are difficult subjects for developmental analysis. A possible solution is the recently devised "organoid" culture system.

Cells from adult skin can be reprogrammed to become multipotential progenitors called induced pluripotent stem cells (iPSCs) by methods that we will discuss in Chapter 50. When placed into culture under carefully controlled conditions and allowed to expand in three dimensions (quite unlike conventional two-dimensional cultures), they proliferate and self-organize into structures that resemble the developing forebrain and exhibit species-specific features

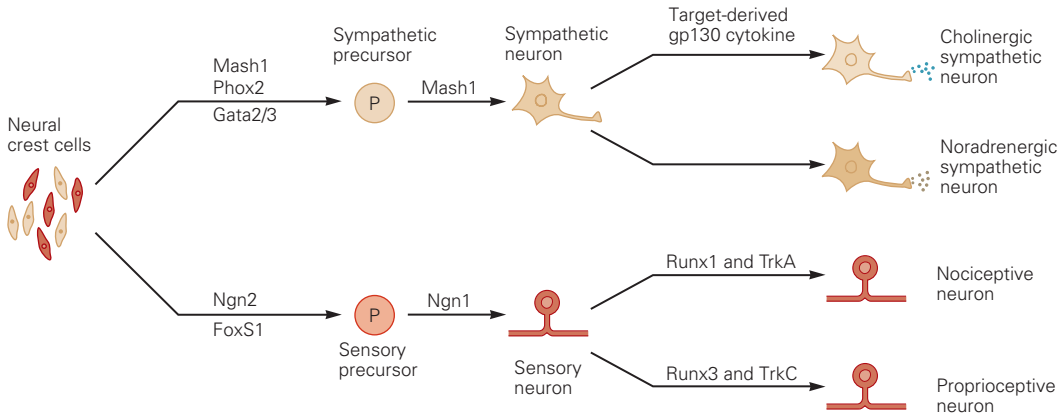

Figure 46–10 **Neural crest cells differentiate into sympathetic and sensory neurons.** The neuronal fates of trunk neural crest cells are controlled by transcription factor expression. Expression of the basic helix-loop-helix (bHLH) protein Mash1 directs neural crest cells along a sympathetic neuronal pathway. Sympathetic neurons can acquire noradrenergic or cholinergic transmitter phenotypes depending on the target cells they innervate and the level of gp130 cytokine signaling (see Figure 46–13). Two bHLH proteins, neurogenin-1 and -2, direct neural crest cells along a sensory neuronal pathway. Sensory neurons that express the transcription factor Runx1 and the tyrosine kinase receptor TrkA become nociceptors; those that express Runx3 and TrkC become proprioceptors. (Abbreviations: **Ngn-1**, neurogenin-1; **Ngn-2**, neurogenin-2.)

(Figure 46–11B). Most notably, organoids from human cells contain a bilayered, large subventricular zone with numerous outer radial glia, whereas organoids from mouse cells contain a smaller subventricular zone containing predominately conventional or inner radial glia. These organoids can be used to elucidate the development of at least some early aspects of human cortical development.

Additional applications abound. One is to obtain iPSCs from patients with brain disorders. Organoids derived from such patients have features that may lead to cortical malformations such as lissencephaly (see Figure 46–5). The hope is that these organoids can be used to elucidate disease mechanisms and eventually test therapies. A second application is to compare organoids derived from chimpanzee and human iPSCs. This comparison provides a novel means of investigating the most recent evolutionary innovations that separate us from our closest living relatives.

Intrinsic Programs and Extrinsic Factors Determine the Neurotransmitter Phenotypes of Neurons

Neurons continue to develop after they have migrated to their final position, and no aspect of their later differentiation is more important than the choice of chemical neurotransmitter. Neurons that populate the brain use two major neurotransmitters: The amino acid L-glutamate is the major excitatory transmitter, whereas γ-aminobutyric acid (GABA) is the major inhibitory transmitter. Some spinal cord neurons use another amino acid, glycine, as their inhibitory transmitter. In the peripheral nervous system, sensory neurons use glutamate, motor neurons use acetylcholine, and autonomic neurons use acetylcholine or norepinephrine. Smaller numbers of neurons use other transmitters, such as serotonin and dopamine. The choice of neurotransmitter determines which postsynaptic cells a neuron can talk to and what it can say.

Neurotransmitter Choice Is a Core Component of Transcriptional Programs of Neuronal Differentiation

Distinct molecular programs are used to establish neurotransmitter phenotype in different brain regions and neuronal classes. We shall illustrate the general strategy for assignment of amino acid neurotransmitter phenotypes by focusing on neurons in the cerebral cortex and cerebellum.

The cerebral cortex contains glutamatergic pyramidal neurons that are generated within the cortical plate and rely on the bHLH factors neurogenin-1 and neurogenin-2 for their differentiation. In contrast, as discussed earlier in the chapter (see Figure 46–8), most GABAergic inhibitory interneurons migrate into the cortex from the ganglionic eminences; their inhibitory transmitter character is specified by the bHLH protein

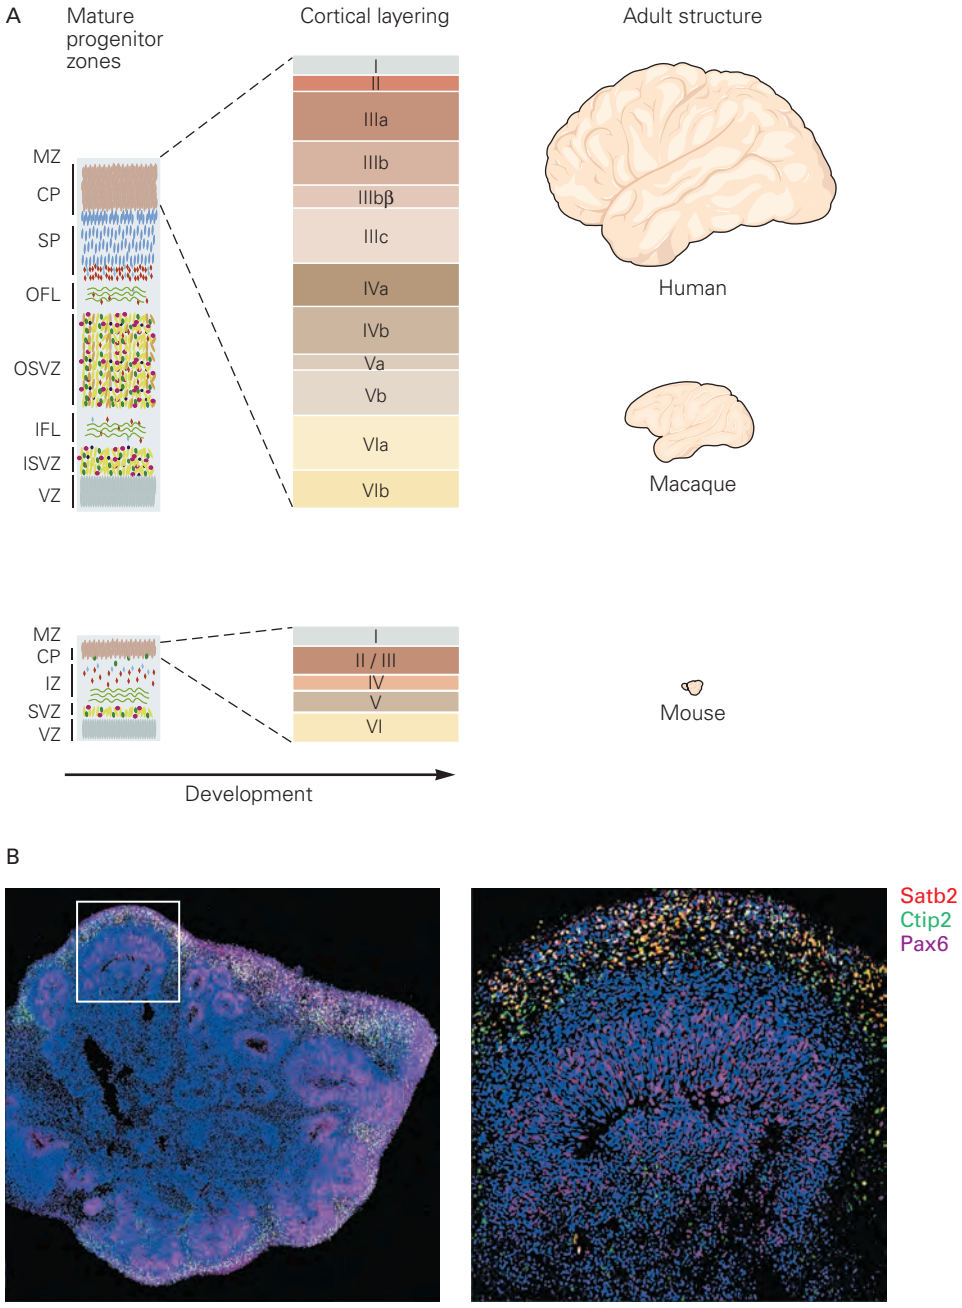

Figure 46–11 Expansion of the proliferative zones contributes to cortical specialization in humans and other primates.

A. The size of the neuroepithelium is initially small in both rodents and humans, but their relative size differs dramatically as development proceeds, owing to increased self-renewal rates and larger numbers of progenitors in humans. The primate subventricular zone is greatly enlarged compared to the mouse and becomes subdivided into inner and outer regions, which contain large populations of radial glial cells, both of which generate neurons. In mice, nearly all radial glial cells are of the inner type. (Abbreviations: **CP**, cortical plate; **IFL**, inner fiber layer; **ISVZ**, inner subventricular zone; **IZ**, intermediate zone; **MZ**, marginal zone; **OFL**, outer fiberlayer; **OSVZ**, outer subventricular zone; **SP**, subplate; **SVZ**, subventricular zone; **VZ**, ventricular zone.) (Adapted, with permission, from Giandomenico and Lancaster 2017.)

B. Section through an organoid generated from human induced pluripotent stem cells. The area between the white lines is enlarged in the micrograph on the right. The section was stained with antibodies to transcription factors (Satb2, Ctip2, and Pax6) selectively expressed in specific layers in human cortex, demonstrating that a layered cortical structure develops in the organoid. (Micrographs reproduced, with permission, from P. Arlotta.)

Mash1 (Figure 46–12A) as well as by the Dlx1 and Dlx2 proteins.

Similarly, the cerebellum contains several different classes of inhibitory neurons (Purkinje, Golgi, basket, and stellate neurons) and two major classes of excitatory neurons (granule neurons and large cerebellar nucleus neurons). These inhibitory and excitatory neurons have different origins; GABAergic neurons derive from the ventricular zone, whereas glutamatergic neurons migrate into the cerebellum from the rhombic lip. The generation of GABAergic and glutamatergic neurons is controlled by two different bHLH transcription factors, Ptf1a for inhibitory and Math-1 for excitatory neurons (Figure 46–12B). These bHLH factors are expressed by neuroepithelial cells but not by mature neurons, implying that differentiation into glutamatergic and GABAergic neurons is initiated prior to neuronal generation.

Transcriptional programs also determine the transmitter phenotype in the peripheral nervous system. For example, BMPs promote noradrenergic neuronal differentiation by inducing the expression of a variety of transcription factors that include the bHLH protein Mash1, the homeodomain protein Phox2, and the zinc finger protein Gata2. In contrast, Runx proteins are determinants of the glutamatergic phenotype of sensory neurons (Figure 46–10).

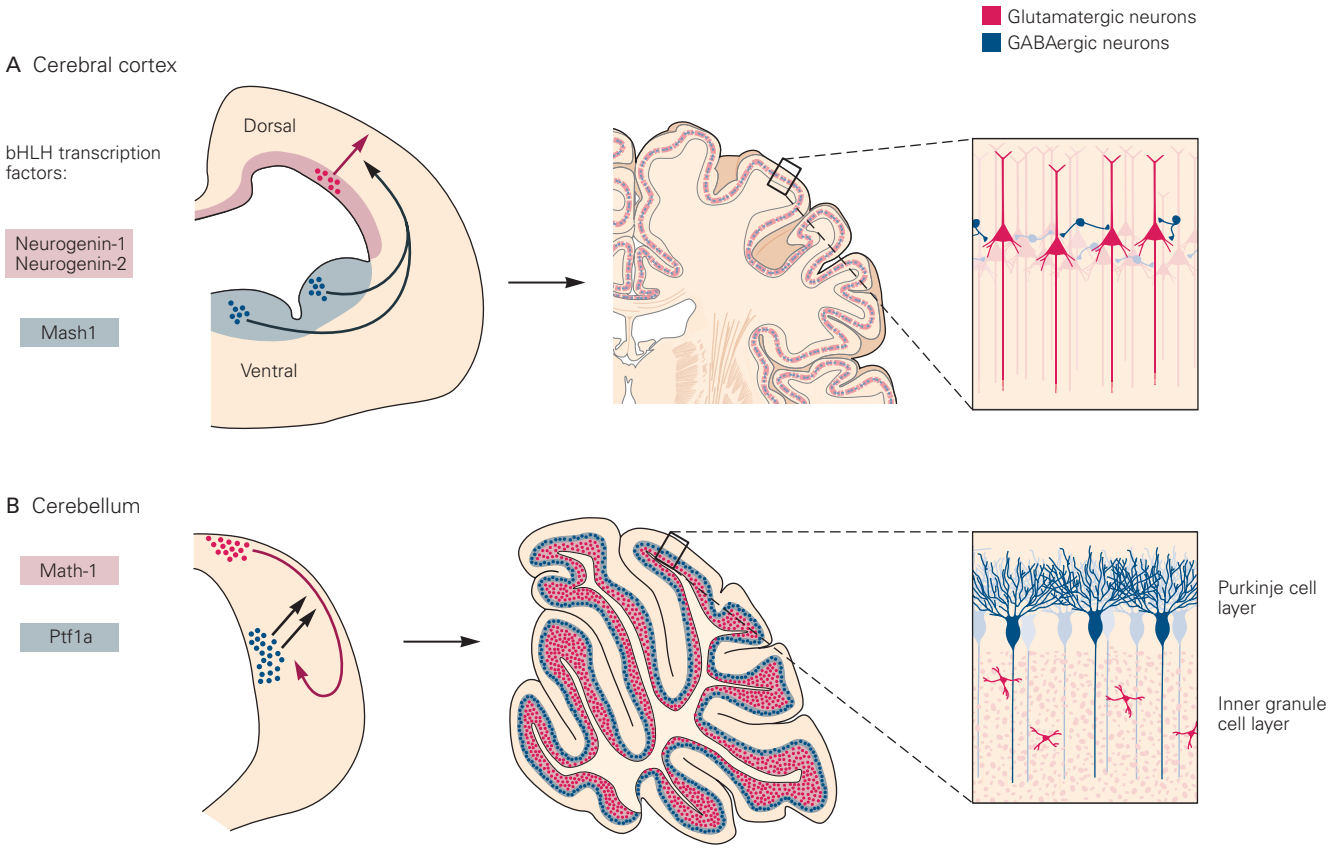

Figure 46–12 The neurotransmitter phenotype of central neurons is controlled by basic helix-loop-helix transcription factors.

A. GABAergic and glutamatergic neurons in the cerebral cortex are generated in different proliferative zones and are specified by different basic helix-loop-helix (**bHLH**) transcription factors. Glutamatergic pyramidal neurons derive from the cortical ventricular zone, and their differentiation depends on the activities of neurogenin-1 and -2. The differentiation of GABAergic interneurons in the ganglionic eminences of the ventral telencephalon depends on the bHLH protein Mash1. These neurons migrate dorsally to supply the cerebral cortex with most of its inhibitory interneurons.

B. GABAergic and glutamatergic neurons in the developing cerebellum also derive from different proliferative zones and are specified by different bHLH transcription factors. Glutamatergic granule cells migrate into the cerebellum from the rhombic lip, settle in the inner granular layer, and are specified by the bHLH protein Math-1. GABAergic Purkinje neurons migrate from the deep cerebellar proliferative zone, settle in the Purkinje cell layer, and are specified by the bHLH protein Ptf1a.

Signals From Synaptic Inputs and Targets Can Influence the Transmitter Phenotypes of Neurons

Because neurotransmitter phenotype is a core neuronal property, it was long thought that transmitter properties were fixed at the earliest stage of neuronal differentiation. This view was challenged by studies showing that the migratory pathway of a neural crest cell exposes the cell to environmental signals that have a critical role in determining its transmitter phenotype.

Most sympathetic neurons use norepinephrine as their primary transmitter. However, those that innervate the exocrine sweat glands in the footpads use acetylcholine, and even these neurons express norepinephrine when they first innervate the sweat glands of the skin. Only after their axons have contacted the sweat glands do they stop synthesizing norepinephrine and start producing acetylcholine.

When the sweat glands from the footpad of a newborn rat are transplanted into a region that is normally innervated by noradrenergic sympathetic neurons, the synaptic neurons acquire cholinergic transmitter properties, indicating that cells of the sweat gland secrete factors that induce cholinergic properties in sympathetic neurons.

Several secreted factors trigger the switch from a noradrenergic to cholinergic phenotype in sympathetic neurons. The sweat gland secretes a cocktail of interleukin-6–like cytokines, notably cardiotrophin-1, leukemia inhibitory factor, and ciliary neurotrophic factor. Several aspects of neuronal metabolism that are linked to transmitter synthesis and release are controlled by these factors. The neurons stop producing the large dense-core granules characteristic of noradrenergic neurons and start making the small electron-translucent vesicles typical of cholinergic neurons (Figure 46–13).

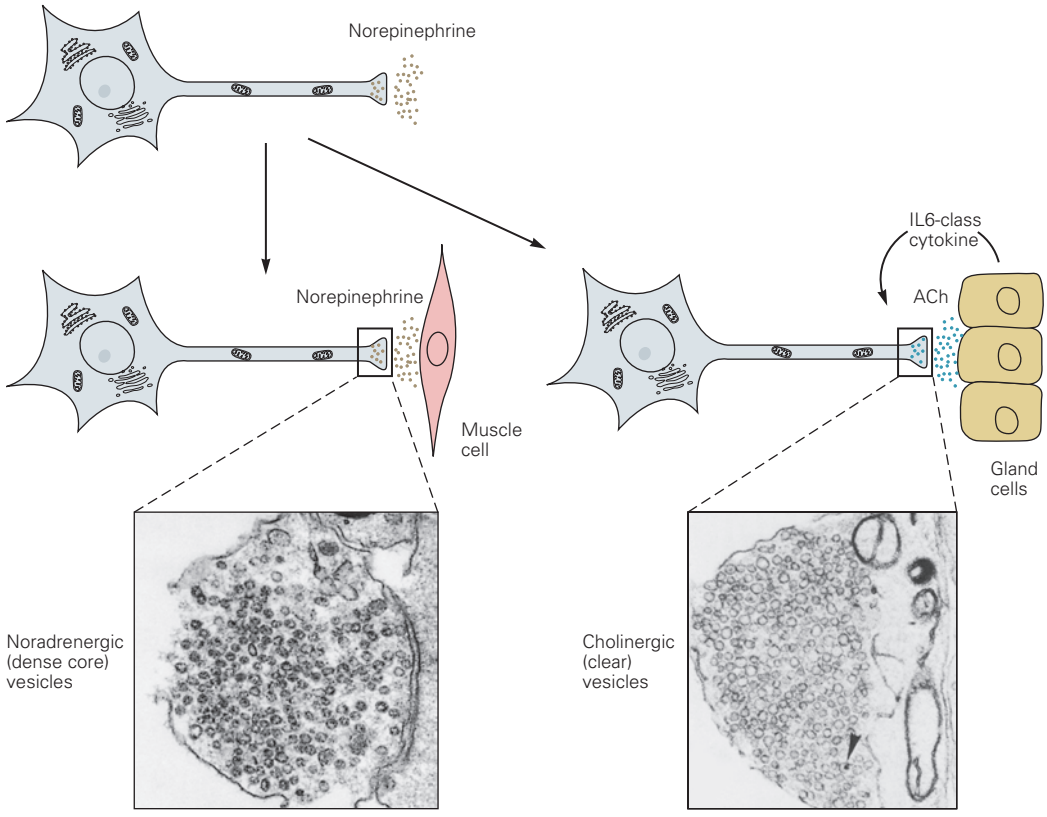

Figure 46–13 **The target of sympathetic neurons determines neurotransmitter phenotype.** Sympathetic neurons are initially specified with a noradrenergic transmitter phenotype. Most sympathetic neurons, including those that innervate cardiac muscle cells, retain this transmitter phenotype, and their terminals are packed with the dense-core vesicles in which norepinephrine is stored. But the sympathetic neurons that innervate sweat gland targets are induced to switch to a cholinergic transmitter phenotype; their terminals become filled with the small clear vesicles in which acetylcholine (**ACh**) is stored. Sweat gland cells direct the switch by secreting members of the interleukin cytokine family. Several members of this family, including leukemia inhibitory factor and ciliary neurotrophic factor, are potent inducers of cholinergic phenotype in sympathetic neurons grown in cell culture. (Abbreviation: **IL6**, interleukin-6.) (Micrographs reproduced, with permission, from S. Landis.)

More recently, evidence has accumulated that the transmitter phenotype of central neurons can also be influenced by signals including hormones and electrical activity. When the spontaneous activity of embryonic amphibian neurons is increased, some motor neurons can be respecified to synthesize and use the inhibitory neurotransmitter GABA instead of or in addition to acetylcholine. Conversely, when activity is decreased, some inhibitory neurons switch to using the excitatory neurotransmitter glutamate along with or instead of GABA. Postsynaptic partners typically express new receptors that correspond to the transmitter being released onto them. These switches occur without overall respecification of the neuron and are best viewed as homeostatic responses aimed at keeping the overall activity of the system in a narrow range.

Although such transmitter switches in central neurons are likely to occur only rarely under natural conditions, activity-dependent neurotransmitter plasticity may be a more common phenomenon in the adult nervous system. For example, changes in the light cycle where rodents are housed can lead to reciprocal changes in the numbers of neurons that use dopamine and somatostatin as neuromodulators in areas of the brain responsible for maintaining a circadian rhythm. In this and other cases, neurotransmitter switching has measurable consequences on the behavior of the animal, suggesting that this process, along with less drastic synaptic changes discussed in Chapter 49, are employed by the brain as responses to novel environments.

The Survival of a Neuron Is Regulated by Neurotrophic Signals From the Neuron's Target

One of the more surprising findings in developmental neuroscience is that a large fraction of the neurons generated in the embryonic nervous system end up dying later in embryonic development. Equally surprising, we now know that the potential for cell death is preprogrammed in most animal cells, including neurons. Thus, decisions about life and death are aspects of a neuron's fate.

The Neurotrophic Factor Hypothesis Was Confirmed by the Discovery of Nerve Growth Factor

The target of a neuron is a key source of factors essential for the neuron's survival. The critical role of target cells in neuronal survival was discovered in studies of the dorsal root ganglia.

In the 1930s, Samuel Detwiler and Viktor Hamburger discovered that the number of sensory neurons in embryos is increased by transplantation of an additional limb bud into the target field and decreased if the limb target is removed. At the time, these findings were thought to reflect an influence of the limb on the proliferation and subsequent differentiation of sensory neuron precursors. In the 1940s, however, Rita Levi-Montalcini made the startling observation that the death of neurons is not simply a consequence of pathology or experimental manipulation, but rather occurs during the normal program of embryonic development. Levi-Montalcini and Hamburger went on to show that removal of a limb leads to the excessive death of sensory neurons rather than a decrease in their production.

These early discoveries on the life and death of sensory neurons were quickly extended to neurons in the central nervous system. Hamburger found that approximately half of all motor neurons generated in the spinal cord die during embryonic development. Moreover, in experiments similar to those performed on sensory ganglia, Hamburger discovered that motor neuron death could be increased by removing a limb and reduced by adding an additional limb (Figure 46–14A,B). These findings indicate that signals from target cells are critical for the survival of neurons within the central as well as peripheral nervous system. In some cases, manipulating synaptic activity affects the extent of death, perhaps by modulating the types or amount of signals that the target cell produces (Figure 46–14C). We now know that the phenomenon of neuronal overproduction, followed by a phase of neuronal death, occurs in most regions of the vertebrate nervous system.

The early discoveries of Levi-Montalcini and Hamburger laid the foundations for the *neurotrophic factor hypothesis.* The core of this hypothesis is that cells at or near the target of a neuron secrete small amounts of an essential nutrient or trophic factor and that the uptake of this factor by nerve terminals is needed for the survival of the neuron (Figure 46–15). This hypothesis was dramatically confirmed in the 1970s when Levi-Montalcini and Stanley Cohen purified the protein we now know as nerve growth factor (NGF) and showed that this protein is made by target cells and supports the survival of sensory and sympathetic neurons in vitro. Moreover, neutralizing antibodies directed against NGF were found to cause a profound loss of sympathetic and sensory neurons in vivo.

Neurotrophins Are the Best-Studied Neurotrophic Factors

The discovery of NGF prompted a search for additional neurotrophic factors. Today, we know of over a

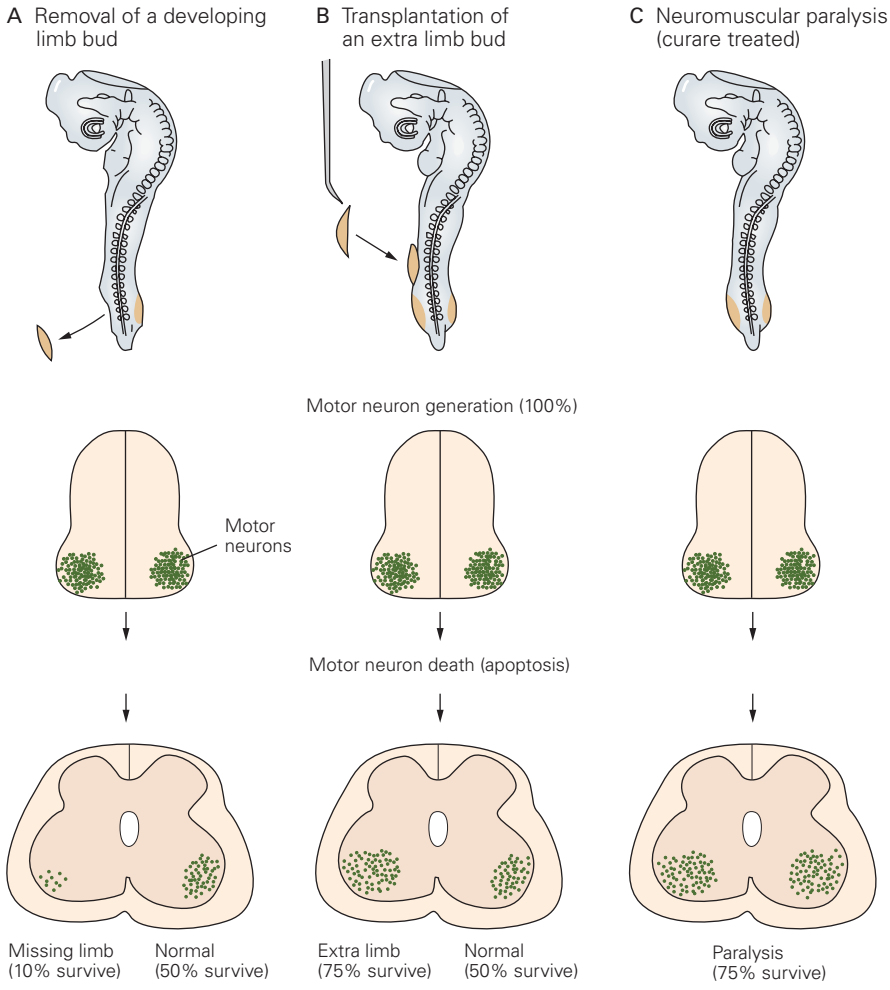

Figure 46–14 **The survival of motor neurons depends on signals provided by their muscle targets.** The role of the muscle target in motor neuron survival was demonstrated by Viktor Hamburger in a classic series of experiments performed on the chick embryo. (Adapted from Purves and Lichtman 1985.)

A. A limb bud was removed from a 2.5-day-old chick embryo soon after the arrival of motor nerves. A section of the lumbar spinal cord 1 week later reveals few surviving motor neurons on the deprived side of the spinal cord. The number of motor neurons on the contralateral side with an intact limb is normal.

B. An extra limb bud was grafted adjacent to a host limb prior to the normal period of motor neuron death. A section of the lumbar spinal cord 2 weeks later shows an increased number of limb motor neurons on the side with the extra limb.

C. Blockade of nerve-muscle activity with the toxin curare, which blocks acetylcholine receptors, rescues many motor neurons that would otherwise die. Curare may act by enhancing the release of trophic factors from inactive muscle.

dozen secreted factors that promote neuronal survival. The best-studied are related to NGF and are called the neurotrophin family.

There are four main neurotrophins: NGF itself, brain-derived neurotrophic factor (BDNF), and neurotrophins-3 and -4 (NT-3 and NT-4). Other classes of proteins that promote neuronal survival include members of the transforming growth factor β family, the interleukin-6–related cytokines, fibroblast growth factors, and even certain inductive signals we encountered earlier (BMPs and hedgehogs). Other neurotrophic factors, notably members of the glial cell line–derived neurotrophic factor (GDNF) family, are responsible for the survival of different types of sensory and sympathetic neurons (Figure 46–16).

Neurotrophins interact with two major classes of receptors, the Trk receptors and p75. Neurotrophins promote cell survival through activation of Trk receptors. The Trk family comprises three membrane-spanning tyrosine kinases named TrkA, TrkB, and TrkC, each of which exists as a dimer (Figure 46–17).

Much is now known about the intracellular signaling pathways activated by binding of neurotrophins to Trks. As with other tyrosine kinase receptors, the binding of neurotrophins to Trk receptors leads to dimerization of the Trk proteins. Dimerization results in phosphorylation of specific tyrosine residues in the activation loop of the kinase domain. This phosphorylation leads to a conformational change in the receptor and to phosphorylation of tyrosine residues that serve as docking sites for adaptor proteins. The adaptors then trigger production of second messengers that both promote the survival of neurons and trigger their maturation. These divergent biological responses involve different intracellular signaling pathways: neuronal differentiation largely via the mitogen-activated protein kinase (MAPK) enzymatic pathways and survival largely via the phosphatidylinositol-3 kinase pathway (Figure 46–18).

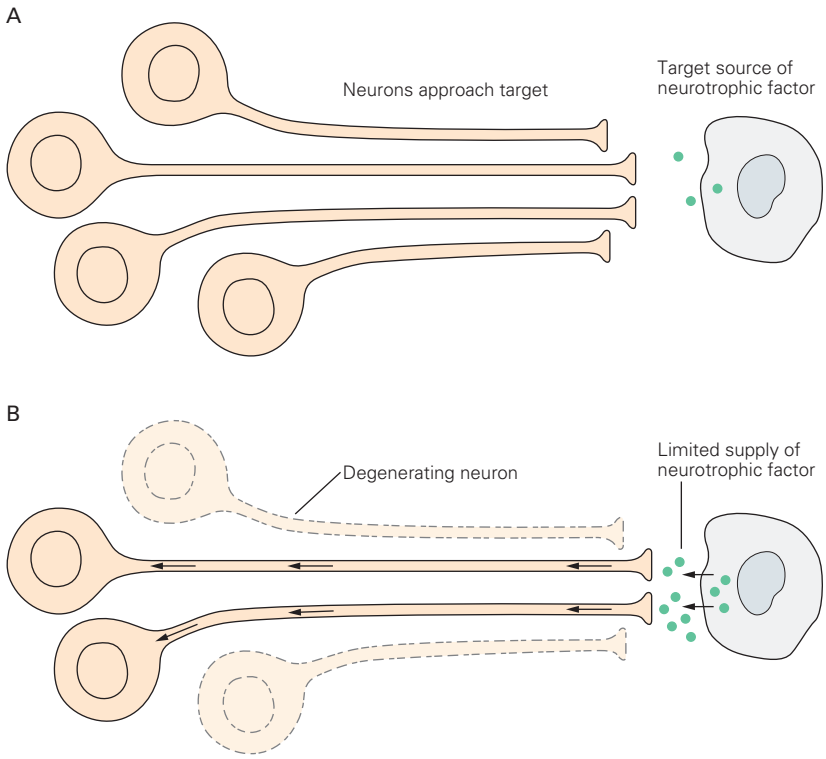

Figure 46–15 The neurotrophic factor hypothesis.

A. Neurons extend their axons to target cells, which secrete low levels of neurotrophic factors. (For simplicity, only one target cell is shown.) The neurotrophic factor binds to specific receptors and is internalized and transported to the cell body, where it promotes neuronal survival.

B. Neurons that fail to receive adequate amounts of neurotrophic factor die through a program of cell death termed apoptosis.

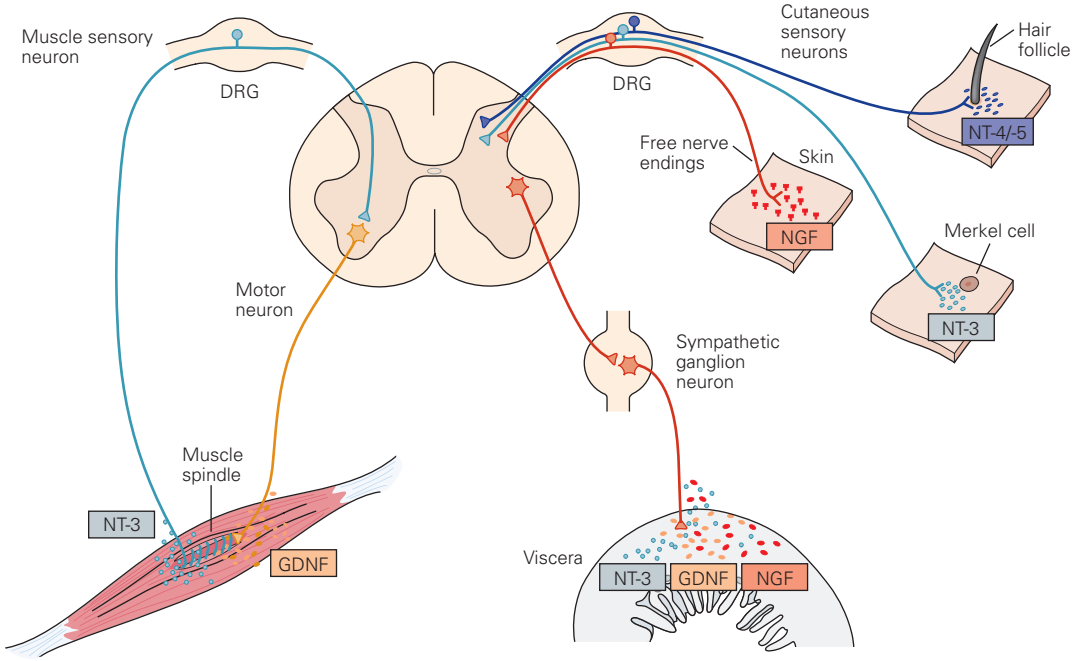

Figure 46–16 Particular neurotrophic factors promote the survival of distinct populations of dorsal root ganglion neurons. Proprioceptive sensory neurons that innervate muscle spindles depend on neurotrophin-3 (**NT-3**); nociceptive neurons that innervate skin depend on nerve growth factor (**NGF**) and neurturin; mechanoreceptive neurons that innervate Merkel cells depend on NT-3; and those that innervate hair follicles depend on neurotrophin-4 and -5 (**NT-4/-5**) and brain-derived neurotrophic factor. Motor neurons depend on glial cell line–derived neurotrophic factor (**GDNF**) and other factors. Sympathetic neurons depend on NGF, NT-3, and GDNF. (Adapted from Reichardt and Fariñas 1997.)

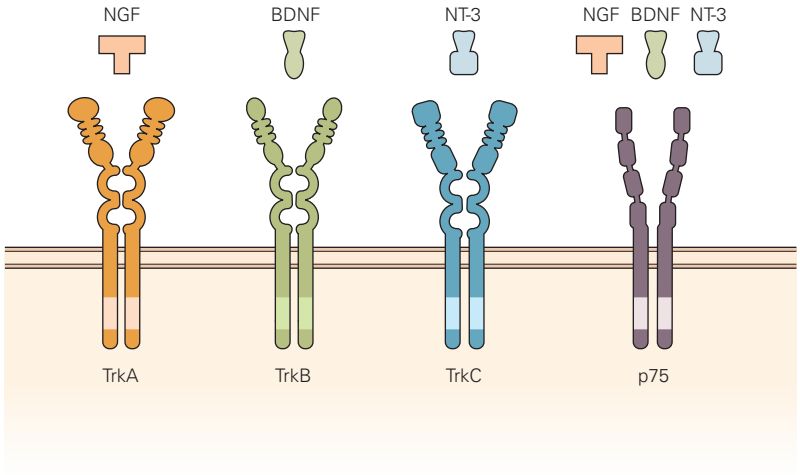

Figure 46–17 **Neurotrophins and their receptors.** Each of the three main neurotrophins interacts with a different transmembrane tyrosine kinase receptor (**Trk**). In addition, all three neurotrophins can bind to the low-affinity neurotrophin receptor p75. (Abbreviations: **BDNF**, brain-derived neurotrophic factor; **NGF**, nerve growth factor; **NT-3**, neurotrophin-3.) A fourth neurotrophin, NT-4, is not shown. (Adapted from Reichardt and Fariñas 1997.)

In contrast to the specificity of Trk receptor interactions, all neurotrophins bind the receptor p75 (Figure 46–17). In some cases, p75 works along with Trk receptors, tuning the affinity and specificity of Trks for their neurotrophin ligands and thereby contributing to neuronal survival. However, p75 leads a double life. It can also bind unprocessed precursors of neurotrophins, called proneurotrophins, and it can associate with other membrane receptors called sortilins. Binding of proneurotrophins to the p75/sortilin complex promotes neuronal death. Receptor p75 is a member of the tumor necrosis factor (TNF) receptor family and promotes cell death by activating proteases of the caspase family, which we discuss below.

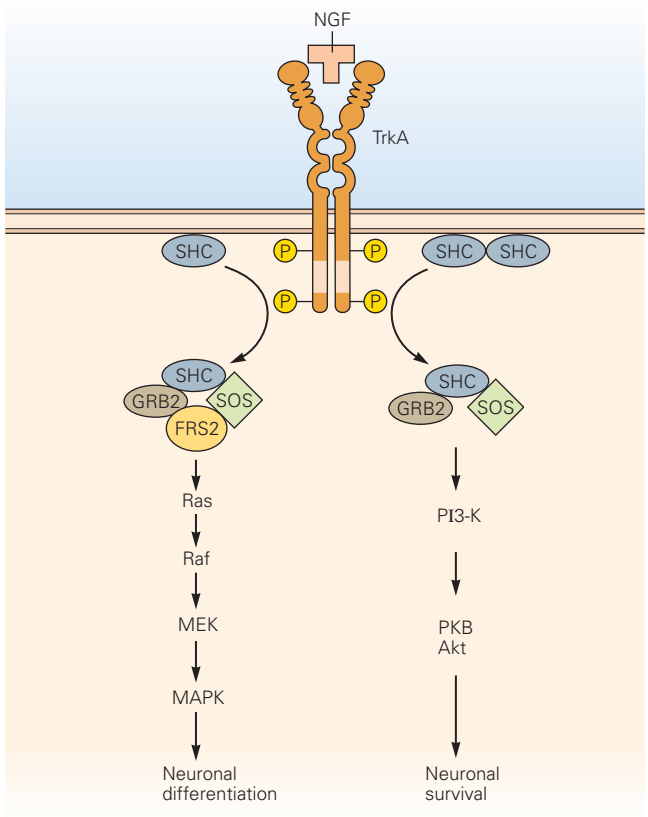

Figure 46–18 **Binding of nerve growth factor to the TrkA receptor activates alternative intracellular signaling pathways.** The binding of nerve growth factor (**NGF**) induces dimerization of the TrkA receptor, which triggers its phosphorylation at many different residues. Phosphorylation of TrkA results in the recruitment of the adaptor proteins SHC, GRB2, and SOS. The additional recruitment of FRS2 to this complex (*left*) activates a Ras kinase signaling pathway that promotes neuronal differentiation. In the absence of FRS2 (*right*), the complex activates a phosphatidylinositol-3 kinase (**PI3-K**) pathway that promotes neuronal survival. (Abbreviations: **Akt/PKB**, protein kinase B; **MAPK**, mitogen-activated protein kinase; **MEK**, mitogen-activated/ERK kinase; **P**, phosphate.)

Neurotrophin signaling is relayed from the axon terminal to the cell body of the neuron through a process that involves internalization of a complex of neurotrophin bound to Trk receptors. The retrograde transport of this complex occurs in a class of endocytotic vesicles called signaling endosomes. The transport of these vesicles brings activated Trk receptors into cellular compartments able to activate signaling pathways and transcriptional programs essential for neuronal survival, maturation, and synaptic differentiation.

The picture is more complex for neurons in the central nervous system. The survival of motor neurons, for example, is not dependent on a single neurotrophic factor. Instead, different classes of motor neurons require neurotrophins, GDNF, and interleukin-6–like proteins expressed by muscles or peripheral glial cells. The survival of these neuronal classes depends on the exposure of axons to local neurotrophic factors.

Neurotrophic Factors Suppress a Latent Cell Death Program

Neurotrophic factors were once believed to promote the survival of neural cells by stimulating their metabolism in beneficial ways, hence their name. It is now evident, however, that neurotrophic factors suppress a latent death program present in all cells of the body, including neurons.

This biochemical pathway can be considered a suicide program. Once it is activated, cells die by apoptosis (Greek, falling away): They round up, form blebs, condense their chromatin, and fragment their nuclei. Apoptotic cell deaths are distinguishable from necrosis, which typically results from acute traumatic injury and involves rapid lysis of cell membranes without activation of the cell death program.

The first clue that deprivation of neurotrophic factors kills neurons by unleashing an active biochemical program emerged from studies that assessed neuronal survival after inhibition of RNA and protein synthesis. Exposure of sympathetic neurons to protein synthesis inhibitors was found to prevent the death of sympathetic neurons triggered by removal of NGF. These results sparked the idea that neurons have the ability to synthesize proteins that are lethal and that NGF prevents their synthesis, thereby suppressing an endogenous cell death program.

Key insights into the biochemical nature of the endogenous cell death program emerged from genetic studies of the nematode *Caenorhabditis elegans*. During the development of *C. elegans*, a precise number of cells is generated and a fixed number of these cells die—the same number from embryo to embryo. The findings prompted a screen for genes that block or enhance cell death, which led to the identification of the cell death (*ced*) genes. Two of these genes, *ced-3* and *ced-4*, are needed for the death of neurons; in their absence, every one of the cells destined to die instead survives. A third gene, *ced-9*, is needed for survival and works by antagonizing the activities of *ced-3* and *ced-4* (Figure 46–19). Thus, in the absence of *ced-9*, many additional cells die, even though these deaths still depend on *ced-3* and *ced-4* activity.

The cell death pathway in *C. elegans* has been conserved in mammals. Similar proteins and pathways control the apoptotic death of central and peripheral neurons, indeed of all developing cells. The worm *ced-9* gene encodes a protein that is related to members of the mammalian Bcl-2 family, which protect

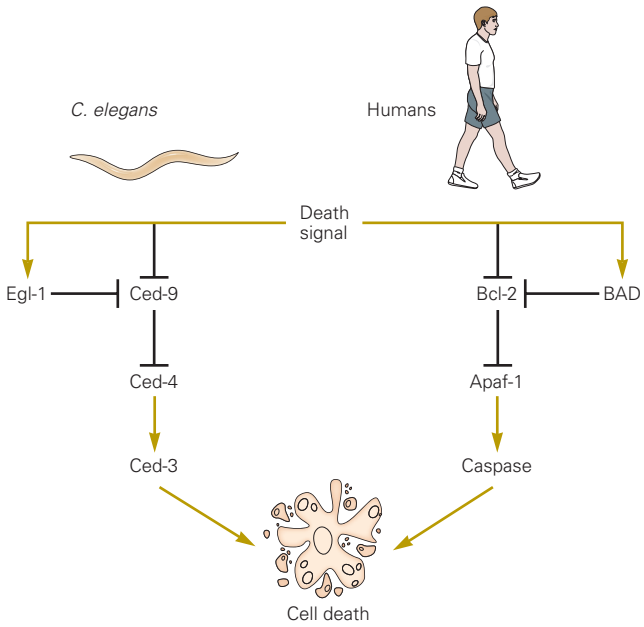

Figure 46–19 Neurons and other cells express a conserved death program. Different cellular insults trigger a genetic cascade that involves a series of death effector genes. These death genes and pathways have been conserved in the evolution of species from worms to humans. The core death pathway activates a set of proteolytic enzymes, the caspases. Caspases cleave many downstream and essential protein substrates (see Figure 46–20), resulting in the death of cells by a process termed *apoptosis*. Genetic analysis of the worm *Caenorhabditis elegans* indicates that the Ced-9 protein acts upstream and inhibits the activity of Ced-4 and Ced-3, two proteins that promote cell death. Many vertebrate homologs of Ced-9, the Bcl-2 family of proteins, have been identified. Some of these proteins, such as Bcl-2 itself, inhibit cell death, but others promote cell death by antagonizing the actions of Bcl-2. The Bcl-2 class proteins act upstream of Apaf-1 (a vertebrate homolog of Ced-4) and the caspases (vertebrate homologs of Ced-3).

lymphocytes and other cells from apoptotic death. The worm *ced-3* gene encodes a protein closely related to a class of mammalian cysteine proteases called caspases. The worm *ced-4* gene encodes a protein that is functionally related to a mammalian protein called apoptosis activating factor-1 (Apaf-1).

The mammalian apoptotic cell death pathway works in a way that resembles the worm pathway (Figure 46–20). The morphological and histochemical changes that accompany the apoptosis of mammalian cells result from the activation of caspases, which cleave specific aspartic acid residues within cellular

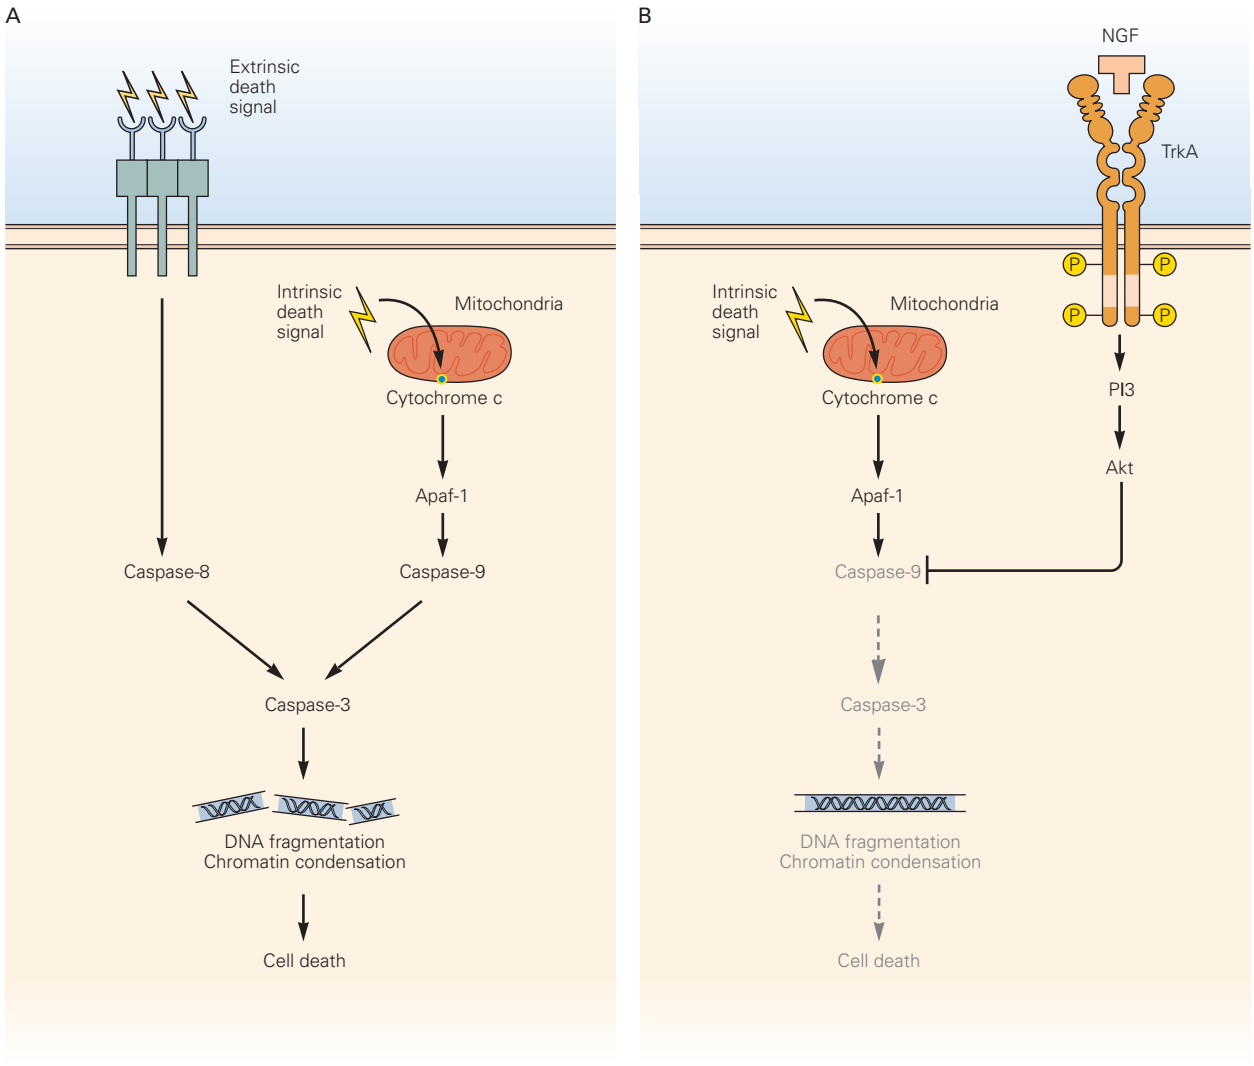

Figure 46–20 **Neurotrophic factors suppress caspase activation and cell death.** (Adapted from Jesenberger and Jentsch 2002.)

A. Two types of pathways trigger cell death: extrinsic activation of surface membrane death receptors and intrinsic activation of a mitochondrial pathway. Both pathways result in activation of caspases such as caspase-8 and caspase-9, which initiate a proteolytic cleavage cascade that converges at the level of caspase-3 activation. Cleavage of the caspase precursor removes the caspase prodomain and produces a proteolytically active enzyme conformation.

The extrinsic pathway involves activation of death receptors by ligands such as tumor necrosis factor receptor 1 or Fas/CD95. The intrinsic pathway involves stress-induced signals such as DNA damage that initiate the release of cytochrome c from the mitochondrial intermembrane space. Cytochrome c binds to Apaf-1 and recruits and activates caspase-9.

B. Binding of neurotrophins to Trk receptors recruits the PI3 kinase pathway and Akt and suppresses the cell death pathway by inhibiting caspase-9. This pathway is inhibited in developing neurons by neurotrophic factors, explaining why withdrawal of these factors leads to apoptosis. (Abbreviations: **NGF**, nerve growth factor; **P**, phosphate.)

proteins. Two classes of caspases regulate apoptotic death: the initiator and effector caspases. Initiator caspases (caspase-8, -9, and -10) cleave and activate effector caspases. Effector caspases (caspase-3 and -7) cleave other protein substrates, thus triggering the apoptotic process. Perhaps 1% of all proteins in the cell serve as substrates for effector caspases. Their cleavage contributes to neuronal apoptosis through many pathways: by activation of proteolytic cascades, inactivation of repair, DNA cleavage, mitochondrial permeabilization, and initiation of phagocytosis.

The survival of mammalian neurons depends on the balance between antiapoptotic and proapoptotic members of the Bcl-2 family of proteins. Some Bcl-2 proteins such as BAX and BAK increase the permeability of the mitochondrial outer membranes, causing the release of proapoptotic proteins such as cytochrome *c* into the cytosol. The release of cytochrome *c* induces Apaf-1 to bind and activate caspase-9, leading to the cleavage and activation of effector caspases. The binding of neurotrophic factors to their tyrosine kinase receptors is thought to lead to the phosphorylation of protein substrates that promote Bcl-2–like activities (Figure 46–20B). Thus, withdrawal of neurotrophic factors from neurons changes the balance from antiapoptotic to proapoptotic members of the Bcl-2 family, which triggers the neuron's demise.

The caspase cell death program can also be activated by many cellular insults, including DNA damage and anoxia. The activation of cell-surface death receptors such as Fas by extracellular ligands results in the activation of caspase-8 or -10 as well as the recruitment of death effector proteins such as FADD. Recruitment of an initiator caspase to the Fas-FADD complex then leads to activation of effector caspases. Because many neurodegenerative disorders result in apoptotic death, pharmacological strategies to inhibit caspases are under investigation.

Highlights

1. Stem cells near the ventricular surface of the neural tube divide to expand the neuroepithelium. Further divisions then generate the neurons and glia of the central nervous system as well as radial glia.
2. Processes of radial glia extend from the ventricular to the pial surface. Radial glial cells continue dividing to form neurons and astrocytes. In the cortex, they also serve as a scaffold on which newborn excitatory neurons migrate to appropriate layers.
3. The choice between neuronal and glial fate is determined by signals from ligands of the Delta family to receptors of the Notch family on neighboring cells. Initially, cells express both Notch and Delta. Activation of Notch leads to a glial fate, downregulating Delta, which in turn attenuates Notch activity on the neighbors, promoting their differentiation into neurons.
4. As cortical principal (excitatory) neurons migrate along radial glia, they form cortical layers in an inside-out sequence (layer 6 forms before layer 5, and so on). Disruptions of migration are among the causes of intellectual disability and epilepsy.
5. Unlike excitatory neurons, forebrain interneurons arise subcortically in ganglionic eminences and then migrate tangentially into the cortex, basal ganglia, and other forebrain structures.
6. Neural crest cells migrate from their source at the dorsal tip of the neural tube through somites and mesenchyme to form sensory and autonomic neurons and glia, as well as several nonneural cell types.
7. For principal neurons, interneurons, and peripheral neurons, intrinsic differences and cues encountered along the migratory path interact to induce expression of distinct combinations of transcription factors. The transcriptional programs then lead to diversification of the developing neurons into multiple classes and types.
8. The greater complexity of the primate, and particularly the human brain compared to those of lower mammals is due in part to a larger pool of neuronal progenitors, including a second type of radial glial cell.
9. A recent advance in the ability to study the human brain is the discovery that complex neuronal ensembles called cerebral organoids can be generated from stem cells. Although they fail to acquire characteristics of the mature cortex, they enable analysis of some aspects of early brain development and its disorders and may be useful in testing possible therapeutics.
10. The neurotransmitters that neurons use are determined as part of the transcriptional program that endows each neuronal type with its defining characteristics. However, extrinsic factors, including patterns of electric activity and hormonal milieu, can lead to transmitter switching in some cases.
11. The nervous system generates up to twice as many neurons as survive in adulthood. The excess is eliminated by a cell death program that is conserved from invertebrates to humans.

12. Trophic factors play a crucial role in determining which neurons within a population live or die. They control survival by holding the cell death program in check. In some cases, neurons appear to compete for a limited supply of neurotrophic factors; the cell death program is activated in those that lose the competition.
13. Multiple trophic factors are produced in the body, with each controlling the fate of only some neuronal types. The best-studied, called neurotrophins (nerve growth factor, brain-derived neurotrophic factor, neurotrophin-3, and neurotrophin-4), bind to and activate kinases called Trk receptors.

The Growth and Guidance of Axons

In the two preceding chapters, we saw how neurons are generated in appropriate numbers, at correct times, and in the right places. These early developmental steps set the stage for later events that direct neurons to form functional connections with target cells. To form connections, neurons have to extend long processes—axons and dendrites—which permit connectivity with postsynaptic cells and synaptic input from other neurons. In this chapter, we examine how neurons elaborate axons and dendrites and how axons are guided to their targets.

We begin the chapter by discussing how certain neuronal processes become axons and others dendrites. We then describe the growing axon, which may have to travel a long distance and ignore many inappropriate neuronal partners before terminating in just the right region and recognizing its correct synaptic targets. We consider the strategies by which the axon overcomes these challenges. Finally, we illustrate general features of axonal guidance by describing the development of two well-studied axonal pathways: one that conveys visual information from the retina to the brain and another that conveys cutaneous sensory information from the spinal cord to the brain.

Differences Between Axons and Dendrites Emerge Early in Development

The processes of neurons vary enormously in their length, thickness, branching pattern, and molecular architecture. Nonetheless, most neuronal processes fit into one of two functional categories: axons and dendrites. More than a century ago, Santiago Ramón y Cajal hypothesized that this distinction underlies the ability of neurons to transmit information in a particular direction, an idea he formalized as the law of dynamic polarization. Cajal wrote that "the transmission of the nerve impulse is always from the dendritic branches and the cell body to the axon." In the decades before electrophysiological methods were up to the task, this law provided a means of analyzing neural circuits histologically. Although exceptions have been found, Ramón y Cajal's law remains a basic principle

that relates structure to function in the nervous system and highlights the importance of knowing how neurons acquire their polarized form.

Progress in understanding how neuronal polarization occurs comes in large part from studies of neurons taken from the rodent brain and grown in tissue culture. Hippocampal neurons grown in isolation develop processes reminiscent of those seen in vivo: a single, long, cylindrical axon and several shorter, tapered dendrites (Figure 47–1A). As cytoskeletal and synaptic proteins are differentially targeted to these components, axons and dendrites acquire distinctive molecular profiles. For example, a particular form of the Tau protein is localized in axons and the MAP2 protein in dendrites (Figure 47–1B)

Cultured neurons are especially useful for developmental studies because they initially show no obvious sign of polarization and acquire their specialized features gradually in a stereotyped sequence of cellular steps. This sequence begins with extension of several short processes, each equivalent to the others. Soon thereafter, one process is established as an axon and the remaining processes acquire dendritic features (Figure 47–1A).

How does this occur? Cytoskeletal proteins that maintain elongated processes and drive growth are central to this process. If the actin filaments in an early neurite are destabilized, the cytoskeleton becomes reconfigured in a way that commits the neurite to becoming the axon; secondarily, the remaining neurites react by becoming dendrites. If the nascent axon is removed, one of the remaining neurites quickly assumes an axonal character. This sequence suggests that axonal specification is a key event in neuronal polarization and that signals from newly formed axons both suppress the generation of additional axons and promote dendrite formation.

The nature of the axonally derived signal that represses other axons is not known, but some insight into signals that control cytoskeletal arrangements has come from the study of a group of proteins encoded by the *Par* complex genes. As first shown in the nematode worm *Caenorhabditis elegans*, Par proteins are involved in diverse aspects of cytoskeletal reorganization, including the polarization of neuronal processes. Mammalian forebrain neurons lacking *Par3*, *Par4*, *Par6*, or relatives of *Par1* grow multiple processes that are intermediate in length between axons and dendrites and bear markers of both processes (Figure 47–1B).

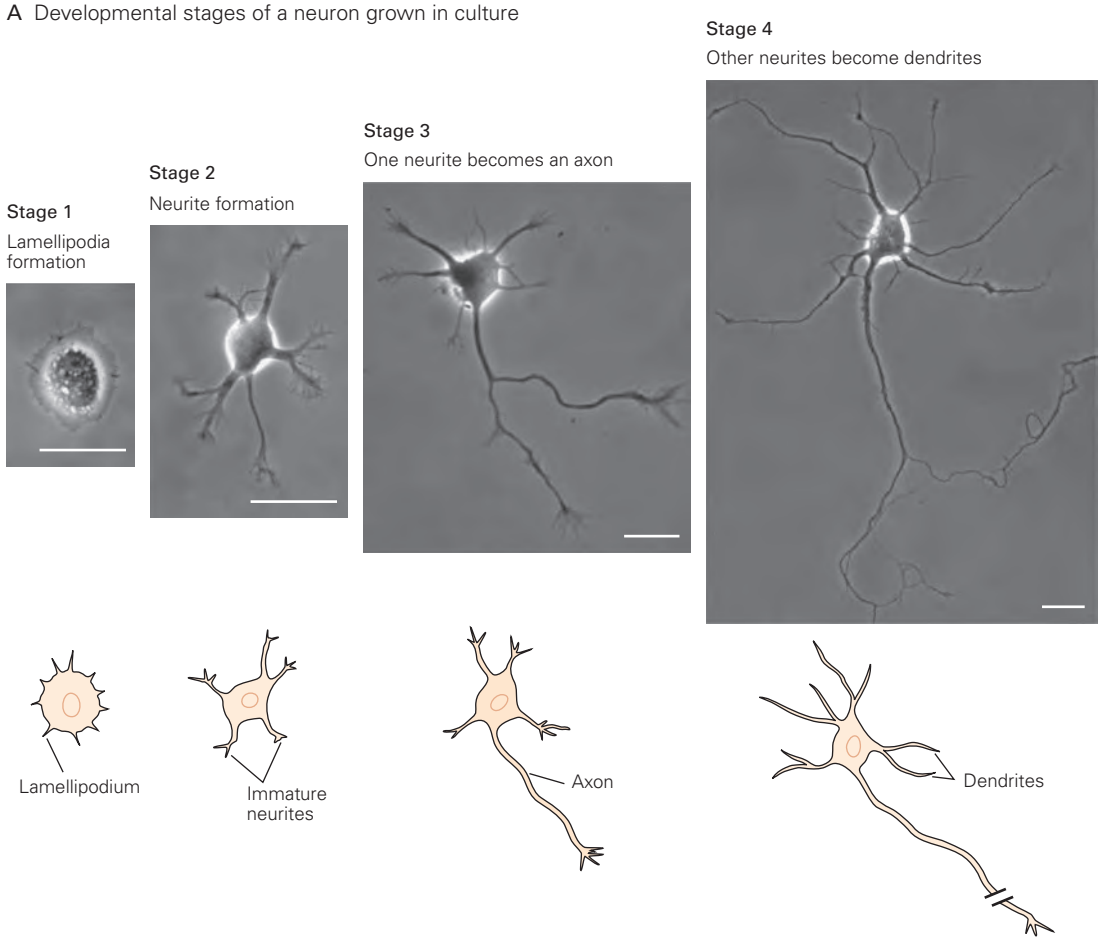
Although neurons grown in culture are similar to those in the brain, they are deprived of key extrinsic cues and signals. Cultured neurons become randomly arranged with respect to each other, whereas in many regions of the developing brain, neurons line up in rows, with their dendrites pointing in the same direction (Figure 47–2A). As the neurons migrate to their destinations (Chapter 46), axons and dendrites often grow as extensions of their trailing and leading processes, respectively. This difference in vivo and in vitro implies that extrinsic signals regulate the polarization machinery. In the developing brain, the local release of semaphorins and other axonal guidance factors, discussed later in the chapter, may help to orient dendrites (Figure 47–2C). The job of the Par protein complex is to link these extracellular signals to the cellular machinery that rearranges the cytoskeleton, a process achieved in part through the regulation of proteins that modify actin or tubulin function. In fact, both the Tau protein in axons and the MAP2 protein in dendrites associate with and affect microtubules. Cytoskeletal differences also contribute to other mechanisms that amplify distinctions between axons and dendrites, such as polarized trafficking of molecules and generation of a specialized initial segment in axons.

If local signals are needed to polarize neurons in the brain, how is polarity established in the uniform environment of a tissue culture? One possible explanation is that minor variations in the intensity of signaling within a neuron, or in signals from its immediate environment, will activate Par proteins in one small domain of the neuron, triggering the nearest cell process to become an axon. If, by happenstance, one process grows slightly faster than its neighbors or encounters an environment that speeds neurite extension (Figure 47–2B), its chances of becoming an axon increase markedly. Presumably, this proto-axonal process emits signals that decrease the chance of other processes following suit, forcing them to become dendrites.

Dendrites Are Patterned by Intrinsic and Extrinsic Factors

Once polarization occurs, dendrites grow and mature, acquiring the structural features that distinguish them from axons. Nascent dendrites form branched arbors, with their branches generally being more numerous and closer to the cell body than those of axons. In addition, small protrusions called spines extend from the distal branches of many dendrites. Finally, some dendritic branches are retracted or "pruned" to give the arbor its final and definitive shape (Figure 47–3).

Although the core features of dendrite formation are common to many neurons, there is striking variation in their number, shape, and branching pattern among neuronal types. Indeed, the shape of dendritic arbors is one of the main ways in which neurons can



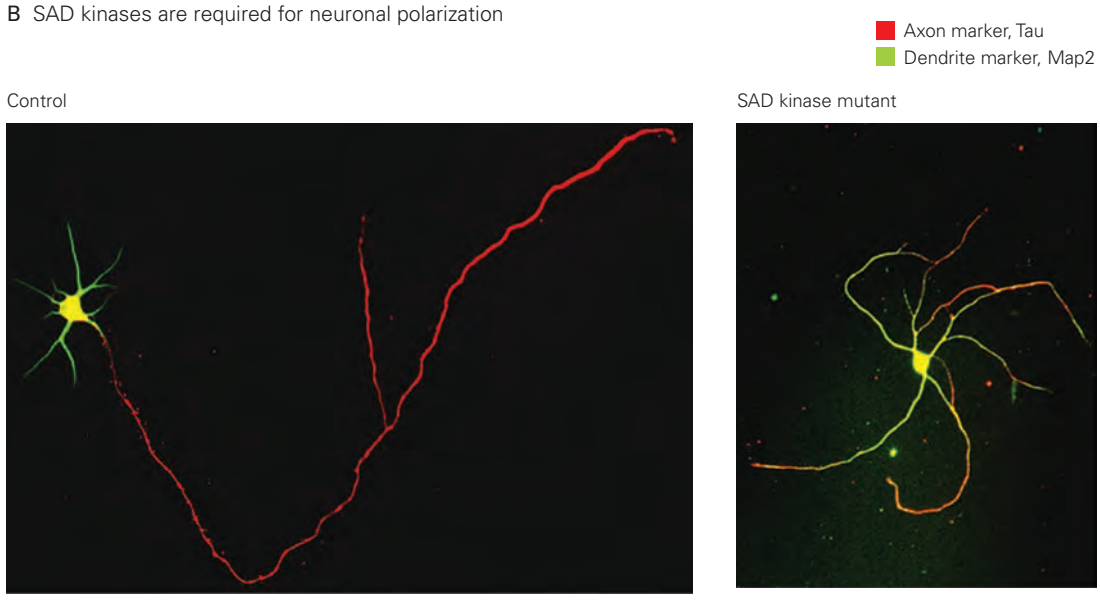


Figure 47–1 The differentiation of axons and dendrites marks the emergence of neuronal polarity.

B. Hippocampal neurons grown in culture possess multiple short, thick dendrites that are enriched in the microtubule-associated protein MAP2. They also possess a single long axon that is marked by a dephosphorylated form of the microtubule-associated protein tau (*left*). A cultured neuron isolated from a mutant mouse lacks expression of a *Par* family gene (SAD kinase). The neuron generates neurites that express both tau and MAP2, markers of axons and dendrites, respectively. The length and diameter of these neurites are intermediate in size between those of axons and dendrites (*right*). (Reproduced, with permission, from Kishi et al. 2005.)

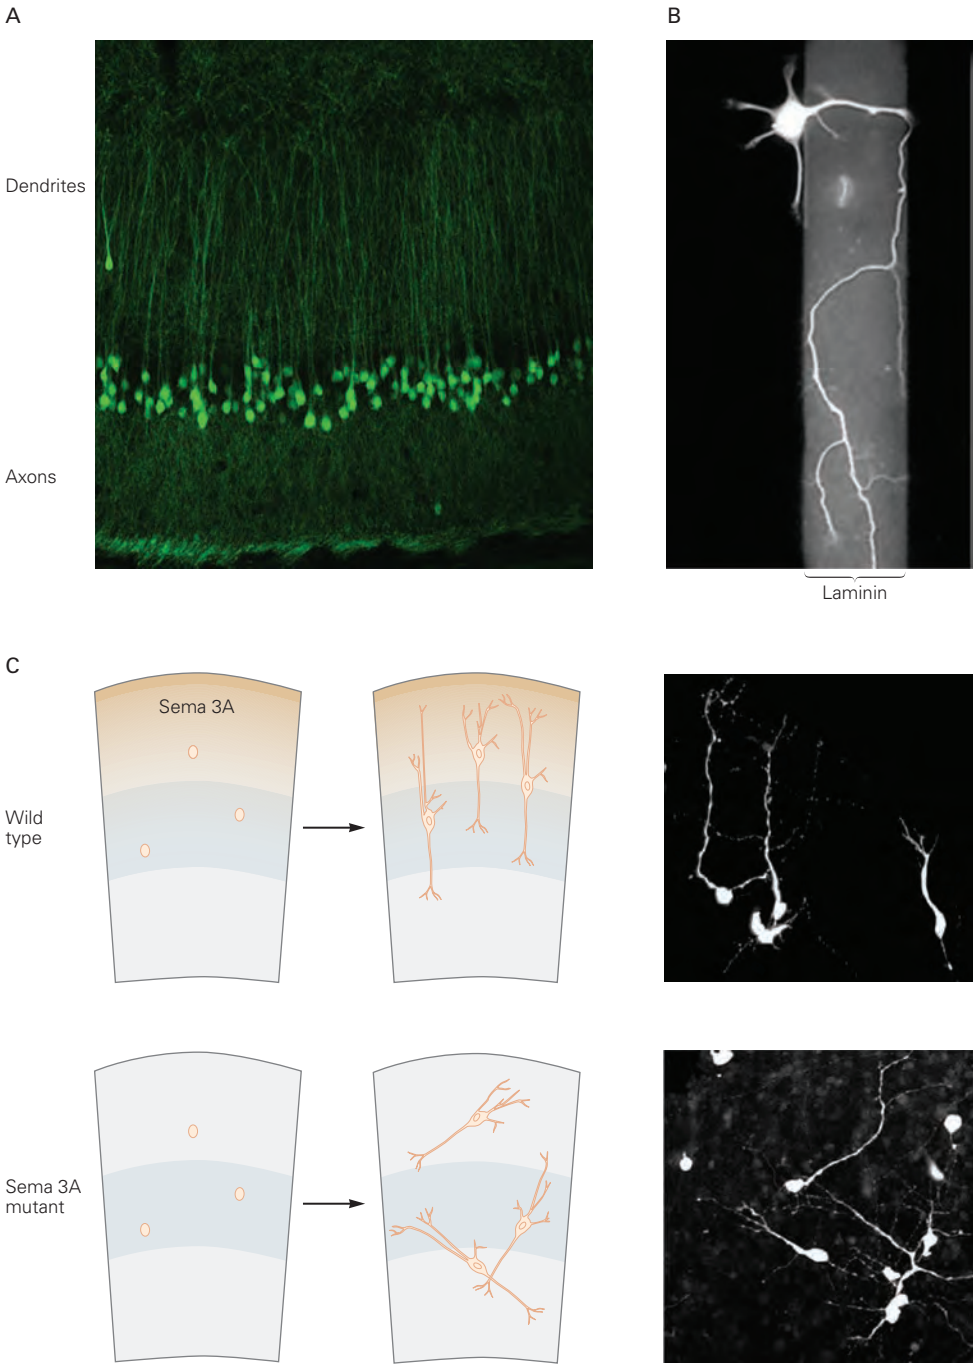

Figure 47–2 Extracellular factors determine whether neuronal processes become axons or dendrites.

A. Cortical pyramidal neurons in vivo display a common axonal and dendritic orientation.

B. Neurons growing on laminin acquire polarity. When a cortical neuron extends a process from a less attractive substrate onto laminin, the process grows faster and usually becomes an axon. (Image reproduced, with permission, from Paul Letourneau.)

C. In the developing neocortex, semaphorin-3A (**Sema 3A**) is secreted by cells near the pial surface. Semaphorin-3A is an attractant for growing dendrites, helping to establish neuronal polarity and orientation. The parallel orientation of cortical pyramidal neurons is disrupted in mutant mice lacking functional semaphorin-3A. (Reproduced, with permission, from Polleux, Morrow, and Ghosh 2000. Figure 47–3 Dendritic branching develops in a series of steps. The outgrowth of dendrites involves the formation of elaborate branches from which spines develop. Certain branches and spines are later pruned to achieve the mature pattern of dendrite arborization. (Image of spines at right reproduced, with permission, from Stefan W. Hell.)

be classified. Cerebellar Purkinje cells can be distinguished from granule cells, spinal motor neurons, and hippocampal pyramidal neurons simply by looking at the pattern of their dendrites. These variations are critical for the distinct functions of different neuronal types. For example, the size of a dendritic arbor and the density of its branches are main determinants of the number of synapses it receives.

How is dendritic pattern established? Neurons must have intrinsic information about their shape because the patterns in tissue culture are strikingly reminiscent of those in vivo (Figure 47–4). The transcriptional programs that specify neuronal subtype (Chapter 46) presumably also encode information about neuronal shape. In both invertebrates and vertebrates, some transcription factors are selectively expressed by specific neuronal types and appear to be devoted to controlling the size, shape, and complexity of their dendritic arbors. They do so by coordinating the expression of downstream genes, including those encoding components of the cytoskeletal apparatus and membrane proteins that mediate interactions with neighboring cells.

A second mechanism for establishing the pattern of dendritic arbors is the recognition of one dendrite by others of the same cell. In some neurons, dendrites are spaced evenly with respect to each other, an arrangement that allows them to sample inputs efficiently without major gaps or clumps (Figure 47–5A). In many cases, this process, called self-avoidance, occurs through a mechanism in which branches belonging to the same neuron repel each other. Several cell-surface adhesion molecules have now been found that mediate self-avoidance by interacting in a way that results in repulsion (Figure 47–5D). Although it seems counterintuitive that an adhesive interaction between adjacent membranes would lead to repulsion rather than attachment, the consequences of most intercellular interactions are determined by the signaling they initiate rather than by adhesion per se, as we will see later in this chapter.

The dendrites of neighboring neurons also provide cues. In many cases, the dendrites of a particular neuron type cover a surface with minimal overlap, a spacing pattern called *tiling* (Figure 47–5B). The tiling of dendrites is conceptually related to self-avoidance, but in tiling, the inhibitory dendritic interactions are among neurons of a particular type, whereas in self-avoidance, they are among sibling dendrites of a single neuron. Tiling allows each class of neuron to receive information from the entire surface or area it innervates. Tiling of a region by the dendrites of one class of neuron also avoids the confusion that could arise if the dendrites of many different neurons occupied the same area.

A particularly interesting situation is one in which dendrites engage in self-avoidance but synapse on the dendrites of other cells of the same type. In this situation, dendrites face the challenging task of distinguishing nominally identical dendrites from dendrites of

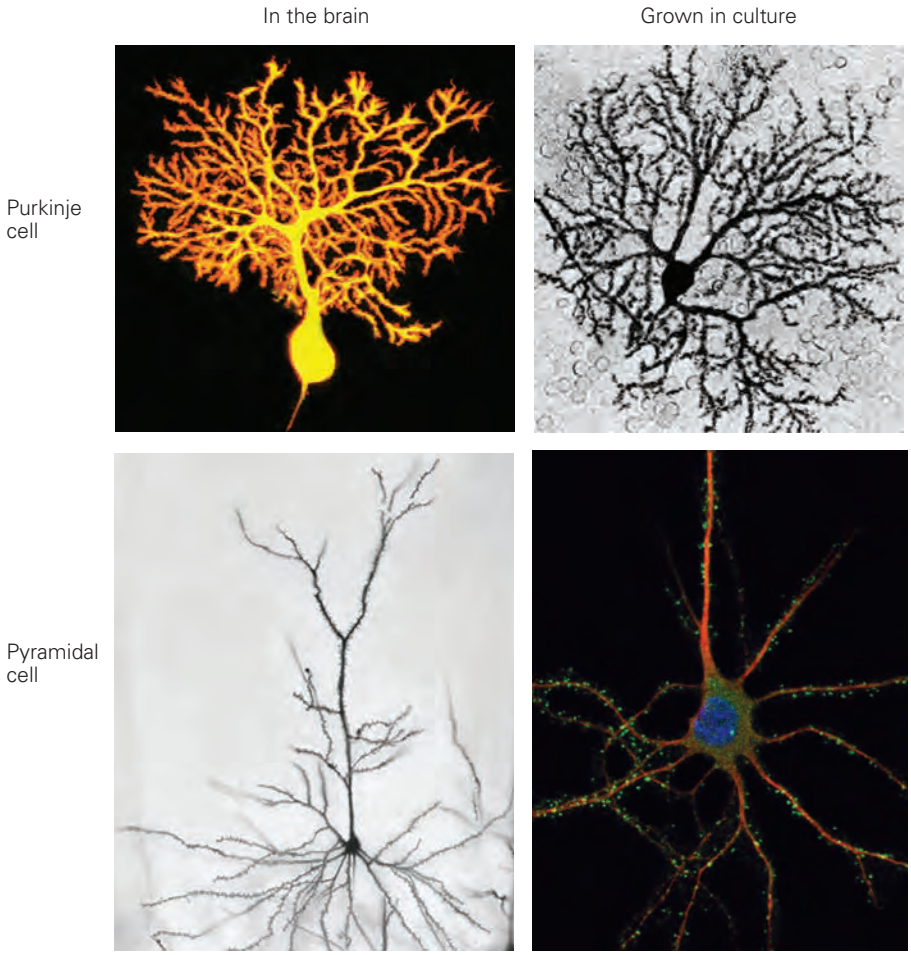

Figure 47–4 The morphologies of neurons are preserved in dissociated cell culture. Cerebellar Purkinje neurons and hippocampal pyramidal neurons have distinctive patterns of dendritic branching. These basic patterns are recapitulated when these two classes of neurons are isolated and grown in dissociated cell culture. (Image upper left: Dr. David Becker; upper right reproduced, with permission, from Yoshio Hirabayashi; lower left reproduced, with permission, from Terry E. Robinson; lower right reproduced, with permission, from Kelsey Martin.)

nominally identical cells (Figure 47–5C). Two groups of molecules have been identified that mediate this self-/non–self-discrimination: clustered protocadherins in mammals and DS-CAMs in *Drosophila*. Although they are unrelated structurally, they share several features (Figure 47–5D).

First, both are encoded by large, complex genes that generate large numbers of isoforms. *Drosophila* Dscam1 encodes around 38,000 distinct proteins through alternative splicing, and the clustered protocadherins encode around 60 proteins that can assemble into thousands of distinct multimers. Second, nearly all of the isoforms bind homophilically; for example, protocadherin γa1 on the surface of one dendrite binds well to protocadherin γa1 on a neighboring membrane, but poorly if at all to other isoforms. Third, in ways that remain incompletely understood, each neuron within a population expresses a random subset of all possible Dscam1 or protocadherin isoforms. Given the large number of isoforms, it is unlikely that individual neurons express identical sets of isoforms on their cell surface. The upshot is that dendrites of each neuron in a population bind homophilically to sibling dendrites, leading to repulsion and self-avoidance, whereas they bind poorly to dendrites of neighboring neurons, enabling other recognition systems to foster synaptogenesis.

Together, the mechanisms we have described, and many others, establish an overall arborization pattern through a combination of intrinsic and extracellular mechanisms. For dendrites, the extrinsic patterning signals determine neuronal morphology. For axons, which we consider next, the signals guide the axons to their targets.

The Growth Cone Is a Sensory Transducer and a Motor Structure

Once an axon forms, it begins to grow toward its synaptic target. The key neuronal element responsible for axonal growth is a specialized structure at the tip of the axon called the *growth cone.* Both axons and dendrites

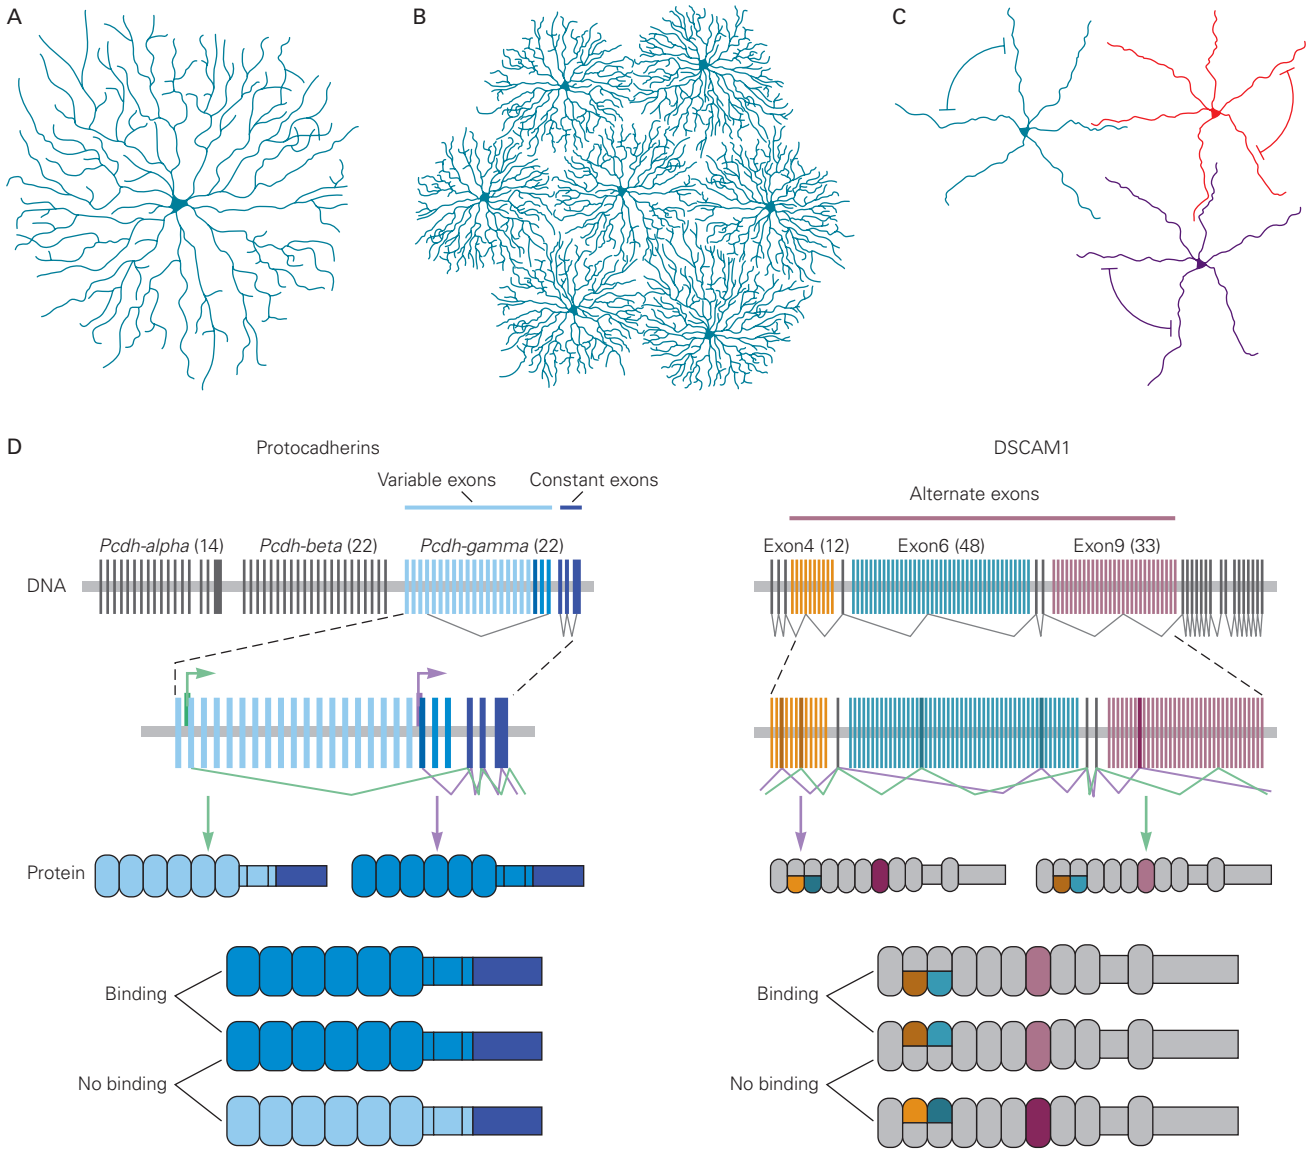

Figure 47–5 Interactions among dendritic branches pattern dendritic arbors.

A. Self-avoidance among sibling dendrites leads to even spacing of branches, minimizing gaps and clumps. In retinal starburst amacrine cells, self-avoidance fails when gamma protocadherins are lost.

B. Tiling of dendrites is conceptually similar to self-avoidance but applies to groups of neurons. It ensures that neighboring neurons of a single type cover territory efficiently.

C. Self-/non-self–discrimination allows sibling dendrites to avoid each other while interacting freely with dendrites of other neurons of the same type.

D. Generation of numerous adhesion molecules from a single genomic complex by promoter choice at the mouse clustered protocadherin (**Pcdh**) locus (*left*) and by alternative splicing at the *Drosophila* DSCAM1 locus (*right*).

use growth cones for elongation, but those linked to axons have been studied more intensively.

Ramón y Cajal discovered the growth cone and had the key insight that it was responsible for axonal pathfinding. With static images alone for inspiration (Figure 47–6A), he envisioned the growth cone to be "endowed with exquisite chemical sensitivity, rapid ameboid movements and a certain motive force, thanks to which it is able to proceed forward and overcome obstacles met in its way . . . until it reaches its destination."

Many studies over the past century have confirmed Ramón y Cajal's intuition. We now know

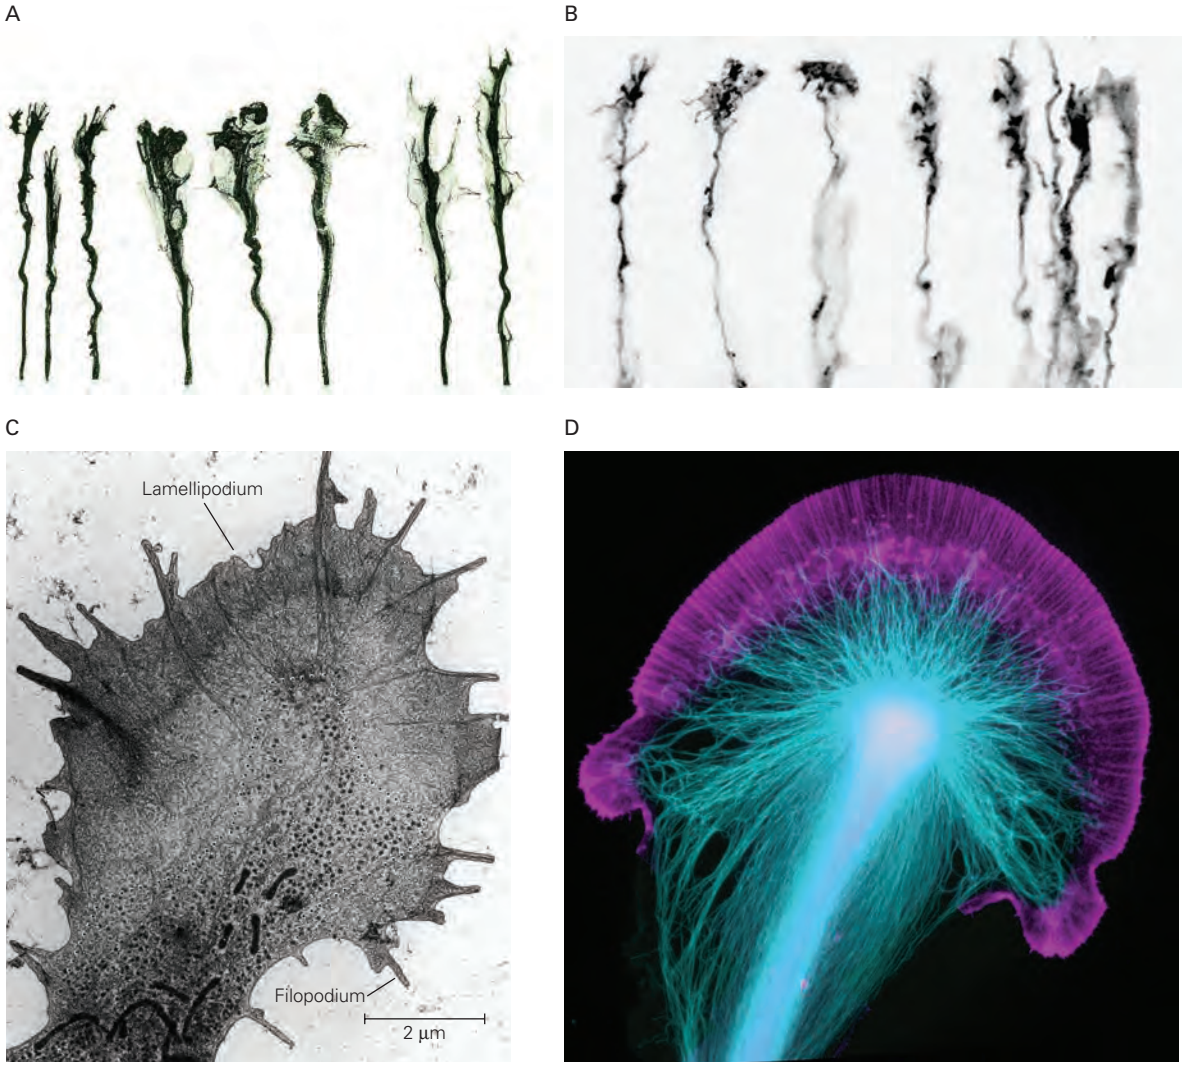

Figure 47–6 Neuronal growth cones.

(Reproduced, with permission, from Paul Forscher and Dylan Burnette.)

that the growth cone is both a sensory structure that receives directional cues from the environment and a motor structure whose activity drives axon elongation. Ramón y Cajal also pondered "what mysterious forces precede the appearance of these processes . . . promote their growth and ramification . . . and finally establish those protoplasmic kisses . . . which seem to constitute the final ecstasy of an epic love story." In more modern and prosaic terms, we now know that the growth cone guides the axon by transducing positive and negative cues into signals that regulate the cytoskeleton, thereby determining the course and rate of axonal growth toward its targets, where it will form synapses.

Growth cones have three main compartments. Their *central core* is rich in microtubules, mitochondria, and other organelles. Long slender extensions called

filopodia project from the body of the growth cone. Between the filopodia lie *lamellipodia*, which are also motile and give the growth cone its characteristic ruffled appearance (Figure 47–6C,D).

Growth cones sense environmental signals through their filopodia: rod-like, actin-rich, membrane-limited structures that are highly motile. Their surface membranes bear receptors for the molecules that serve as directional cues for the axon. Their length—tens of micrometers in some cases—permits the filopodia to sample environments far in advance of the central core of the growth core. Their rapid movements permit them to compile a detailed inventory of the environment, and their flexibility permits them to navigate around cells and other obstacles.

When filopodia encounter signals in the environment, the growth cone is stimulated to advance, retract, or turn. Several motors power these orienting behaviors. One source of power is the movement of actin along myosin, an interaction similar to the one that powers the contraction of skeletal muscle fibers, although the actin and myosin of neurons are different from those in muscle. The assembly of actin monomers into polymeric filaments also contributes a propulsive force for filopodial extension. As the actin filaments are constantly depolymerized at the base of filopodia, the balance of polymerization and depolymerization enables the filopodia to move forward without becoming longer. Depolymerization slows during periods of growth cone advance, leading to greater net forward motion. The movement of membranes along the substrate provides yet another source of forward motion.

The contribution of each type of molecular motor to the advance of the growth cone is likely to vary from one situation to another. Nevertheless, the final step involves the flow of microtubules from the central core of the growth cone into the newly extended tip, thus moving the growth cone ahead and leaving in its wake a new segment of axon. New lamellipodia and filopodia form in the advancing growth cone and the cycle repeats (Figure 47–7).

Accurate pathfinding can occur only if the growth cone's motor action is linked to its sensory function. Therefore, it is crucial that the recognition proteins on the filopodia are signal-inducing receptors and not merely binding moieties that mediate adhesion. The binding of a ligand to its receptor affects growth in diverse ways. In some cases, it engages the cytoskeleton directly, through the intracellular domain of receptors (Figure 47–7). Integrin receptors couple to actin in growth cones when they bind molecules associated with the surface of adjoining cells or the extracellular matrix, thereby influencing motility.

Of equal if not greater importance is the ability of ligand binding to stimulate the formation, accumulation, and even breakdown of soluble intracellular molecules that function as second messengers. These second messengers affect the organization of the cytoskeleton, and in this way regulate the direction and rate of movement of the growth cone.

One important second messenger is calcium. The calcium concentration in growth cones is regulated by the activation of receptors on filopodia, and this affects the organization of the cytoskeleton, which in turn modulates motility. Growth cone motility is optimal within a narrow range of calcium concentrations, called a *set point*. Activation of filopodia on one side of the growth cone leads to a concentration gradient of calcium across the growth cone, providing a possible basis for changes in the direction of growth.

Other second messengers that link receptors and motor molecules include cyclic nucleotides, which modulate the activity of enzymes such as protein kinases, protein phosphatases, and rho-family guanosine triphosphatases (GTPases). In turn, these messengers and enzymes regulate the activity of proteins that regulate the polymerization and depolymerization of actin filaments, thereby promoting or inhibiting axonal extension.

The critical role of intracellular signals in growth cone motility and orientation can be demonstrated using embryonic neurons grown in culture. Application of growth factors to one side of a growth cone activates receptors locally and leads to extension and turning of the growth cone toward the source of the signal. In essence, the factor attracts the growth cone. Yet when cyclic adenosine monophosphate (cAMP) levels in the neuron are decreased, the same stimulus acts as a repellent and the growth cone turns away from the signal (Figure 47–8A). Other repulsive factors can become attractive when levels of the second messenger cyclic guanosine 3′,5′-monophosphate (cGMP) are raised.

Recently, another mechanism for coupling guidance molecules to growth cone behavior has come to light. It was long thought that all neuronal protein synthesis occurs in the cell body, but we now know that growth cones (as well as some dendrites) contain the machinery for protein synthesis, including a subset of messenger RNAs. Initial evidence that these molecules play an important role came from experiments in which axons were severed from their parent cell body. The growth cones continued to advance for a few hours; they could be stimulated to turn toward or away from local depots of guidance molecules, and these behaviors were abolished by inhibitors of protein

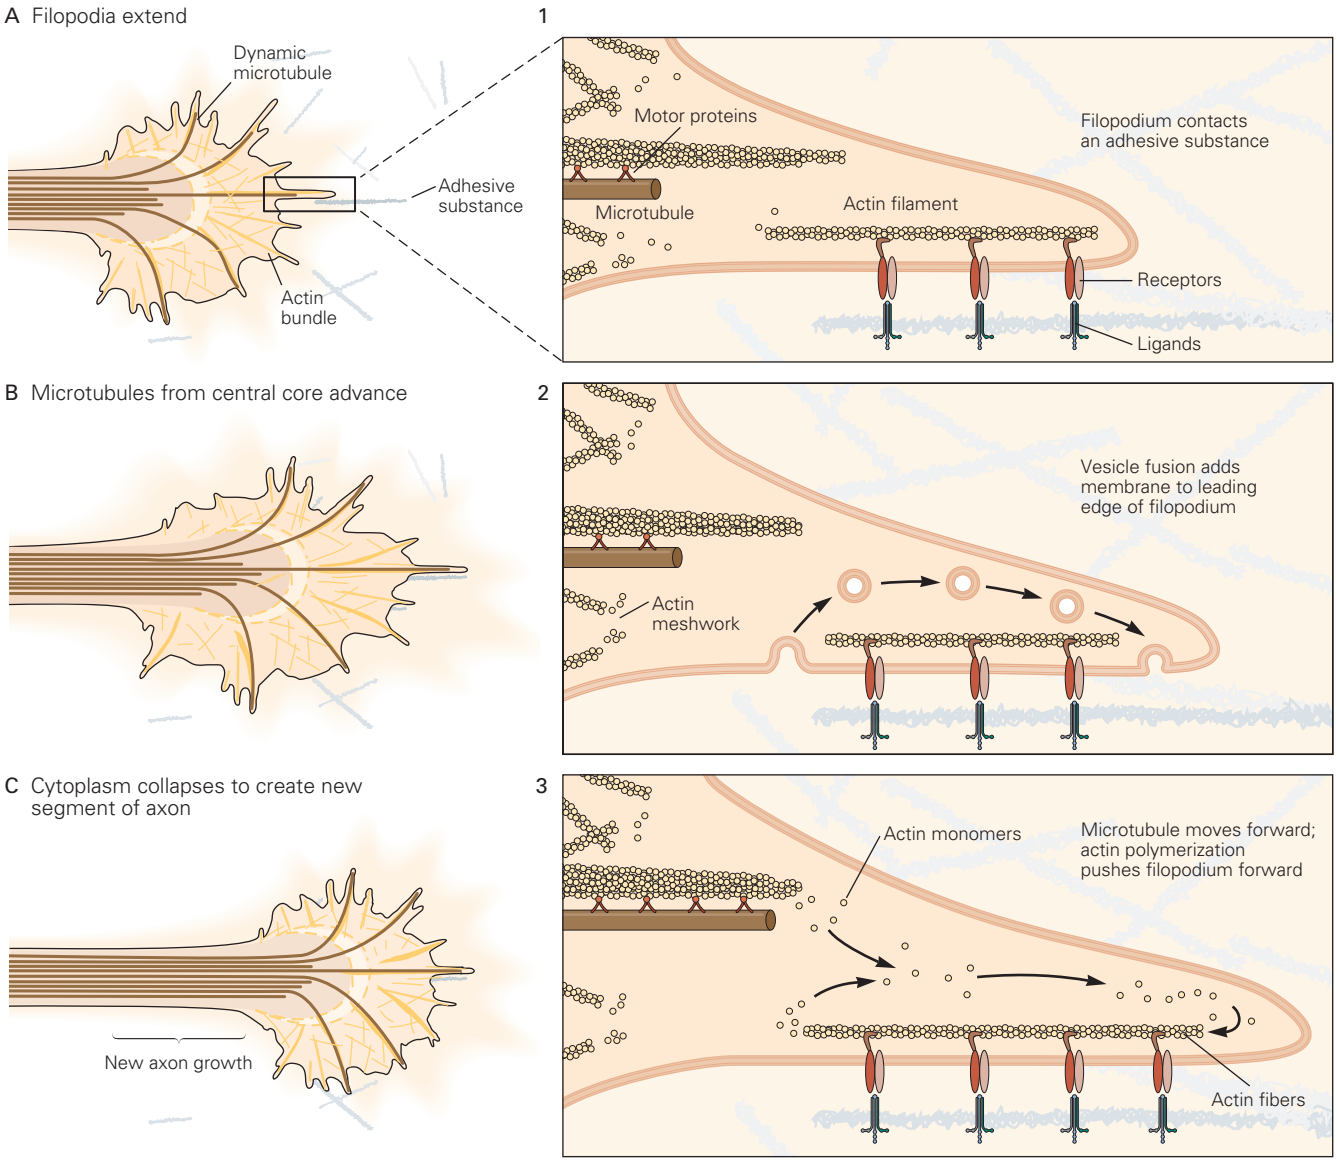

Figure 47–7 **The growth cone advances under the control of cellular motors.** (Adapted, with permission, from Heidemann 1996. Copyright © 1996 Academic Press Inc.)

A. A filopodium contacts an adhesive cue and contracts, thus pulling the growth cone forward (**1**). Actin filaments assemble at the leading edge of a filopodium and disassemble at the trailing edge, interacting with myosin along the way (**2**). Actin polymerization pushes the filopodium forward (**3**). Force generated by the retrograde flow of actin pushes the filopodium forward. Exocytosis adds membrane to the leading edge of the filopodium and supplies new adhesion receptors to maintain traction. Membrane is recovered at the back of the filopodium. The actin polymer is linked to adhesion molecules on the plasma membrane.

B. The combined action of these motors creates an actin-depleted space that is filled by the advance of microtubules from the central core.

C. Individual microtubules condense to form a thick bundle, and the cytoplasm collapses around them to create a new segment of axonal shaft.

synthesis. The local protein synthesis is regulated by second messengers produced in response to activation of guidance receptors on the growth cones (Figure 47–8). This mechanism leads to synthesis of new motor proteins precisely when and where they are needed. Thus, the growth cone has many strategies and mechanisms for integrating molecular signals to direct the axon in specific directions.

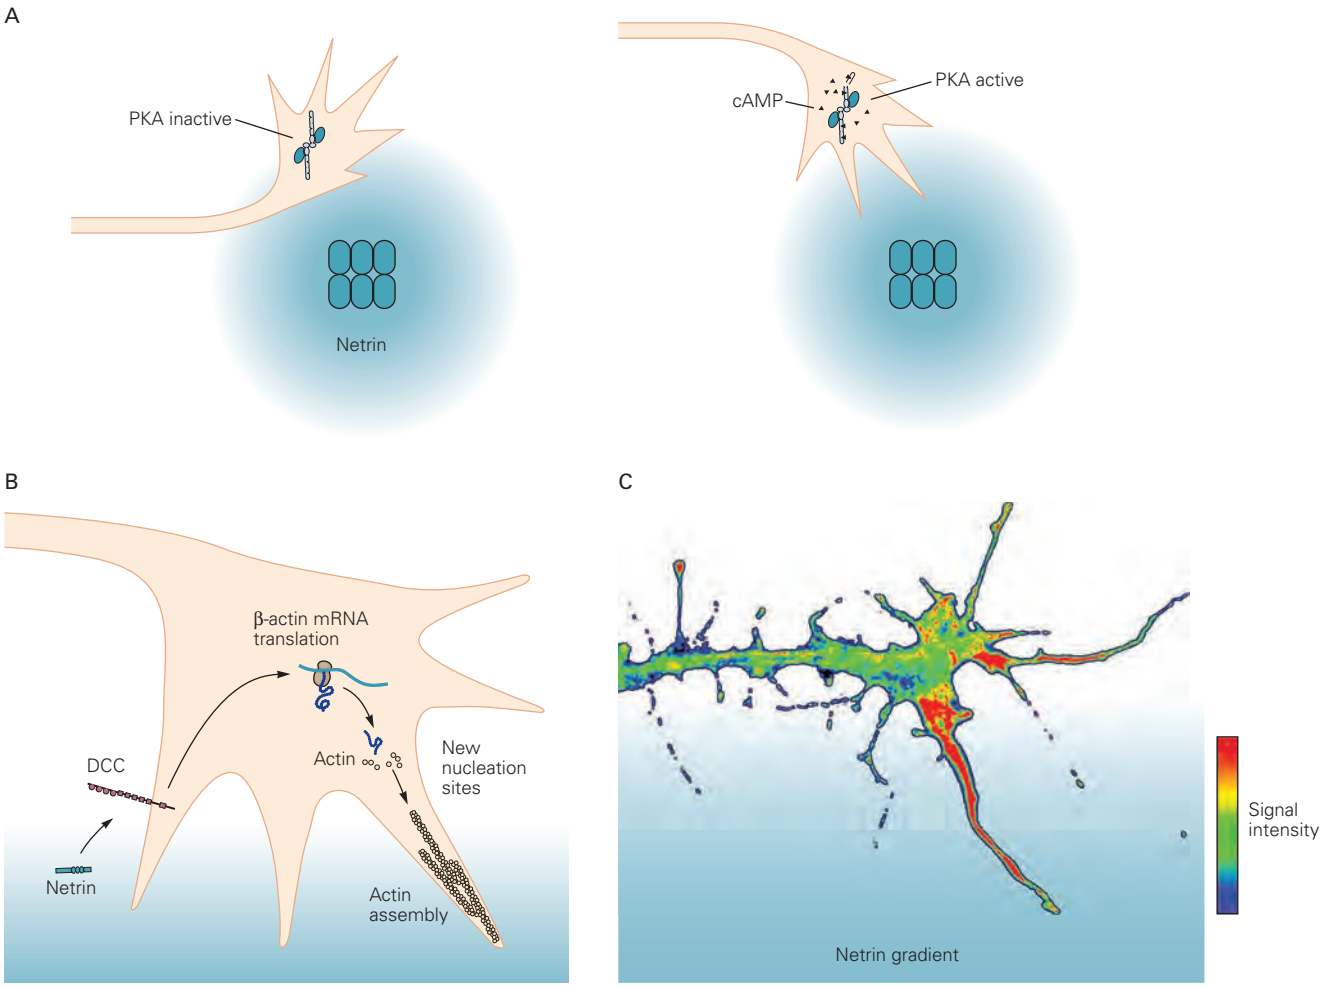

Figure 47–8 Changes in the level of intracellular regulatory proteins can determine whether the same extrinsic cue attracts or repels the growth cone.

A. The state of protein kinase A (**PKA**) activity can alter the growth cone's response to an extracellular orienting factor, in this instance, the protein netrin. When PKA activity and intracellular cyclic adenosine monophosphate (**cAMP**) levels are low, the growth cone is repelled by netrin. When PKA activity is high, the resulting elevation in intracellular cAMP causes the growth cone to be attracted to a local source of netrin. (Adapted, with permission, from Ming et al. 1997.)

B. Netrin activation of growth cone receptors (deleted in colon cancer, **DCC**) leads to local synthesis of actin, which leads to turning.

C. Immunohistochemical analysis of a growth cone showing local synthesis of actin in response to local application of netrin. (Reproduced, with permission, from Christine Holt. Adapted, with permission, from Leung et al. 2006.)

Molecular Cues Guide Axons to Their Targets

For much of the 20th century, a debate raged between advocates of two very different views of how growth cones navigate embryonic terrains to reach their targets. A molecular view of axonal guidance was first articulated at the turn of the 20th century by the physiologist J. N. Langley. But by the 1930s, many eminent biologists, including Paul Weiss, believed that axonal outgrowth was essentially random and that appropriate connections persisted largely because of productive, matching patterns of electrical activity in the axon and its target cell.

In our molecular age, Weiss's ideas may seem simplistic, but they were not unreasonable at the time. In tissue culture, axons grow preferentially along mechanical discontinuities (scratches and bumps on a cover slip), and embryonic nerve trunks often align themselves with solid supports (blood vessels or cartilage). It seemed logical to Weiss that mechanical guidance, called *stereotropism*, could account for axonal patterning. Today, we are quite comfortable with the

idea that electrical signals can be used to change the way current flows in a computer without the need to resolder connections. Likewise, patterns of activity and experience can strengthen or weaken neural connections without requiring the formation of new axonal pathways. Then why not consider that congruent activity, called *resonance* by Weiss, is involved in establishing appropriate connections?

Today, few scientists believe that stereotaxis or resonance is a crucial force in initial patterning of neuronal circuits. The tipping point that shifted opinion in favor of the molecular view was an experiment performed with frogs and other amphibia in the 1940s by Roger Sperry (ironically, a student of Weiss). Sperry manipulated the information carried from the eye to the brain by the axons of retinal ganglion cells. These axons terminate in their target areas—the lateral geniculate body in the thalamus and the superior colliculus (called optic tectum in lower vertebrates) in the midbrain—in such a way that an orderly retinotopic map of the visual field is created.

Because of the optics of the eye, the visual image on the retina is an inversion of the visual field. The retinal ganglion cells reinvert the image by the pattern in which their axons terminate in the optic tectum, the main visual center in the brain of frogs (Figure 47–9A). If the optic nerve is cut, the animal is blinded. In lower vertebrates, cut retinal axons can reestablish projections to the tectum, whereupon vision is restored. This is not the case in mammals, as we will discuss in Chapter 50.

Sperry's key experiment was to sever the optic nerve in a frog and then rotate the eye in its socket by 180° before regeneration of the nerve. Remarkably, the frog exhibited orderly responses to visual input, but the behavior was wrong. When the frog was presented with a fly on the ground, it jumped up, and when offered a fly above its head, it struck downward (Figure 47–9B). Importantly, the animal never learned to correct its mistakes. Sperry suggested—and later verified with anatomical and physiological methods—that the retinal axons had reinnervated their original tectal targets, even though these connections provided the brain with erroneous spatial information that led to aberrant behavior. The inference of these experiments was that recognition between axons and their targets relied on molecular matching rather than functional validation and refinement of random connections.

But Weiss's ideas are by no means obsolete. Indeed, we now recognize that the activity of neural circuits can play a crucial role in shaping connectivity. The current view is that molecular matching predominates during embryonic development and that activity and experience modify circuits after they have formed. In this chapter and the next, we describe the molecular cues that guide the formation of neural connections, and then in Chapter 49, we examine the role of activity and experience in the fine-tuning of synaptic connections.

Sperry's conjecture, often called the *chemospecificity hypothesis*, prompted developmental neurobiologists to search for axonal and synaptic "recognition molecules." Success was limited for the first few decades, in part because these molecules are present in small amounts and on discrete subsets of neurons and there were no effective methods for isolating rare molecules from complex tissues. Eventually advances in biochemical and molecular-biological methods made this task more feasible, and many proteins involved in the guidance of axons to their targets have now been discovered. These proteins typically consist of paired ligands and receptors: The ligands are presented by cells along the pathway an axon follows and the receptors by the growth cone itself.

In the most general terms, guidance cues can be presented on cell surfaces, in the extracellular matrix, or in soluble form. As described above (Figure 47–8), they interact with receptors embedded in the growth cone membrane to promote or inhibit outgrowth of the axon. Most receptors have an extracellular domain that selectively binds the cognate ligand and an intracellular domain that couples to the cytoskeleton, either directly or through intermediates such as second messengers. The ligands can speed or slow growth. Ligands presented to one side of the growth cone can result in local activation or inhibition, leading to turning. In this way, the local distribution of environmental cues determines the pathway of the advancing growth cone.

As a result of these recent discoveries, axon guidance—a process that appeared mysterious years ago—can now be viewed as the orderly consequence of protein–protein interactions that instruct the growth cone to grow, turn, branch, or stop (Figures 47–10, 11). This limited set of instructions is sufficient, when presented with spatial precision, to choreograph growth cone behaviors with exquisite subtlety. Axonal guidance can therefore be explained by describing how and where ligands are presented and how the growth cone integrates this information to generate an orderly response. In the rest of the chapter, we illustrate lessons learned by describing the journeys of two types of axons: those of retinal ganglion neurons and those of a particular class of sensory relay neurons in the spinal cord.

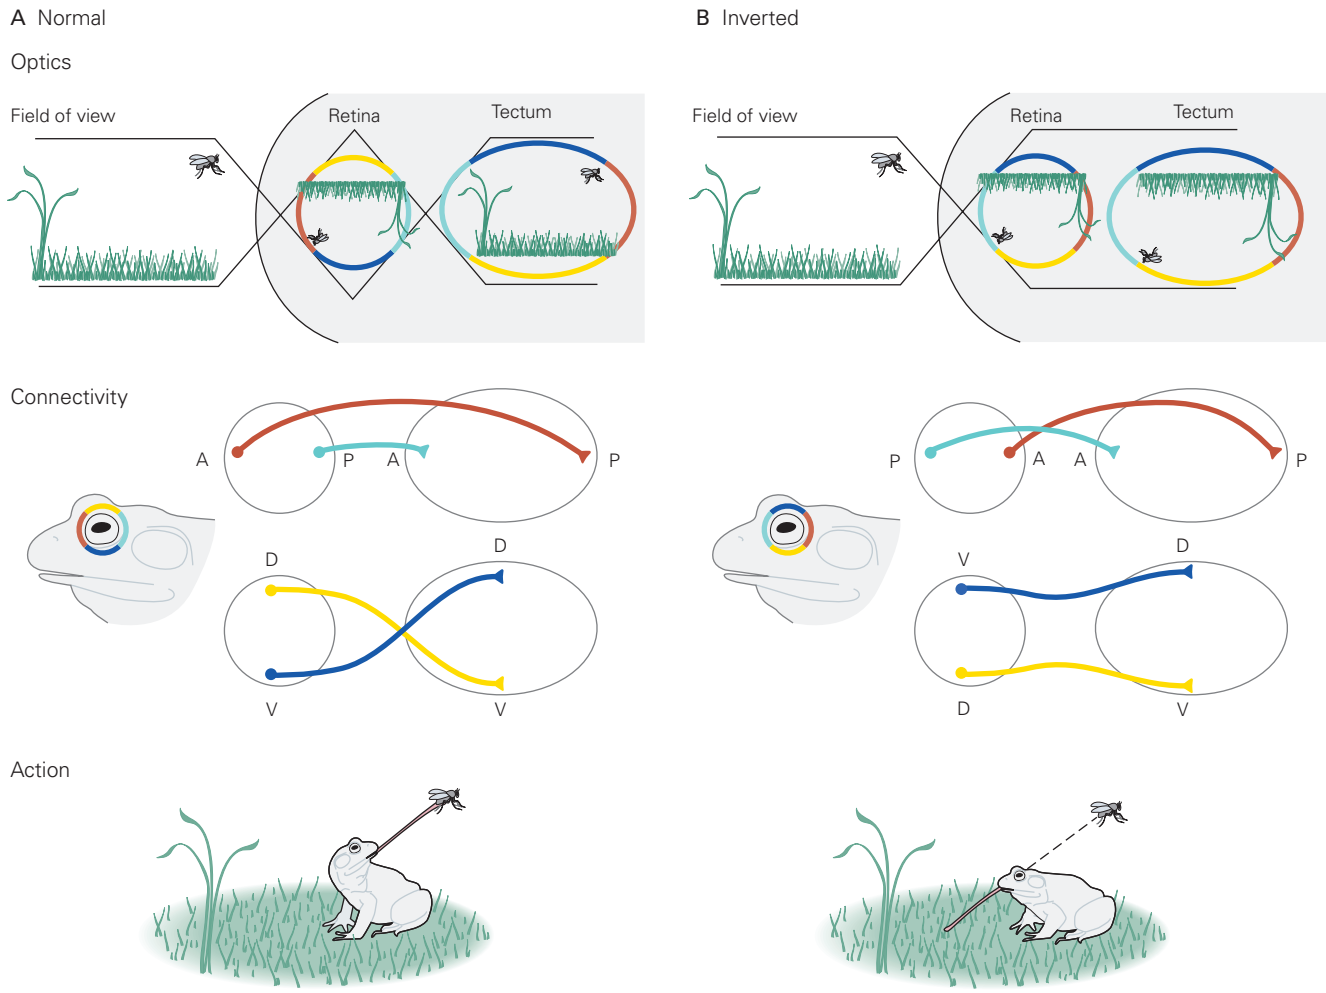

Figure 47–9 Roger Sperry's classical experiments on regeneration in the visual system provided evidence for chemoaffinity in the wiring of connections.

A. In the visual system of the frog, the lens projects an inverted visual image onto the retina and the optic nerve then transfers the image, with an additional inversion, to the optic tectum. The spatial arrangement of retinal inputs to the tectum allows for this transfer. Neurons in the anterior retina project axons to the posterior tectum, while neurons in the posterior retina project to the anterior tectum. Similarly, neurons in the dorsal retina project to the ventral tectum, and neurons in the ventral retina project to the dorsal tectum. As a result, visually guided behaviors (here catching a fly) are accurate. (Abbreviations: **A**, anterior; **D**, dorsal; **P**, posterior; **V**, ventral.)

B. If the optic nerve is cut and the eye is surgically rotated in its socket before the nerve regenerates, visually guided behavior is aberrant. When a fly is presented overhead, the frog perceives it as below, and vice versa. The inversion of behavioral reflexes results from the connection of regenerating retinal axons to their original targets, even though these connections now transfer an inverted, inappropriate map of the world into the brain.

The Growth of Retinal Ganglion Axons Is Oriented in a Series of Discrete Steps

Sperry's experiment implied the existence of axon guidance cues but did not reveal where they were or how they worked. For a time, one prominent view was that recognition occurred mostly at or near the target and that mechanical forces or long-range chemotactic factors sufficed to get axons to the vicinity of the target.

We now know that axons reach distant targets in a series of discrete steps, making frequent decisions at closely spaced intervals along their route. To illustrate this point, we shall trace in greater detail the path that Sperry was trying to understand, that of a retinal axon growing to the optic tectum.

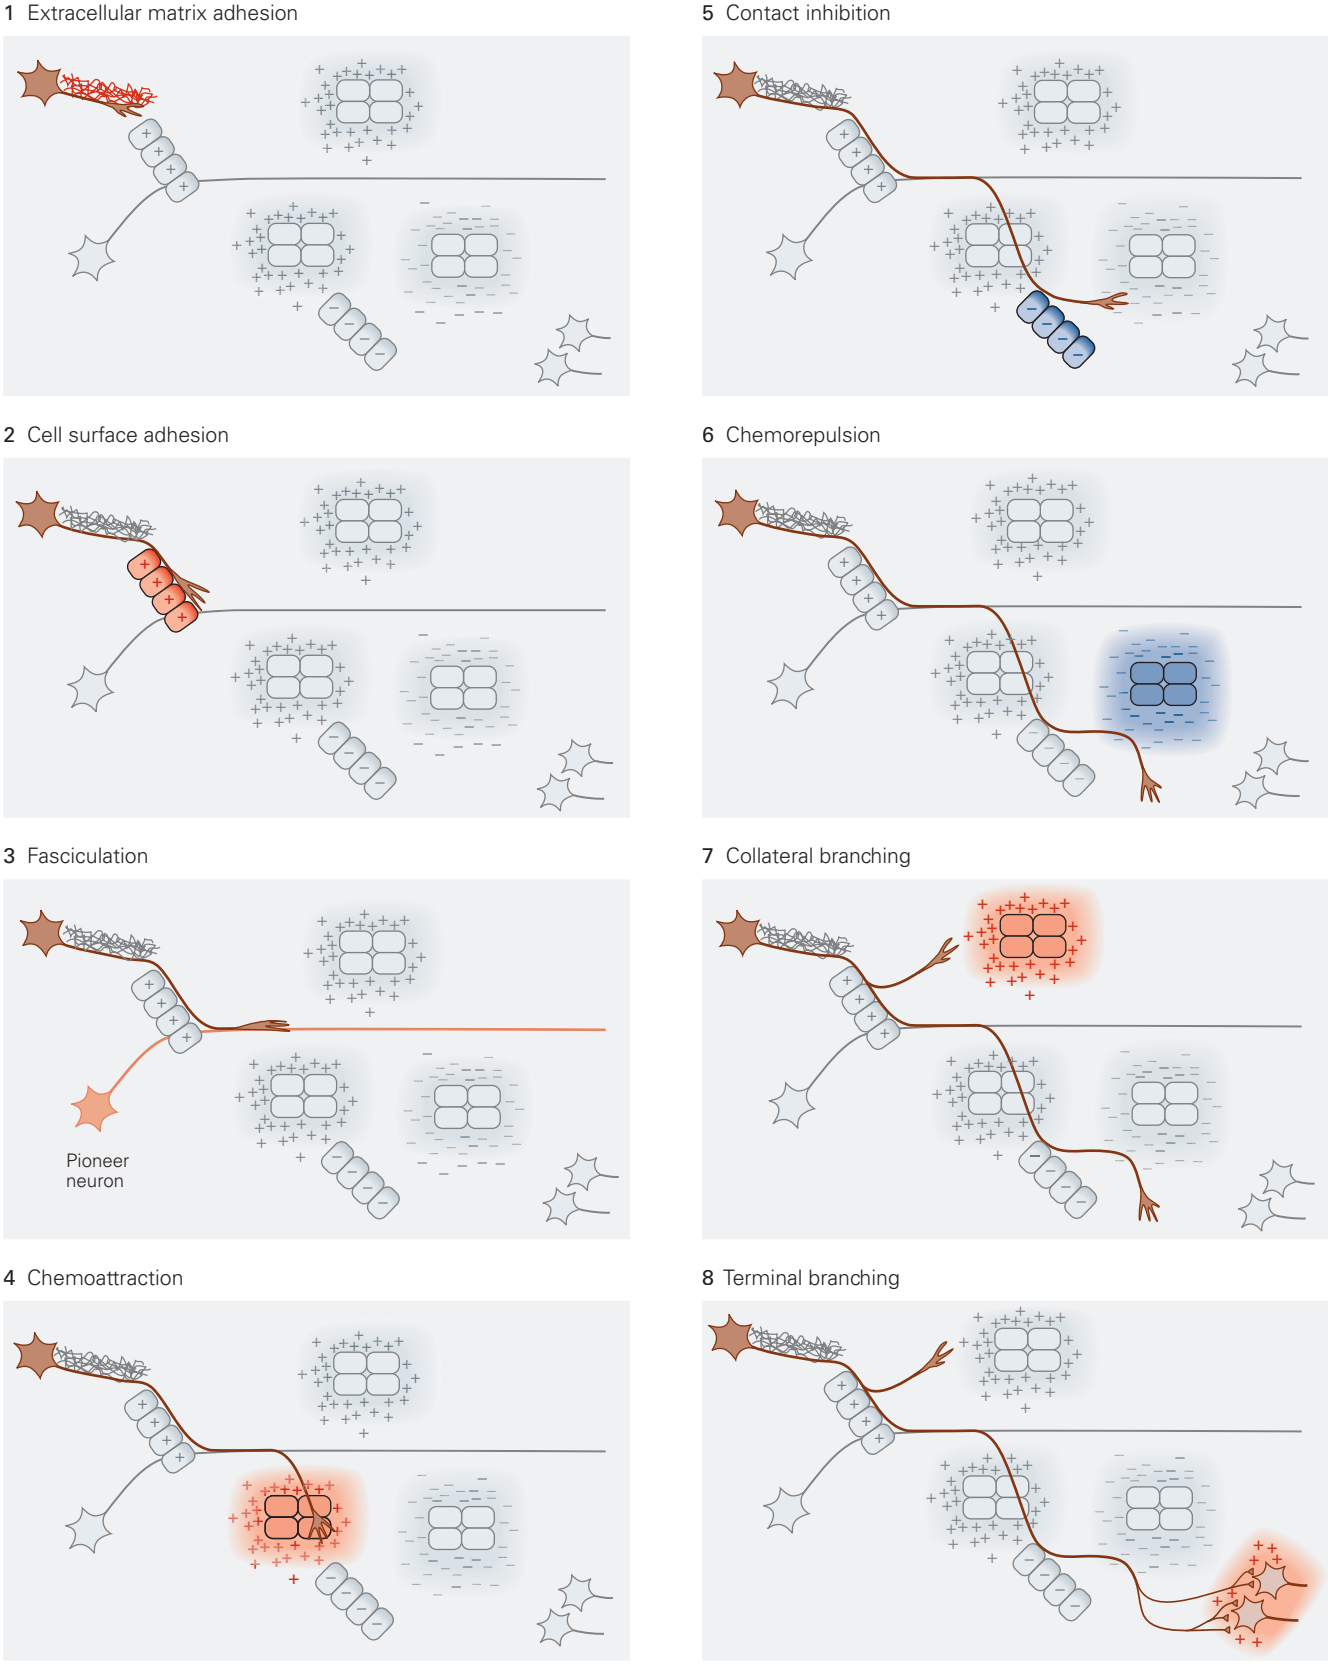

Figure 47–10 Extracellular cues use a variety of mechanisms to guide growth cones. The axon can interact with growth-promoting molecules in the extracellular matrix (**1**). It can interact with adhesive cell-surface molecules on neural cells (**2**). The growing axon can encounter another axon from a "pioneer" neuron and track along it, a process termed *fasciculation* (**3**). Soluble chemical signals can attract the growing axon to its cellular source (**4**). Intermediate target cells that express cell-surface repellent cues can cause the axon to turn away (**5**). Soluble chemical signals can repel the growing axon (**6**). Extracellular signals also lead to formation of collaterals from axon shafts (**7**) or branching of the growing axon (**8**).

Growth Cones Diverge at the Optic Chiasm

The first task of the axon of a retinal ganglion cell is to leave the retina. As it enters the optic fiber layer, it extends along the basal lamina and glial end-feet at the retina's edge. The growth of the axon is oriented from the outset, indicating that it can read directional cues in the environment. As it approaches the center of the retina, it comes under the influence of attractants emanating from the optic nerve head (the junction of the optic nerve with the retina proper), which guide it into the optic stalk. It then follows the optic nerve toward the brain (Figure 47–12).

The first axons to travel this route follow the cells of the optic stalk, the rudiment of the neural tube that connects the retina to the diencephalon from which it arose. These "pioneer" axons then serve as scaffolds for later-arriving axons, which are able to extend accurately simply by following their predecessors (see "fasciculation" in Figure 47–10). Once they reach the optic chiasm, however, the retinal axons must make a choice. Axons that arise from neurons in the nasal hemiretina of each eye cross the chiasm and proceed to the opposite side of the brain, whereas those from the temporal half are deflected as they reach the chiasm and so stay on the same side of the brain (Figure 47–13A).

This divergence in trajectory reflects the differential responses of axons from the nasal and temporal hemiretinas to guidance cues presented by midline chiasm cells. Some retinal axons contact and traverse chiasm cells, whereas others are inhibited by these cells and deflected away, thus remaining on the ipsilateral side. One of the key molecules presented by chiasm cells is a membrane-bound repellent of the ephrin-B family (Figure 47–13B), which also figures in later steps of retinal ganglion cell axon guidance.

The fraction of temporal retinal axons that project ipsilaterally varies among species: few in lower vertebrates, some in rodents, and many in humans. These differences reflect placement of the eyes. In many animals, the eyes point to the sides and monitor different parts of the visual world, so that information from the two eyes need not be combined. In humans, both eyes look forward and sample largely overlapping regions of the visual world, so coordination of visual input is essential.

After crossing the optic chiasm, retinal axons assemble in the optic tract along the ventral surface of the diencephalon. Axons then leave the tract at different points. In most vertebrate species, the tectum of the midbrain (called the superior colliculus in mammals) is the major target of retinal axons, but a small number of axons project to the lateral geniculate nucleus of the thalamus. In humans, however, most axons project to the lateral geniculate, a sizable number reach the

Figure 47–11 (Opposite) Diverse molecular families control the growth and guidance of developing axons.

A. A large family of classical cadherins promote cell and axonal adhesion, primarily through homophilic interactions between cadherin molecules on adjacent neurons. Adhesive interactions are mediated through interactions of the extracellular EC1 domains. Cadherins transduce adhesive interactions though their cytoplasmic interactions with catenins, which link cadherins to the actin cytoskeleton.

B. A diverse array of immunoglobulin superfamily proteins are expressed in the nervous system and mediate adhesive interactions. The three examples shown here, NCAM, L1, and TAG1, can bind both homophilically and heterophilically to promote axon outgrowth and adhesion. These proteins contain both immunoglobulin domains (**circles**) and fibronectin type III domains (**squares**). Homophilic interactions typically involve amino terminal immunoglobulin domains. Different immunoglobulin adhesion molecules interact with the cytoskeleton via diverse cytoplasmic mediators, only a few of which are shown here.

C. Different ephrin proteins bind to Eph class tyrosine kinase receptors. Class A ephrins are linked to the surface membrane through a glycosyl phosphatidylinositol tether, whereas class B ephrins are transmembrane proteins. Class A ephrins typically bind class A Eph kinases, and class B ephrins typically bind class B Eph kinases. Forward Eph signaling usually elicits repellant or inhibitory responses in receptive cells, whereas reverse ephrin signaling can elicit adhesive or inhibitory responses. Ephrin-Eph signaling involves many different cytoplasmic mediators.

D. Laminin proteins are components of the extracellular matrix and promote cell adhesion and axon extension through interactions with integrin receptors. Integrins mediate adhesion and axon growth through interactions with the cytoskeleton via many intermediary proteins.

E. Semaphorin proteins can promote or inhibit axonal growth through interaction with a diverse array of plexin and neuropilin receptors, which transduce signals via Rho class GTPases and downstream kinases.

F. Slit proteins typically mediate repellant responses through interaction with Robo class receptors, which influence axonal growth via intermediary GTPases such as Rac.

G. The secreted or extracellular matrix–associated netrin proteins mediate both chemoattractant and chemorepellent responses. Attractant responses are mediated through interaction with **DCC** (deleted in colorectal cancer) receptors, whereas repellent responses involve interactions with DCC and unc-5 coreceptors. Netrin receptors signal via GTPases and cyclic guanosine monophosphate (**cGMP**) cascades.

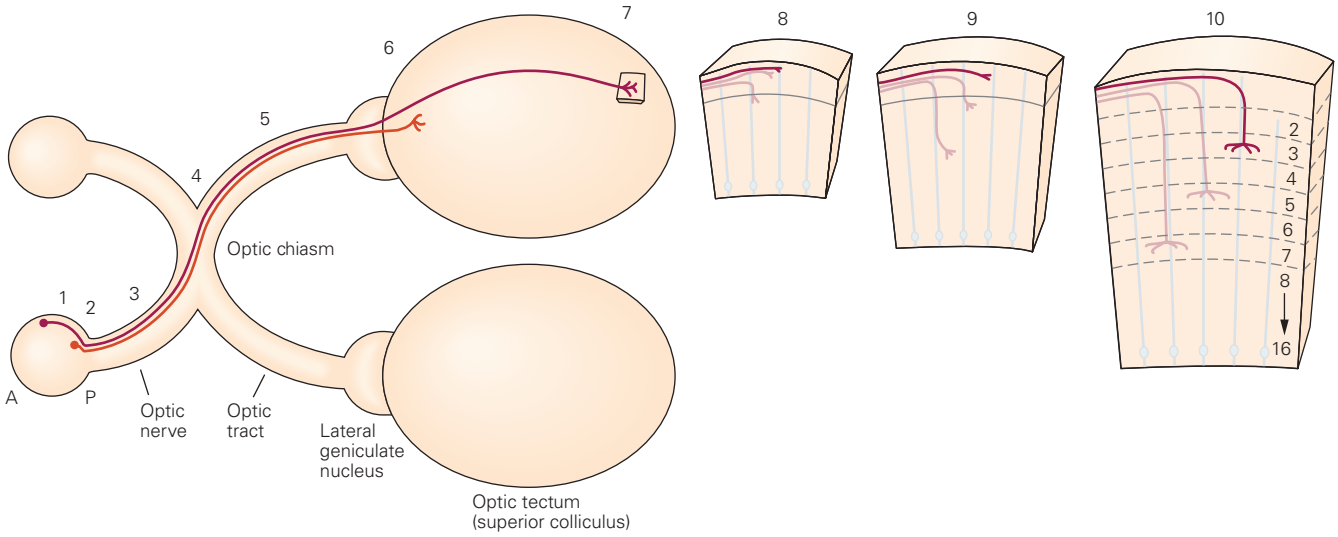

Figure 47–12 The axons of retinal ganglion cells grow to the optic tectum in discrete steps. Two neurons that carry information from the nasal half of the retina are shown. The axon of one crosses the optic chiasm to reach the contralateral optic tectum. The axon of the other also crosses the optic chiasm but projects to the lateral geniculate nucleus. The numbers indicate important landmarks on the axon's journey. The growing axon is directed toward the optic nerve head (the junction of the nerve with the retina) (**1**), enters into the optic nerve (**2**), extends through the optic nerve (**3**), swerves to remain ipsilateral (not shown) or crosses to the contralateral side at the optic chiasm (**4**), extends through the optic tract (**5**), enters into the optic tectum or lateral geniculate nucleus (not shown) (**6**), navigates to an appropriate rostrocaudal and dorsoventral position on the tectum (**7**), turns to enter the neuropil (descends in chicks as shown here; ascends in mammals) (**8**), stops at an appropriate layer where a rudimentary terminal arbor is formed (**9**), and finally is remodeled (**10**). (Abbreviations: **A**, anterior; **P**, posterior).

colliculus, and small numbers project to the pulvinar, superchiasmatic nucleus, and pretectal nuclei. Within these targets, different retinal axons project to different regions. As Sperry showed, the retinal axons form a precise retinotopic map on the tectal surface. Similar maps form in other areas innervated by retinal axons such as the lateral geniculate nucleus.

Having reached an appropriate position within the tectum, retinal axons need to find an appropriate synaptic partner. To achieve this last leg of their journey, retinal axons turn and dive into the tectal neuropil (Figure 47–12), descending (or, in mammals, ascending) along the surface of radial glial cells, which provide a scaffold for radial axonal growth. Although radial glial cells span the entire extent of the neuroepithelium, each retinal axon confines its synaptic terminals to a single layer. The dendrites of many postsynaptic cells extend through multiple layers and form synapses along their entire length, but retinal inputs are restricted to a small fraction of the target neuron's dendritic tree. These organizational features imply that layer-specific cues arrest axonal elongation and trigger arborization.

The problem of long-distance axon navigation is therefore solved by dividing the journey into short segments in which intermediate targets guide the axons along the path to their final targets. Some intermediate targets, such as the optic chiasm, are "decision" regions where axons diverge.

Reliance on intermediate targets is an effective solution to the problem of long-distance axonal navigation but is not the only one. In some cases, the first axons reach their targets when the embryo is small and the distance to be covered is short. These "pioneer" axons respond to molecular cues embedded in cells or the extracellular matrix along their way. The first axons to exit the retina fall within this class. Axons that appear later, when distances are longer and obstacles more numerous, can reach their targets by following the pioneers. Yet another guidance mechanism is a molecular gradient. Indeed, as we will see, gradients of cell-surface molecules in the tectum inform axons about their proper termination zone.

Gradients of Ephrins Provide Inhibitory Signals in the Brain

So far, we have seen how retinal axons reach the tectum by responding to a series of discrete directional cues. However, these choices during growth do not account

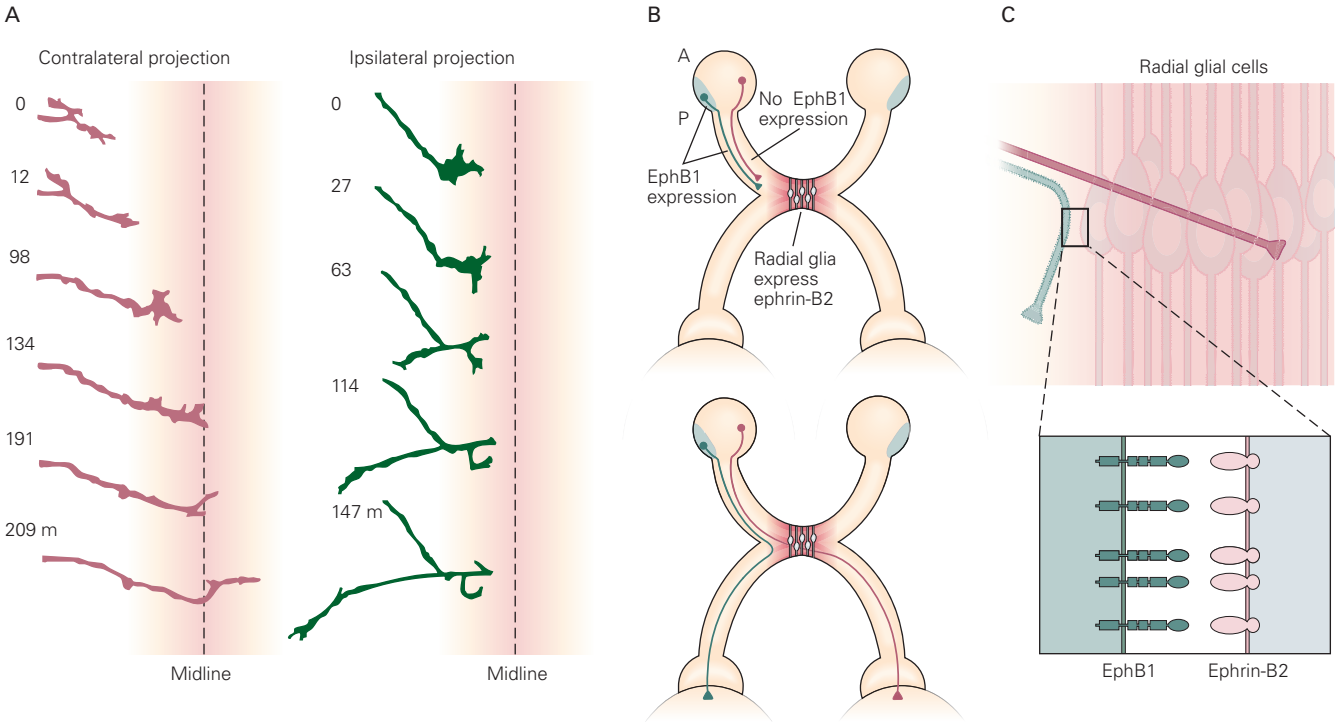

Figure 47–13 Axons of retinal ganglion neurons diverge as they reach the optic chiasm.

A. A time lapse series shows axons approaching the midline. Axons that arise from the nasal hemiretina cross the optic chiasm and project to the contralateral tectum (*left*). In contrast, axons from the temporal hemiretina reach the chiasm but fail to cross and thus project toward the ipsilateral tectum (*right*). (Reproduced, with permission, from Godement, Wang, and Mason 1994.)

B. The axons of neurons from the temporal hemiretina, which express the tyrosine kinase receptor EphB1, encounter ephrin-B2 expressed by midline radial glial cells at the optic chiasm and so are prevented from crossing the midline. The axons of nasal hemiretina neurons, which lack EphB1 receptors, are unaffected by the presence of ephrin-B2 and cross to the contralateral side. (Abbreviations: **A**, anterior; **P**, posterior.)

C. Higher-power view illustrating the trajectories of retinal ganglion cell axons at the chiasm.

for the smoothly graded connections implied by Sperry's analysis of the retinotopic map in the tectum. The quest for the hypothetical "map molecules" became a major focus for developmental neurobiologists, and so we describe it in some detail.

A key breakthrough in the quest for these molecules came with the development of bioassays in which explants from defined portions of the retina were laid on substrates of tectal membrane fragments. The membrane fragments were taken from defined anteroposterior portions of the tectum and arranged in alternating stripes. Axons from the temporal (posterior) hemiretina were found to grow preferentially on membranes from anterior tectum, a preference similar to that exhibited in vivo (Figure 47–14). This preference was found to result from the presence of inhibitory factors in posterior membranes rather than from attractive or adhesive substances in anterior membranes. This observation was one of the first to demonstrate the role of inhibitory or repellent substances in axon guidance.

This stripe assay permitted the characterization of an inhibitory cue, present in membranes from the posterior but not the anterior tectum. Independently, molecular biologists identified a family of receptor tyrosine kinases, the Eph kinases, and a large family of membrane-associated ligands, the ephrins. Both receptors and ligands are divided into A and B subfamilies. The ephrin-A proteins bind and activate EphA kinases; conversely, ephrin-B proteins bind and activate EphB kinases (Figure 47–11C).

The two lines of research converged when the tectal inhibitory cue was identified as ephrin-A5. We now know that the Eph kinases and ephrins serve many functions in neural and nonneural tissues and that each class of proteins can serve as ligands or receptors, depending on cellular context. In the developing

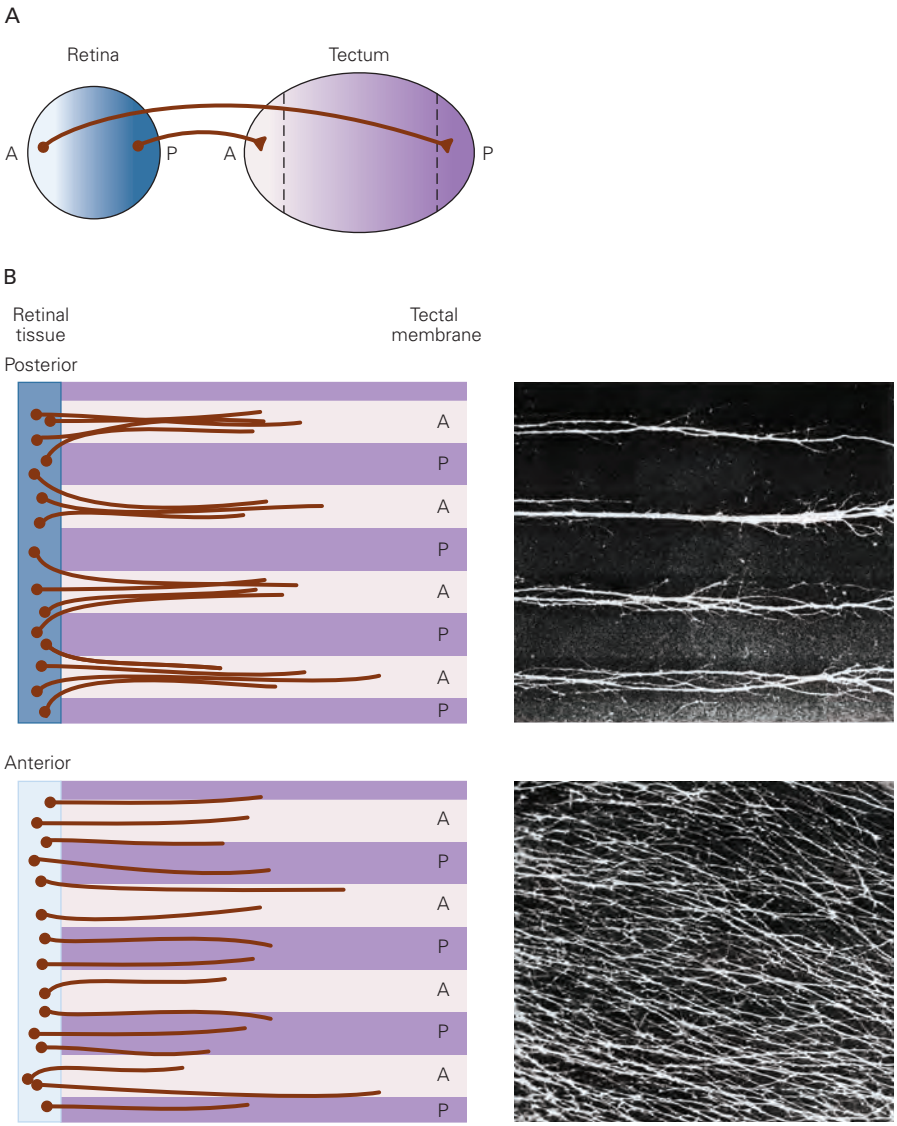

Figure 47–14 Repellent signals guide developing retinal axons in vitro.

A. Retinal ganglion axons from the posterior (temporal) hemiretina project into the anterior developing tectum. Conversely, axons from the anterior (nasal) hemiretina project into the posterior tectum.

B. Fragments of membrane were taken from specified anteroposterior portions of the tectum and arranged in alternating strips. Axons from explants of posterior retina grow selectively on the fragments from anterior tectum. The preferential growth of axons on anterior membrane results from an inhibitory cue in the posterior membrane. In contrast, axons from anterior retina grow on both anterior and posterior tectal membrane fragments. (Abbreviations: A, anterior; P, posterior.) (Adapted, with permission, from Walter, Henke-Fahle, and Bonhoeffer 1987.)

nervous system, these proteins comprise a major group of repellent signals.

Ephrin–Eph interactions account in large part for formation of the retinotopic map in the tectum. Levels of ephrin-A2 and ephrin-A5 in the tectum as well as levels of the Eph receptors in the retina are graded along the anteroposterior axis. These gradients run in the same direction. Ephrin-A concentrations run from posterior-high to anterior-low in tectum, while Eph A concentrations run from posterior-high to anterior-low in retina (Figure 47–15A). Such counter-gradients account, at least in part, for topographic mapping. Axons from posterior retinal ganglion cells with high levels of EphA receptors are repelled most strongly by the high level of ephrin-A in the posterior tectum and thus are confined to the anterior tectum. The less sensitive axons from the anterior retina are able to penetrate further into the posterior domain of the tectum. Ephrin-A2 and ephrin-A5 are therefore strong candidates for chemospecificity factors of the type postulated by Sperry.

The crucial role of the interaction of ephrins and Eph kinases in the formation of retinotopic maps has been confirmed in vivo. Overexpression of ephrin-A2 in the developing optic tectum of chick embryos generates small patches of cells in the rostral tectum that are abnormally rich in ephrin-A2. Temporal retinal axons, which normally avoid the ephrin-rich caudal tectum, also avoid these patches in the rostral tectum, and they terminate in abnormal positions. In contrast, nasal retinal axons, which normally grow toward the

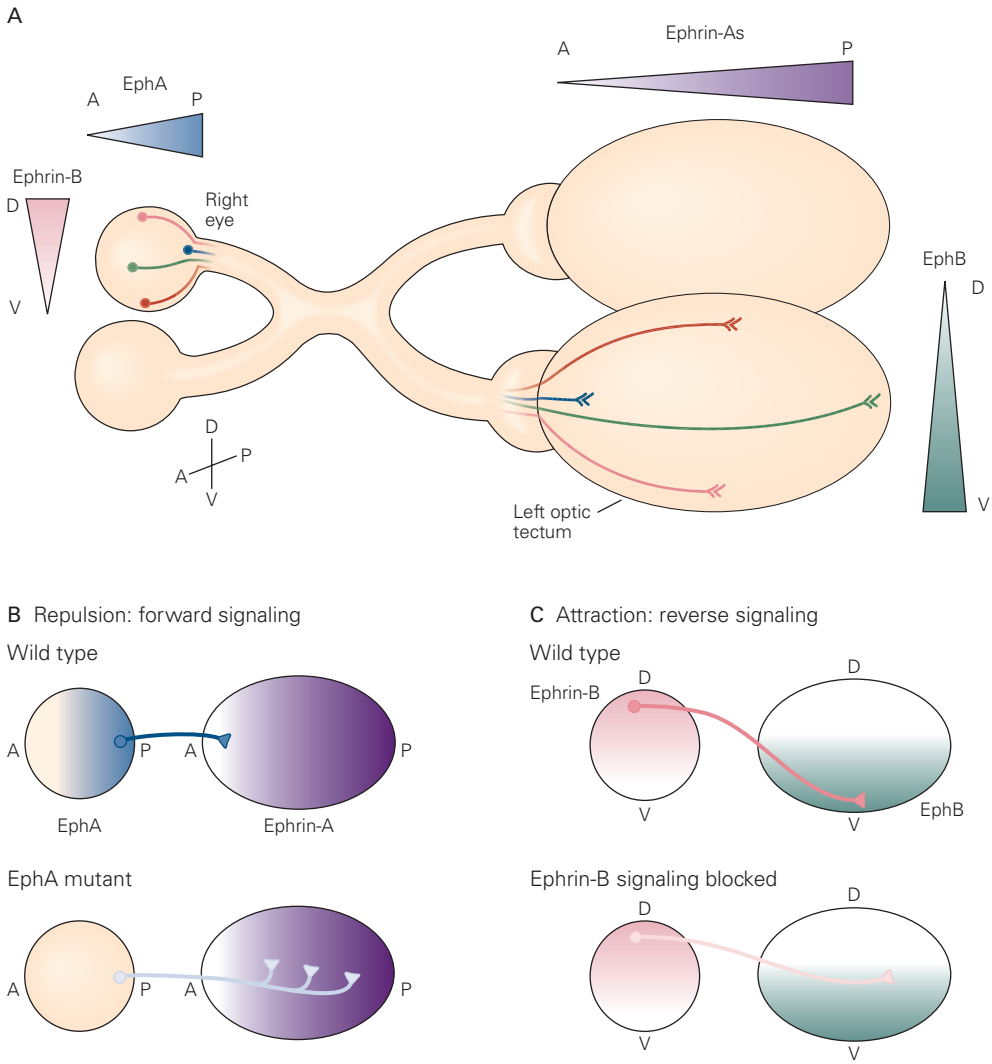

Figure 47–15 The formation of retinotopic maps in vivo depends on ephrin-Eph kinase signaling.

A. In the retina, EphA receptors are expressed in an anteroposterior (**A-P**) gradient, and ephrin-B is expressed in a dorsoventral (**D-V**) gradient. In the tectum, ephrin-A receptors are distributed in an anteroposterior gradient and EphB in a dorsoventral gradient.

B. Expression of EphA in retinal axons that derive from neurons in the posterior (temporal) retina directs axon growth to the anterior tectum through avoidance of ephrin-A proteins. In EphA mutant mice, posterior retinal axons are able to project to a more posterior domain within the tectum.

C. EphB signaling directs the projection of dorsal retinal axons to the ventral tectum. Blocking ephrin-B signaling with soluble EphB protein causes dorsal axons to project to an abnormally dorsal domain within the tectum.

caudal tectum, are not perturbed by encounters with excess ephrin-A.

Conversely, in mice with targeted mutations in the relevant *ephA* or *ephrin-A* genes, some posterior retinal axons terminate in inappropriately posterior tectal regions (Figure 47–15B). Anterior retinal axons, which naturally express low levels of EphA proteins, project normally in these mutants. In mice lacking both ephrin-A proteins, these deficits are more severe than with either single mutant. Thus, the interaction of ephrin-A with EphA receptors is crucial for the targeting of retinal axons in the tectum. These ephrin/EphA pairs possess the properties of the recognition molecules that Sperry predicted were necessary to direct

topographic mapping along the anteroposterior axis of the tectum.

Of course, the retinal map also has a dorsoventral axis. Ephrin/EphB pairs are involved in establishing order along this axis. Just as ephrin-A and EphA are graded along the anteroposterior axis, ephrin-B and EphB are graded along the dorsoventral axis, and manipulation of ephrin-B and EphB levels affects dorsoventral mapping (Figure 47–15C). Thus, at a simple level, the retinotopic map is arranged in rectangular coordinates with ephrin-A/EphA and ephrin-B/EphB labeling the anteroposterior and dorsoventral axes, respectively.

Although this simple view is satisfying, the reality is more complex. First, EphB kinases are expressed in the tectum as well as in the retina, and ephrins-A are expressed in the retina as well as in the tectum. Thus, so-called "*cis*" interactions (Eph and ephrin on the same cell) as well as "*trans*" interactions (Eph on growth cone, ephrin on target cell) may be involved. Second, both ligands and receptors are present at multiple points along the optic pathway and play multiple roles. As we have seen, ephrin-B/EphB interactions affect not only dorsoventral mapping but also the decision of an axon to cross to the contralateral side at the optic chiasm. Finally, in developing visual circuits, more precise spatial mapping of retinal inputs is regulated by patterns of neural activity, as discussed in the next two chapters. Nonetheless, we now have the outline of a molecular strategy for the initial formation of topographic projections from the eye to the brain.

Axons From Some Spinal Neurons Are Guided Across the Midline

One of the fundamental features of the central nervous system is the need to coordinate activity on both sides of the body. To accomplish this task, certain axons need to project to the opposite side.

We have seen one example of axonal crossing in the optic chiasm. Another example that has been studied in detail is the axonal crossing of *commissural neurons* that convey sensory information from the spinal cord to the brain at the ventral midline of the spinal cord across the floor plate. After crossing, axons turn abruptly and grow up toward the brain. This simple trajectory raises several questions. How do these axons reach the ventral midline? How do they cross the midline, and after crossing, how do they *ignore* cues that axons on the other side are using to get to the midline? In other words, why do they turn toward the brain instead of crossing back?

Netrins Direct Developing Commissural Axons Across the Midline

Many of the neurons that send axons across the ventral midline are generated in the dorsal half of the spinal cord. The first task for these axons is to reach the ventral midline. Ramón y Cajal considered the possibility that chemotactic factors emitted by targets could attract axons, but this idea lay dormant for nearly a century. We now know that such factors do exist, and one of them, the protein netrin-1, is expressed by cells of the floor plate as well as by progenitors along the ventral midline. When presented in culture, netrin attracts commissural axons; when mice are deprived of netrin-1 function, axons fail to reach the floor plate (Figure 47–16). It may act as both a secreted factor (chemotaxis) and a membrane guidance molecule (haptotaxis) to guide the axons of commissural neurons to the floor plate.

The netrin protein is structurally related to the protein product of *unc-6*, a gene shown to regulate axon guidance in the nematode *Clostridia elegans.* Two other *C. elegans* genes, *unc-5* and *unc-40*, encode receptors for the unc-6 protein. Vertebrate netrin receptors are related to the unc-5 and unc-40 receptors. The unc-5H proteins are homologs of unc-5, and DCC (deleted in colorectal cancer) are related to unc-40 (see Figure 47–11G). These receptors are members of the immunoglobulin superfamily, and their functions have been remarkably conserved throughout animal evolution (Figure 47–17). This conservation supports the use of simple and genetically accessible invertebrates to unravel developmental complexities. In no area has this approach been more fruitful than in the analysis of axon guidance. Dozens of genes that affect this process were first identified and cloned in *Drosophila* and *C. elegans* and then shown to play important and related roles in mammals.

Chemoattractant and Chemorepellent Factors Pattern the Midline

Other signaling systems work with netrins to guide commissural axons. One group consists of bone morphogenetic proteins, which are secreted by the roof plate. They act as repellents, directing commissural axons ventrally as they begin their journey. Additional factors from the floor plate, such as the hedgehog proteins initially involved in patterning the spinal cord (Chapter 45), may collaborate with netrins at a later stage, serving as axonal attractants.

Once commissural axons reach the midline, they find themselves exposed to the highest available levels

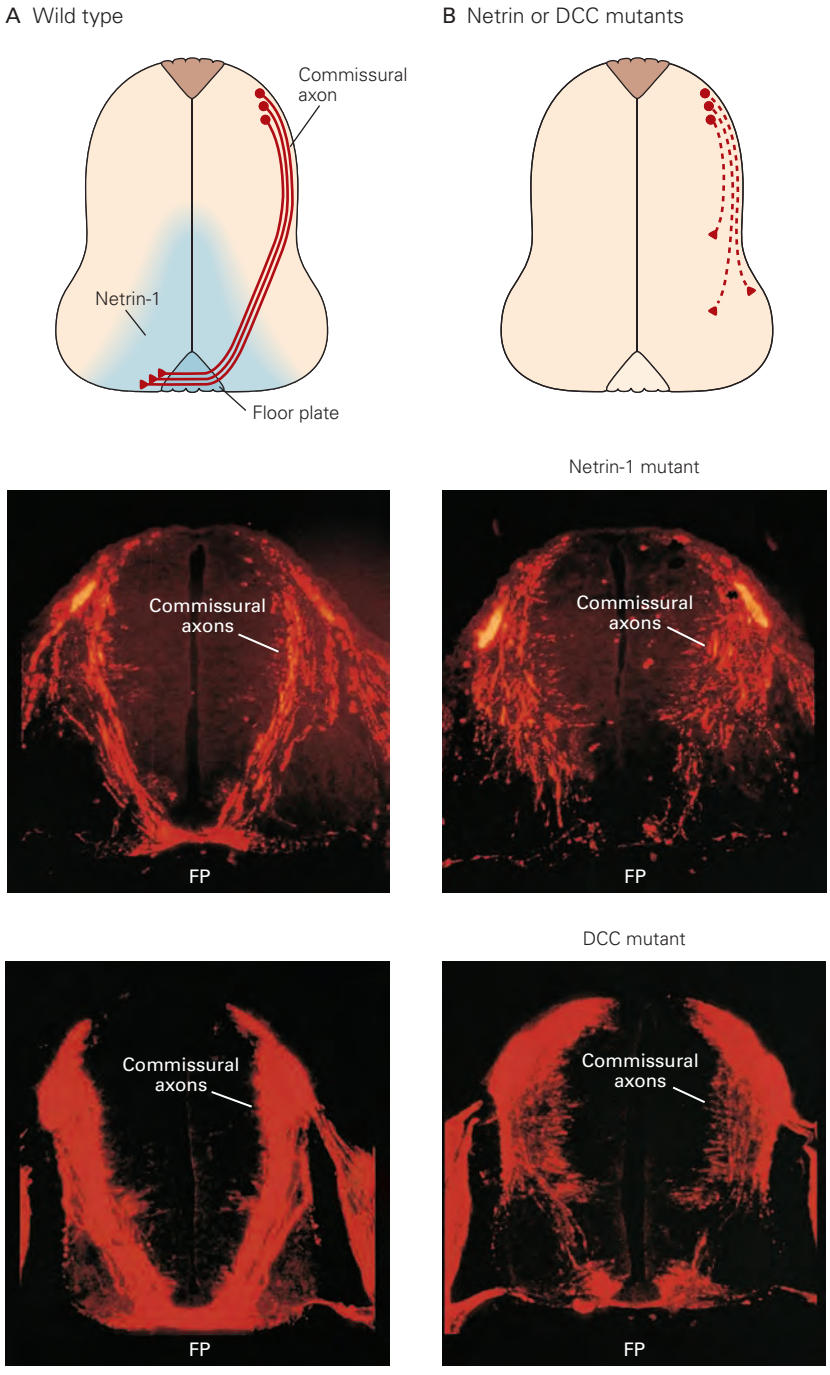

Figure 47–16 Netrin signaling attracts the axons of spinal commissural neurons to the floor plate. (Micrographs reproduced, with permission, from Marc Tessier-Lavigne.)

A. Netrin-1 is generated by floor plate cells and ventral neural progenitors. It attracts the axons of commissural neurons to the floor plate (**FP**) at the ventral midline of the spinal cord.

B. Most commissural axons fail to reach the floor plate when netrin or deleted in colorectal cancer (**DCC**) proteins are eliminated.

of netrin-1 and sonic hedgehog. Yet this netrin-rich environment does not keep the axons at the midline indefinitely. Instead they cross to the other side of the spinal cord, even while their contralateral counterparts are navigating up the netrin chemoattractant gradient.

This puzzling behavior is explained by the fact that growth cones change their responsiveness to attractive and repellent signals as a consequence of exposure to floor plate signals. This switch illustrates an important property of intermediate targets involved in axon guidance. Factors presented by intermediate targets not only guide the growth of axons but also change the sensitivity of the growth cone, preparing it for the next leg of its journey.

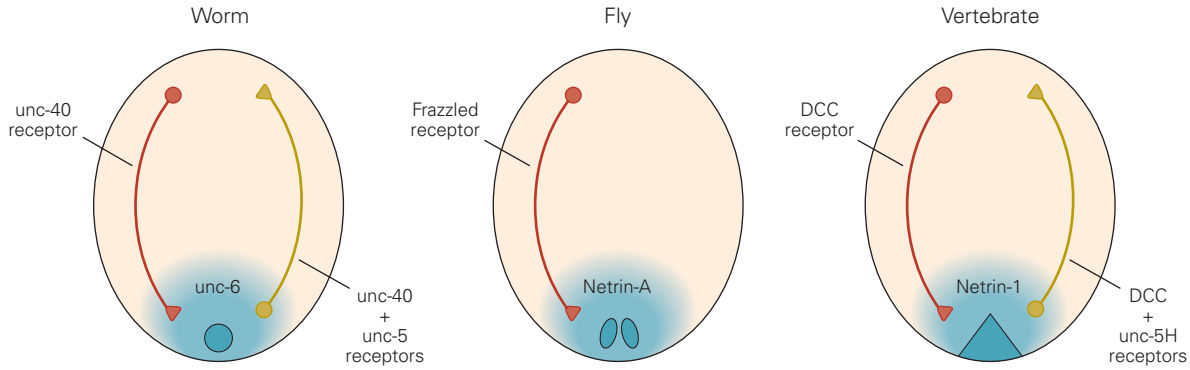

Figure 47–17 **The expression and activity of netrins have been conserved throughout evolution.** Netrins are secreted by ventral midline cells in worms, flies, and vertebrates and interact with receptors on cells or axons that migrate or extend along the dorsoventral axis. The netrin receptors unc-40 (worm), frazzled (fly), and deleted in colorectal cancer (**DCC**) (vertebrate) mediate netrin's attractant activity, whereas unc-5 class receptors mediate its repellent activity.

Once axons arrive at the floor plate, they become sensitive to Slit, a chemorepellent signal secreted by floor plate cells (Figure 47–18). Before commissural axons reach the floor plate, the Robo proteins that serve as Slit receptors are kept inactive by expression of a related protein, Rig-1. As axons reach the floor plate, levels of Rig-1 on their surface decline, unleashing Robo activity and causing axons to respond to the repellant actions of Slit. This repellent action propels growth cones *down* the Slit gradient into the contralateral side

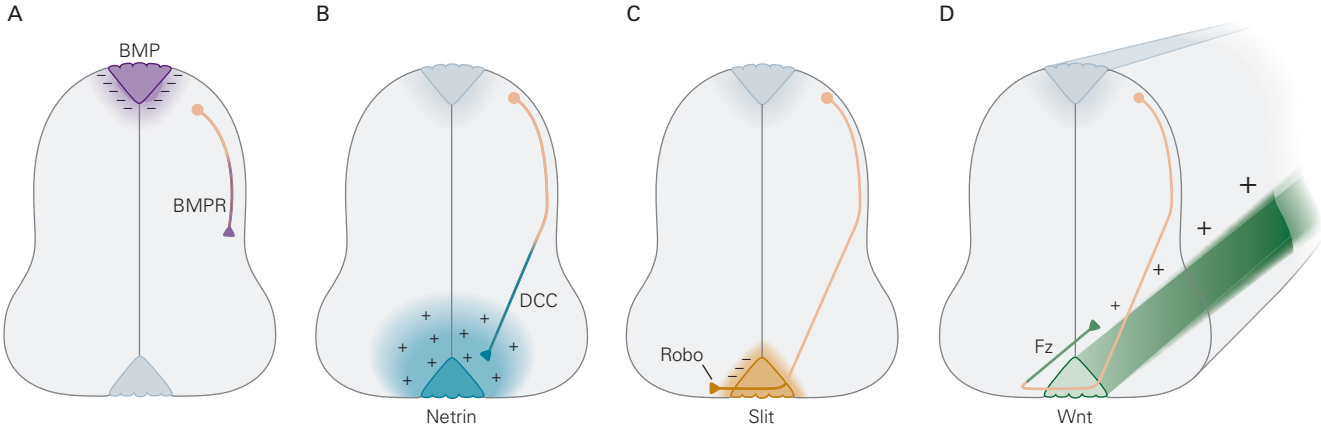

Figure 47–18 **Guidance cues expressed by roof plate and floor plate cells guide commissural axons in the developing spinal cord.**

A. Bone morphogenetic proteins (**BMP**) secreted by roof plate cells interact with BMP receptors (**BMPR**) on commissural axons to direct the axons away from the roof plate.

B. Netrin expressed by floor plate cells attracts deleted in colorectal cancer (**DCC**)-expressing commissural axons to the ventral midline of the spinal cord. Sonic hedgehog has also been implicated in the ventral guidance of commissural axons.

C. Slit proteins secreted by floor plate cells interact with Robo receptors on commissural axons to prevent these axons from recrossing the midline. Prior to crossing, but not after, commissural axons express robo3 (Rig-1) in addition to robo1 and robo2. The Rig-1 protein inactivates the Robo receptors, preventing the axons from responding to the repellent effects of Slits as they approach the ventral midline.

D. After commissural axons cross the midline, Wnt proteins secreted from floor plate cells and distributed in a rostrocaudal gradient interact with frizzled (**Fz**) proteins on the commissural axons, guiding the axons toward the brain.

of the spinal cord. In addition, activated Robo forms a complex with DCC, rendering these Netrin receptors incapable of responding to their ligand. The decreased sensitivity of growth cones to the attractive properties of the floor plate helps to account for the transient influence of floor plate signals on axons.

Finally, once axons have left the floor plate, they turn rostrally toward their eventual synaptic targets in the brain. A rostrocaudal gradient of Wnt proteins expressed by floor plate cells appears to direct axon growth rostrally at the ventral midline (Figure 47–18D). Thus, different cues guide commissural axons during distinct phases of their overall trajectory. This same process is presumably played out for hundreds and even thousands of classes of neurons to establish the mature pattern of brain wiring.

Highlights

1. As neurons extend processes, one generally becomes an axon and the others become dendrites. This process is called polarization. The two types of processes differ in structure and molecular architecture as well as function.
2. Cell types differ markedly in the shape, size, and branching patterns of their dendrites. Type-specific dendritic features arise both from intrinsic differences in transcriptional programs among types and from extrinsic influences on the developing dendrites.
3. Interactions among dendrites are critical for dendritic patterning. Repellent interactions among the dendrites of a single cell, a process called self-avoidance, leads to even coverage of an area, with minimal gaps or clumps. Repellent actions between dendrites of neighboring cells, a process called tiling, minimizes overlap of dendritic fields. In some cases, dendrites avoid other dendrites from their own neuron but interact with dendrites of nominally identical neighboring cells. This process is called self-/non–self-discrimination.
4. Growth cones at the tips of axons serve as both sensory and motor elements to guide axons to their destinations. Cytoskeletal elements of the growth cone, including actin and myosin, propel the growth.
5. Receptors on the growth cone recognize and bind ligands in the environment through which the axon is extending, guiding the growth. These interactions lead to generation of their second messengers that mediate growth, turning and stopping of the growth cone, and branching of the axon.
6. Some growth cones contain protein synthetic machinery including messenger RNAs. In these cases, receptors can promote local synthesis of specific proteins that mediate growth or turning.
7. Ligand–receptor pairs include several key families of molecules including cadherins, Slits and their Robo receptors, semaphorins and their plexin receptors, and ephrins and their Eph kinase receptors.
8. The growth of an axon to a distant target is broken into discrete shorter steps. At each step, molecules on the surface of or secreted by neighboring structures guide the axon. They can also lead to alterations in the growth cone's complement of receptors, allowing it to respond to different sets of cues at the subsequent stage.
9. Roger Sperry proposed a chemospecificity hypothesis to explain the specific growth of axons from different parts of the retina to different parts of the optic tectum (superior colliculus), forming an orderly retinotopic map. The ephrins and their receptors, the Eph kinases, are key molecules that guide map formation. They are graded in expression along the retina and tectum and act in large part by repelling axons from incorrect positions rather than attracting them to correct positions.
10. Both attractive and repellent molecules guide axons across midline structures, a process called decussation. Evolutionarily conserved signals include Slits, netrins, and Wnts. Mutations in genes that encode these ligands and receptors can result in developmental neurological disorders.

Formation and Elimination of Synapses

So far, we have examined three stages in the development of the mammalian nervous system: the formation and patterning of the neural tube, the generation and differentiation of neurons and glia, and the growth and guidance of axons. One additional step must occur before the brain becomes functional: the formation of synapses. Only when synapses are formed and functional can the brain go about the business of processing information.

Three key processes drive synapse formation. First, axons make choices among many potential postsynaptic partners. By forming synaptic connections only on particular target cells, neurons assemble functional circuits that can process information. In many cases, synapses are even formed at specific sites on the postsynaptic cell; some types of axons form synapses on dendrites, others on cell bodies, and yet others on axons or nerve terminals. Although cellular and subcellular specificity are evident throughout the brain, the general features of synapse formation can be illustrated with a few well-studied examples.

Second, after cell–cell contacts have formed, the portion of the axon that contacts the target cell differentiates into a presynaptic nerve terminal, and the domain of the target cell contacted by the axon differentiates into a specialized postsynaptic apparatus. Precise coordination of pre- and postsynaptic differentiation depends on interactions between the axon and its target cell. Much of what we know about these interactions comes from studies of the neuromuscular junction, the synapse between motor neurons and skeletal muscle fibers. The simplicity of this synapse made it a favorable system to probe the structural and electrophysiological principles of chemical synapses (Chapter 12), and this simplicity has also helped in the analysis of developing synapses. We will use the neuromuscular synapse to illustrate key features of

synaptic development and then apply insights from this peripheral synapse to examine synapses that form in the brain.

Finally, once formed, synapses mature, often undergoing major rearrangements. One striking aspect of the rearrangement is that as some synapses grow and strengthen, many others are eliminated. Like neuronal cell death (Chapter 46), synapse elimination at first glance is a puzzling and seemingly wasteful step in neural development. It is increasingly clear, however, that it plays a key role in refining initial patterns of connectivity. We will discuss the main features of synaptic rearrangement at the neuromuscular junction, where it has been studied intensively, as well as at synapses between neurons, where it also is prominent.

Synapse formation stands at an interesting crossroads in the sequence of events that assemble the nervous system. The initial steps in this process appear to be largely "hardwired" by molecular programs. However, as soon as synapses form, the nervous system begins to function, and the activity of neural circuits plays a critical role in subsequent development. Indeed, the information-processing capacity of the nervous system is refined through its use, most dramatically in early postnatal life but also into adulthood. In this sense, the nervous system continues to develop throughout life. We will consider this interplay of molecular programs and neural activity as we describe synapse formation and rearrangement. This discussion will be a useful prelude to Chapter 49, in which we discuss how genes and the environment—nature and nurture—interact to customize nervous systems early in postnatal life.

Neurons Recognize Specific Synaptic Targets

Once axons reach their designated target areas, they must choose appropriate synaptic partners from the many potential targets within easy reach. Although synapse formation is a highly selective process at both cellular and subcellular levels, few of the molecules that confer synaptic specificity have been identified.

The specificity of synaptic connections is particularly evident when intertwined axons select subsets of target cells. In these cases, axon guidance and selective synapse formation can be distinguished. The first report of such specificity came more than 100 years ago when J. N. Langley, studying the autonomic nervous system, proposed the first version of a chemospecificity hypothesis (see Chapter 46). Langley observed that autonomic preganglionic neurons are generated at distinct rostrocaudal levels of the spinal cord. Their axons enter sympathetic ganglia together but form synapses with different postsynaptic neurons that innervate distinct targets. Using behavioral assays as a guide, Langley inferred that the axons of preganglionic neurons located in the rostral spinal cord form synapses on ganglion neurons that project their axons to relatively rostral targets such as the eye, whereas neurons that derive from more caudal regions of the spinal cord synapse on ganglion neurons that project to caudal targets such as the ear (Figure 48–1A). He then showed that similar patterns were reestablished after the preganglionic axons were severed and allowed to regenerate, leading him to postulate that some sort of molecular recognition was responsible (Figure 48–1B).

Electrophysiological studies later confirmed Langley's intuition about the specificity of synaptic connections in these ganglia. Moreover, this selectivity is apparent from early stages of innervation, even though specific types of postsynaptic neurons are interspersed within the ganglion. The reestablishment of selectivity in adults after nerve damage shows that specificity does not emerge through peculiarities of embryonic timing or neuronal positioning.

Recognition Molecules Promote Selective Synapse Formation in the Visual System

To illustrate the idea of target specificity in more detail, we will first consider retinal ganglion cells. These neurons differ in their response properties—some ganglion neurons respond to increases in light level (ON cells), others to decreases (OFF cells), others to moving objects, and still others to light of a particular color. The axons of all ganglion cells run through the optic nerve, forming parallel axonal pathways from the retina to the brain.

The response properties of each class of ganglion cell depend on the synaptic inputs they receive from amacrine and bipolar interneurons, which in turn receive synapses from light-sensitive photoreceptors. All of the synapses from bipolar and amacrine cells onto ganglion cell dendrites occur in a narrow zone of the retina called the inner plexiform layer. Axons and dendrites therefore have the daunting task of recognizing their correct partners within a large crowd of inappropriate bystanders.

One important contributor to synaptic matchmaking in the inner plexiform layer is its division into sublayers. The processes of each amacrine and bipolar cell type, as well as the dendrites of each functionally distinct ganglion cell type, branch and synapse in just one or a few of approximately 10 sublayers. For example, the dendrites of ON and OFF cells are restricted to inner and outer portions of the plexiform layer,

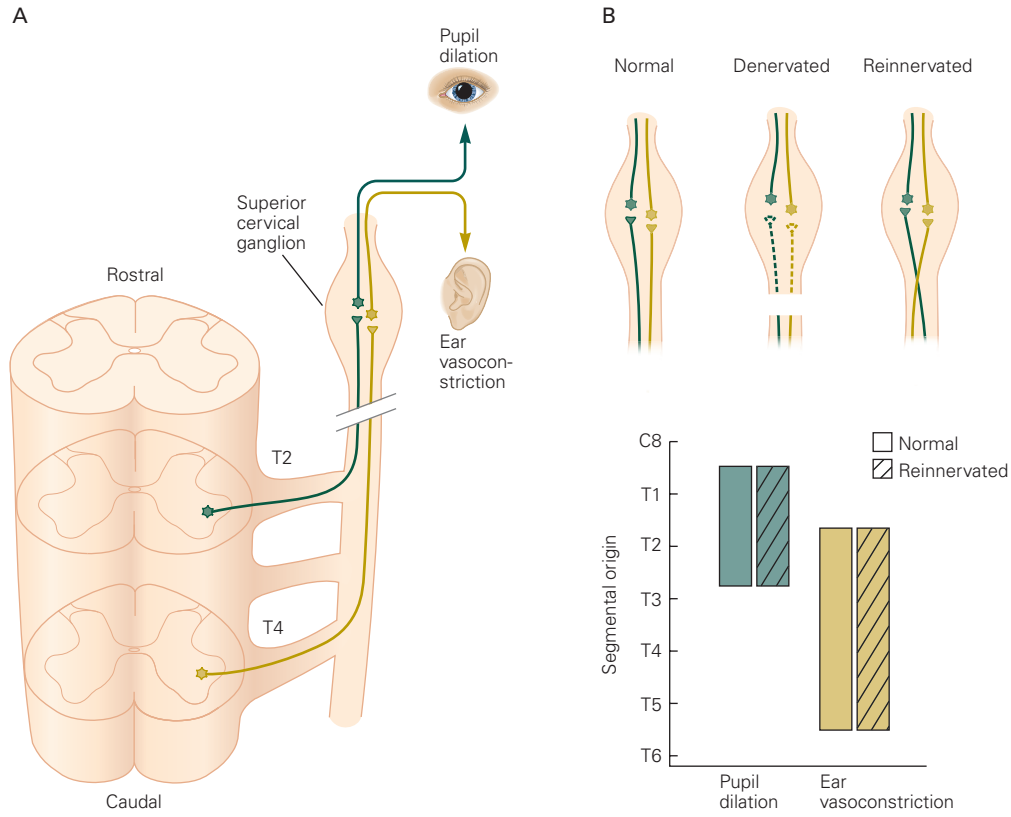

Figure 48–1 Preganglionic motor neurons regenerate selective connections with their sympathetic neuronal targets.

A. Preganglionic motor neurons arise from different levels of the thoracic spinal cord. Axons that arise from rostrally located thoracic neurons innervate superior cervical ganglion neurons that project to rostral targets, including the intrinsic eye muscles. Axons that arise from neurons at caudal levels of the thoracic spinal cord innervate ganglion neurons that project to more caudal targets, such as the blood vessels of the ear. These two classes of ganglion neurons are intermingled in the ganglion, which suggested to J. N. Langley that preganglionic axons from different thoracic levels selectively form synapses with ganglion neurons that terminate in specific peripheral targets.

B. After nerve damage in adults, similar segment-specific patterns of connectivity form during reinnervation, supporting the notion that synapse formation is selective. (Adapted from Njå and Purves 1977.)

respectively, and therefore receive synapses from different interneurons; particular types of ON and OFF cells have narrower restrictions within these zones (Figure 48–2). This layer-specific arborization of pre- and postsynaptic processes restricts the choice of synaptic partners to which they have ready access. Similar lamina-specific connections are found in many other regions of the brain and spinal cord. For example, in the cerebral cortex, distinct populations of axons confine their dendritic arbors and synapses to just one or two of the six main layers.

Laminar specificity does not, however, completely account for the wiring of the retina. As the number of retinal cell types—currently estimated at around 130 in mice—greatly exceeds the number of plexiform sublayers, the processes of many cell types arborize within each sublayer. Anatomical and physiological studies have shown that connectivity is specific even within individual sublayers. Moreover, patterns of connectivity appear to be largely, although not entirely, "hardwired," occurring before visual experience has a chance to affect circuitry. Thus, there must be molecules that restrict axons and dendrites to specific sublayers, as well as molecules that distinguish synaptic partners within a sublayer.

One clue to the basis of both laminar and intralaminar synaptic specificity in the retina comes from the finding that specific types of interneurons and ganglion neurons express different classes of recognition molecules of the immunoglobulin and cadherin families (Chapter 47). Thus, the processes of cells that express a particular recognition molecule are confined

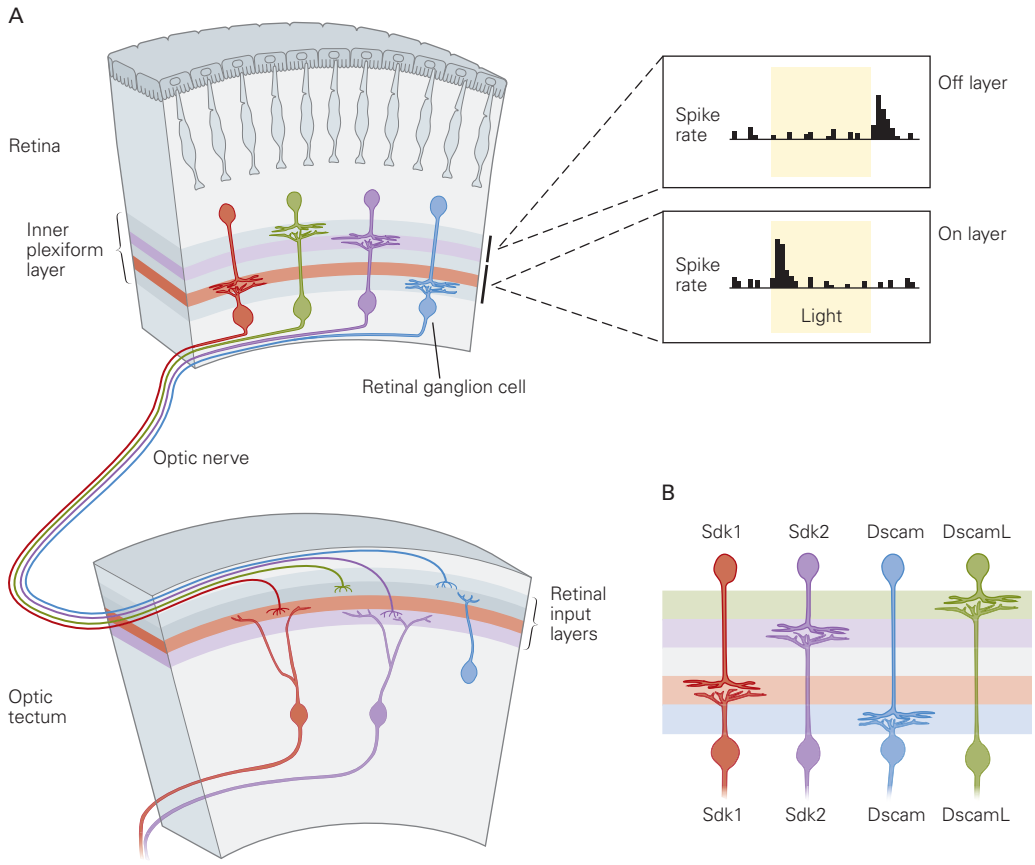

Figure 48–2 Retinal ganglion neurons form layer-specific synapses. (Reproduced, with permission, from Sanes and Yamagata 2009.)

A. The dendrites of retinal ganglion neurons receive input from the processes of retinal interneurons (amacrine and bipolar cells) in the inner plexiform layer, which is subdivided into at least 10 sublaminae. Specific subsets of interneurons and ganglion cells often arborize and synapse in just one layer. These lamina-specific connections determine which aspects of visual stimuli (their onset or offset) activate each type of retinal ganglion cell. The responses of OFF and ON retinal ganglion cells are shown on the right.

B. Immunoglobulin superfamily adhesion molecules (Sdk1, Sdk2, Dscam, and DscamL) are expressed by different subsets of amacrine and retinal ganglion neurons in the developing chick embryo. Amacrine neurons that express one of these four proteins form synapses with retinal ganglion cells that express the same protein. Manipulating Sdk or Dscam expression alters these patterns of lamina-specific arborization.

to one or a few plexiform sublayers (Figure 48–2B). Many of these proteins promote homophilic interactions; that is, they bind to the same protein on other cell surfaces. The roles of several recognition molecules have now been assessed in chick and mouse retina, either by removing them during development or by implanting them into neurons that do not normally express them. Results of these so-called "loss-of-function" and "gain-of-function" experiments hint at the existence of a complex code of recognition molecules that promotes specific connectivity within a target region. In mice, for example, two cadherins direct bipolar interneurons to appropriate sublayers, while Sidekick 2, a member of the immunoglobulin superfamily, is required for interneurons to choose among ganglion cells with dendrites in one particular sublayer.

Sensory Receptors Promote Targeting of Olfactory Neurons

A different type of specificity is evident in the olfactory system. Each olfactory sensory neuron in the nasal epithelium expresses just one of approximately 1,000 types of odorant receptors. Neurons expressing one receptor are randomly distributed across a large sector of the epithelium, yet all of their axons converge on the dendrites of just a few target neurons in the olfactory

bulb, forming synapse-rich glomeruli (Figure 48–3A). When an individual olfactory receptor is deleted, the axons that normally express the receptor reach the olfactory bulb but fail to converge into specific glomeruli or to terminate on the appropriate postsynaptic cells (Figure 48–3B). Conversely, when neurons are forced to express a different odorant receptor, their axons form glomeruli at a different position within the olfactory bulb (Figure 48–3C).

Together, these experiments suggest that olfactory receptors not only determine a neuron's responsiveness to specific odorants but also help the axon to form appropriate synapses on target neurons. Initially, it was suspected that specific olfactory receptors served not only as odor detectors but also as recognition molecules. More recent studies provide evidence for a different mechanism: that second messengers generated from activation of the olfactory receptors influence the expression of recognition molecules that match olfactory axons with appropriate targets in the olfactory bulb.

The matching occurs in two steps. First, intrinsic differences in the abilities of olfactory receptors to stimulate formation of the second messenger cyclic adenosine monophosphate lead to differential expression of guidance molecules in embryos, generating a coarse matching of olfactory neurons and olfactory bulb targets along the anterior-posterior axis. Second, selective expression of recognition molecules by four groups of olfactory sensory neurons targets them to corresponding domains along the dorsoventral axis of the olfactory bulb.

Thus, an early phase of molecular recognition generates a coarse map of nose-to-brain connectivity by activity-independent mechanisms (Figure 48–4A). Then, postnatally, odorant receptors are activated by odorants, and because of developmental changes in

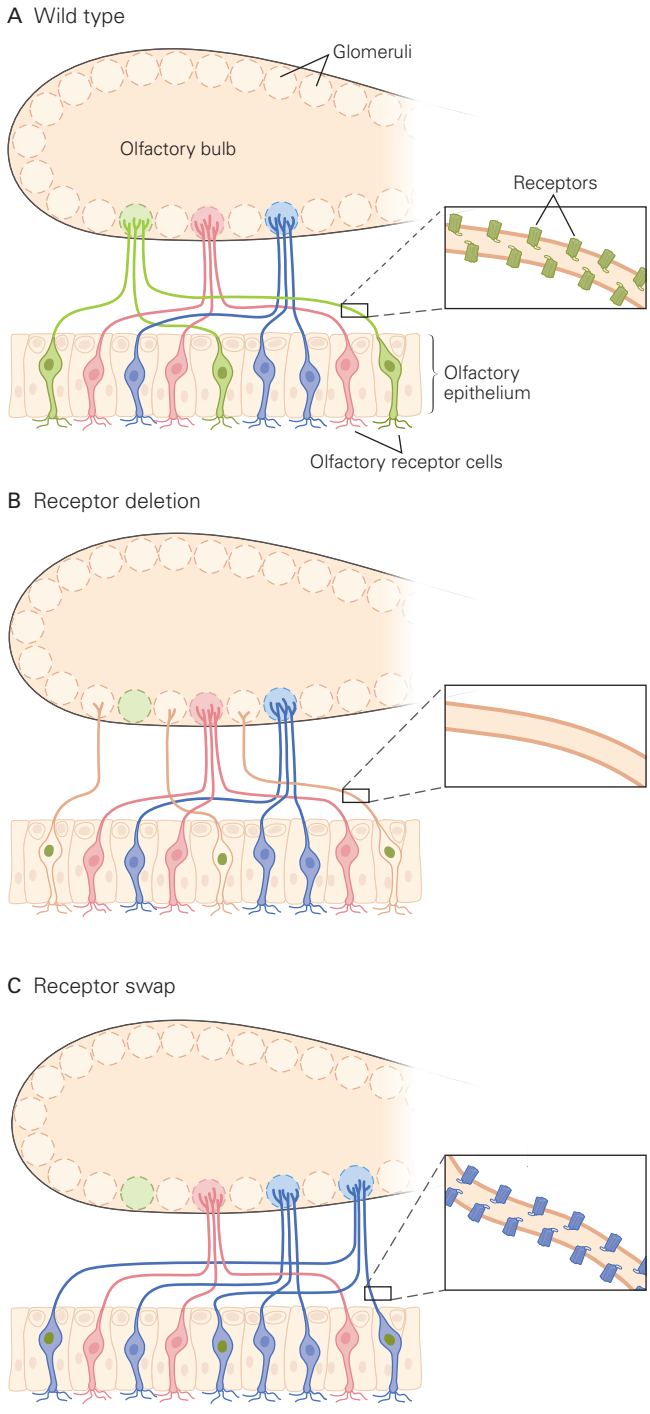

Figure 48–3 (Right) Odorant receptors influence the targeting of sensory axons to discrete glomeruli in the olfactory bulb. (Adapted, with permission, from Sanes and Yamagata 2009.)

A. Each olfactory receptor neuron expresses one of approximately 1,000 possible odorant receptors. Neurons expressing the same receptor are distributed sparsely throughout the olfactory epithelium of the nose. The axons of these neurons form synapses with target neurons in a single glomerulus in the olfactory bulb.

B. In mouse mutants in which an odorant receptor gene has been deleted, the sensory neurons that would have expressed the gene send their axons to other glomeruli, in part because these neurons now express other receptors.

C. When one odorant receptor gene replaces another in a set of sensory neurons, their axons project improperly.

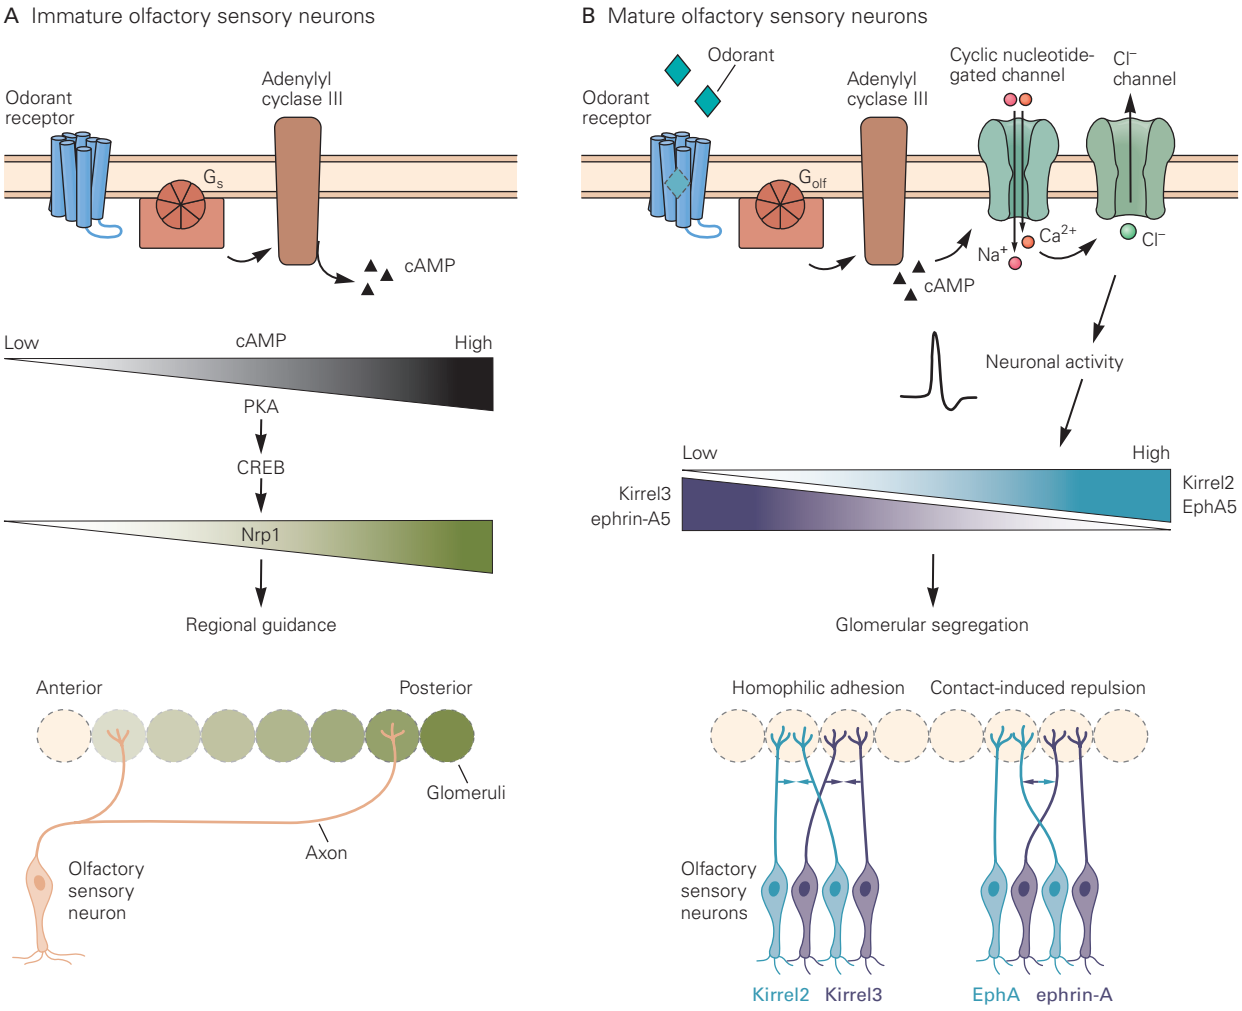

Figure 48–4 Odorant receptors promote specific connections in the olfactory bulb by controlling expression of guidance and recognition molecules. Activation of olfactory receptors in olfactory sensory neurons leads to activation of adenylyl cyclase and production of the second messenger cyclic adenosine monophosphate (**cAMP**).

A. Prenatally, prior to olfaction, the receptors are spontaneously active. Different receptor types exhibit different levels of spontaneous activity and therefore generate different levels of cAMP, which in turn induce distinct, graded levels of axon guidance molecules such as neuropilins and semaphorins. These guidance molecules mediate interactions among axons that guide them to appropriate regions of the olfactory bulb. (Abbreviations: **CREB**, cAMP response element-binding protein; **Nrp1**, neuropilin1; **PKA**, protein kinase A.)

B. Postnatally, olfactory receptors are activated by odorant molecules. This olfactory activity also generates distinct levels of cAMP in each type of odorant receptor neuron, but now the second messenger acts through ion channels to induce new sets of guidance molecules such as kirrels and ephrins. These molecules mediate interactions that segregate axonal terminals into glomeruli. Thus, successive phases of receptor activity, the first spontaneous and the second evoked by odorants, act together to map olfactory sensory axons of different types onto different glomeruli.

intracellular signaling, this activation leads to induction of a second set of recognition molecules. These molecules lead to convergence of axons onto glomeruli, thus refining the projection by an activity-dependent mechanism (Figure 48–4B). Segregation of axons first to particular regions and then to particular glomeruli occurs via both adhesive and repulsive interactions.

Different Synaptic Inputs Are Directed to Discrete Domains of the Postsynaptic Cell

Nerve terminals not only discriminate among candidate targets but also terminate on a specific portion of the target neuron. In the cerebral cortex and hippocampus, for example, axons arriving in layered structures

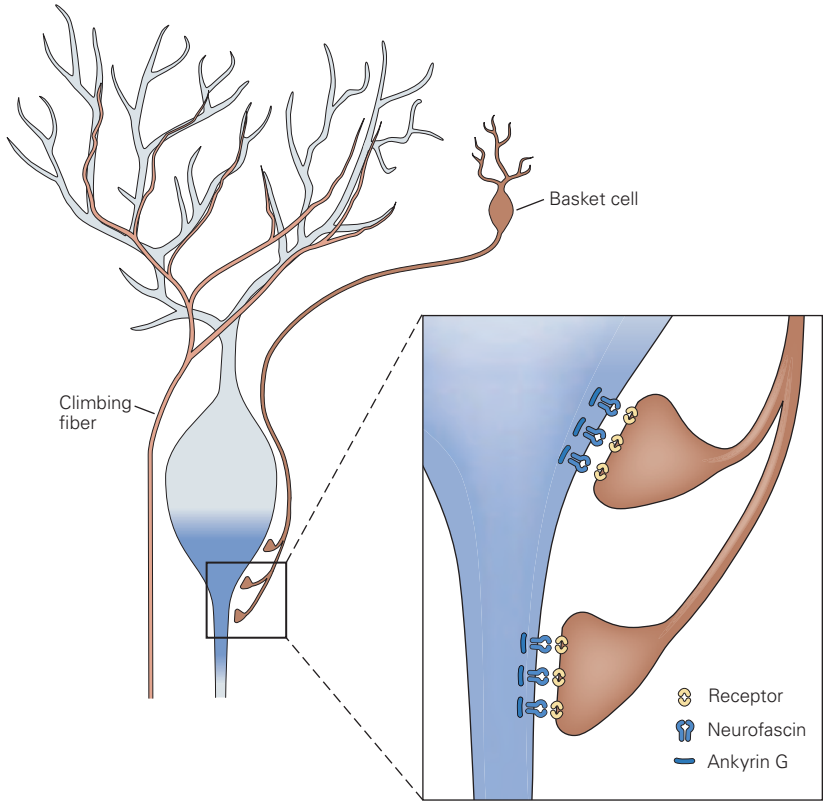

Figure 48–5 The axons of inhibitory interneurons in the cerebellum terminate on a distinct region of the cerebellar Purkinje cell. Many neurons form synapses on cerebellar Purkinje neurons, each selecting a distinct domain on the Purkinje cell. The axons of inhibitory basket cells form most of their synapses on the axon hillock and initial segment. Basket cells select these domains by recognizing neurofascin, a cell surface immunoglobulin superfamily adhesion molecule that is anchored to the initial segment of the axon by ankyrin G. When the localization of neurofascin is perturbed, basket cell axons fail to restrict synapse formation to the initial segment. (Adapted from Huang 2006.)

often confine their terminals to one layer, even if the dendritic tree of the postsynaptic cell traverses numerous layers. In the cerebellum, the axons of different types of neurons terminate on distinct domains of the Purkinje neurons. Granule cell axons contact distal dendritic spines, climbing fiber axons contact proximal dendritic shafts, and basket cell axons contact the axon hillock and initial segment (Figure 48–5).

Such specificity presumably relies on molecular cues on the postsynaptic cell surface. For Purkinje neurons of the cerebellum, one such cue is neurofascin, an adhesion molecule of the immunoglobulin superfamily. Neurofascin is present at high levels on the axonal initial segment, thus directing basket cells to form axons selectively on this axonal domain. Adhesion molecules can therefore also serve as recognition molecules for particular domains of a neuron. Since individual neurons can form synapses with several classes of pre- and postsynaptic cells, it follows that each neuronal subtype must express a variety of synaptic recognition molecules.

Neural Activity Sharpens Synaptic Specificity

So far, we have emphasized the role of recognition molecules in the initial formation of synapses. Once synapses form, however, neural activity within the circuit plays a critical role in refining synaptic patterns. For example, as described above, guidance of olfactory neurons to the olfactory bulb includes an initial activity-independent crude mapping followed by an activity-dependent phase in which the projection is refined.

A similar biphasic pattern has been studied in detail in the visual system. Retinal ganglion cells project to the optic tectum (superior colliculus), where interactions between ephrins and Eph kinases result in formation of a crude retinotopic map of retinal axons on the tectal surface (Chapter 47). Activity-dependent processes then sculpt the axonal arbors of retinal ganglion cells. The axons initially form broad diffuse arbors, which gradually become denser but more focused, sharpening the tectal map (Figure 48–6). This refinement is inhibited when the activity of synapses is blocked. The molecular mechanisms of this activity-dependent refinement are largely unknown. As in the olfactory system, an attractive idea is that the level and pattern of neuronal activity regulate the expression of recognition molecules.

These examples from the olfactory and visual systems illustrate a widespread phenomenon: Molecular cues initially control synapse specificity, but once the circuit begins to function, specificity is sharpened

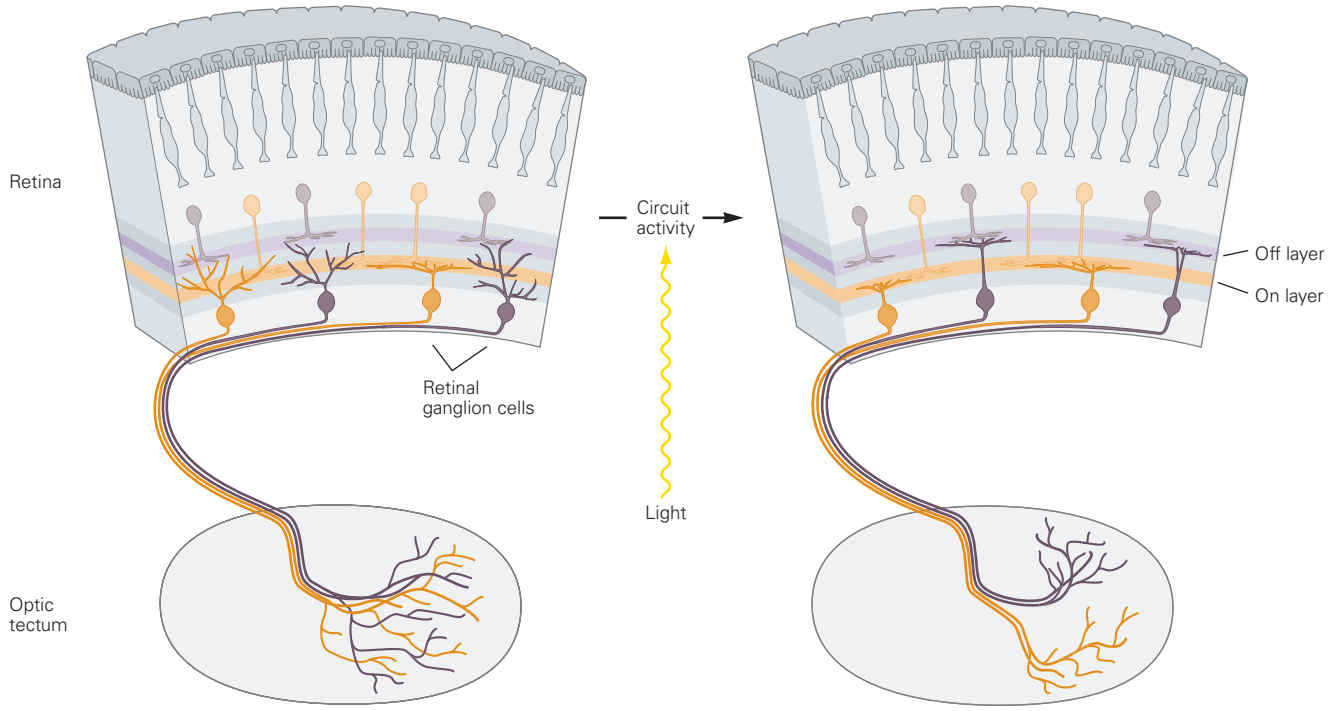

Figure 48–6 Electrical activity refines the specificity of synaptic connections of retinal ganglion cells. Some retinal ganglion cells initially form dendritic arbors that are limited to specific sublaminae in the inner plexiform layer of the retina, whereas others initially form diffuse arbors that are later pruned to form large specific patterns. Similarly, the axonal arbors of retinal ganglion cells initially innervate a large region of their target fields in the superior colliculus. This expansive axonal arbor is then refined so as to concentrate many branches in a small region. Abolishing electrical activity in retinal ganglion cells decreases the remodeling of dendritic and axonal arbors.

through neural activity. In the visual system, sharpening involves loss of synapses. We will return to this process of synapse elimination at the end of this chapter and consider its consequences for behavior in the next chapter.

In a few cases, neural activity promotes specificity in a different way, by turning an inappropriate target into an appropriate one. This mechanism has been most clearly demonstrated in skeletal muscle, where mammalian muscle fibers can be divided into several categories according to their contractile characteristics (Chapter 31). Muscle fibers of particular types express genes for distinctive isoforms of the main contractile proteins, such as myosins and troponins.

Few muscles are composed exclusively of a single type of fiber; most have fibers of all types. Yet the branches of an individual motor axon innervate muscle fibers of a single type, even in "mixed" muscles in which fibers of different types are intermingled (Figure 48–7A). This pattern implies a remarkable degree of synaptic specificity. However, matching does not always come about through recognition in the motor axon of the appropriate type of muscle fiber. The motor axon can also convert the target muscle fiber to an appropriate type. When a muscle is denervated at birth, before the properties of its fibers are fixed, a nerve that normally innervates a slow muscle can be redirected to innervate a muscle destined to become fast, and vice versa. Under these conditions, the contractile properties of the muscle are partially transformed in a direction imposed by the firing properties of the motor nerve (Figure 48–7B,C).

Different patterns of neural activity in fast and slow motor neurons are responsible for the switch in muscle properties. Most strikingly, direct electrical stimulation of a muscle with patterns normally evoked by slow or fast nerves leads to changes that are nearly as dramatic as those produced by cross-innervation (Figure 48–7D). Although activity-based conversion of the type observed at the neuromuscular junction is unlikely to be a major contributor to synaptic specificity in the central nervous system, it is likely that central axons modify the properties of their synaptic targets, contributing to the diversification of neuronal subtypes and refining connectivity imposed by recognition molecules.

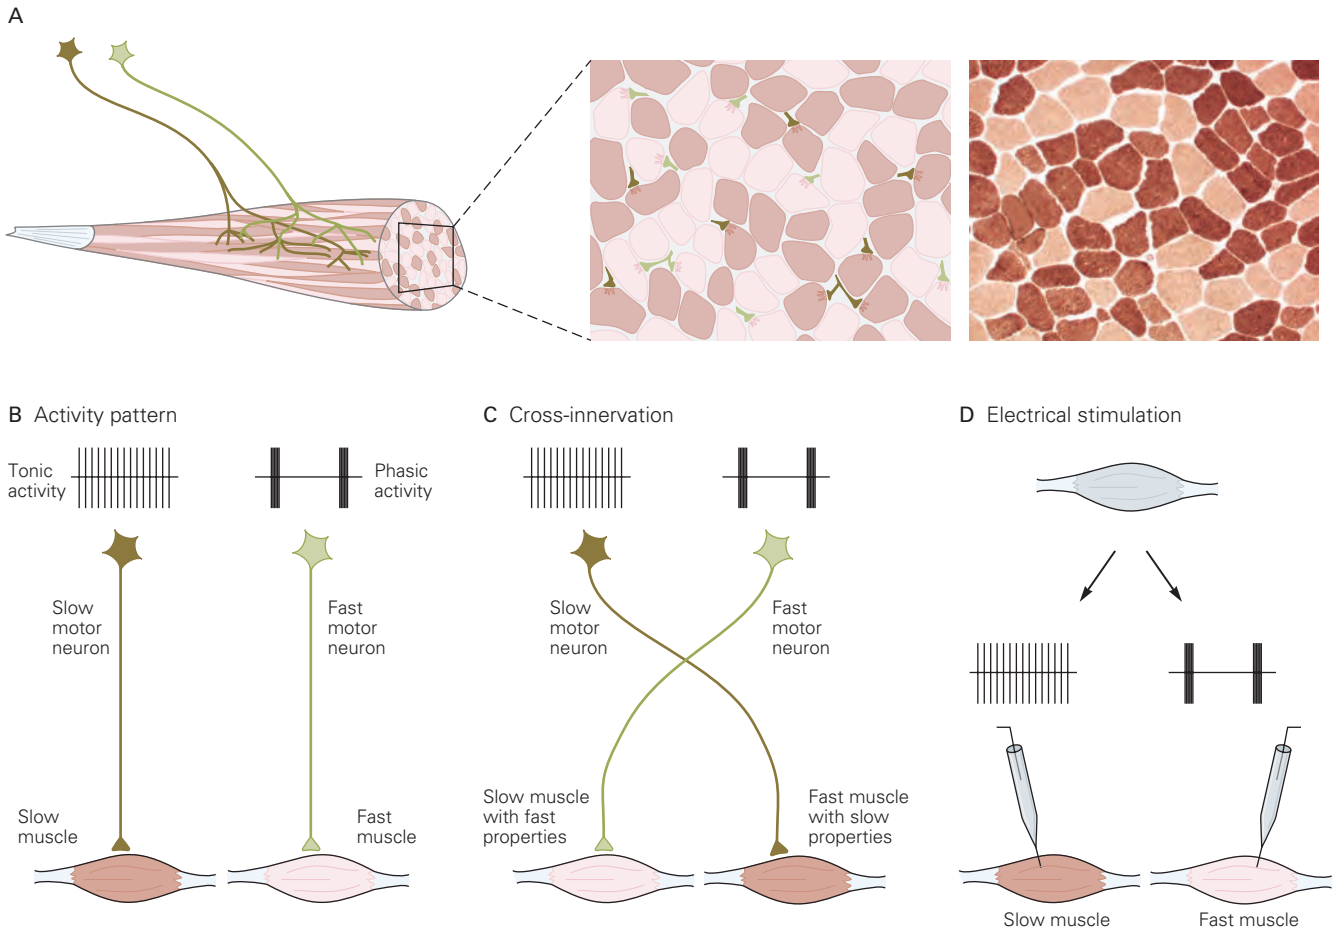

Figure 48–7 The pattern of motor neuron activity can change the biochemical and functional properties of skeletal muscle cells.

A. Muscle fibers have characteristic metabolic, molecular, and electrical properties that identify them as "slow" (tonic) or "fast" (phasic) types. The micrograph on the right shows a section of muscle tissue with histochemical staining for myosin ATPase. The middle sketch shows a section through the muscle, in which motor neurons (**green** and **brown**) form synapses on a single type of muscle fiber. (Photo on right reproduced, with permission, from Arthur P. Hays.)

B. Motor neurons that connect with fast and slow muscle fibers (fast and slow motor neurons) exhibit distinct patterns of electrical activity: steady low-frequency (tonic) firing for slow fibers and intermittent high-frequency bursts (phasic) for fast fibers.

C. Cross-innervation experiments showed that some property of the motor neuron helps to determine whether muscle fibers are fast or slow. Cross-innervation was achieved by surgically rerouting fast axons to slow muscle and vice versa. Although the properties of the motor neurons are little changed, the properties of the muscle change profoundly. For example, fast motor neurons induce fast properties in the slow muscle. (Adapted, with permission, from Salmons and Sreter 1976.)

D. The effects of innervation by fast and slow nerves on muscle are mediated in part by their distinct patterns of activity. Stimulation of a fast muscle in a slow tonic pattern converts the muscle into a slow type. Conversely, fast phasic stimulation of a slow muscle can convert it to a faster type.

Principles of Synaptic Differentiation Are Revealed at the Neuromuscular Junction

The neuromuscular junction comprises three types of cells: a motor neuron, a muscle fiber, and Schwann cells. All three types are highly differentiated in the region of the synapse.

The process of synapse formation is initiated when a motor axon, guided by the multiple factors described in Chapter 47, reaches a developing skeletal muscle and approaches an immature muscle fiber. Contact is made, and the process of synaptic differentiation gets underway. As the growth cone begins its transformation into a nerve terminal, the portion of the muscle

surface opposite the nerve terminal begins to acquire its own specializations. As development proceeds, synaptic components are added and structural signs of synaptic differentiation become apparent in the pre- and postsynaptic cells and in the synaptic cleft. Eventually, the neuromuscular junction acquires its mature and complex form (Figure 48–8).

Three general features of neuromuscular junction development have provided clues about the molecular mechanisms that underlie synapse formation. First, nerve and muscle organize each other's differentiation. In principle, the precise apposition of pre- and postsynaptic specializations might be explained by independent programming of nerve and muscle properties. However, in muscle cells cultured alone, acetylcholine (ACh) receptors are generally distributed uniformly on the surface, although some are clustered as in mature postsynaptic membranes. Yet, when motor neurons are added to the cultures, they extend neurites that contact the muscle cells more or less randomly, instead of seeking out the ACh receptor clusters. New receptor clusters appear precisely at the points of contact with the presynaptic neurites, while preexisting uninnervated clusters eventually disperse (Figure 48–9). Thus, factors on or released by motor axons exert a profound influence on the synaptic organization of the muscle cell.

Likewise, muscles signal retrogradely to motor nerve terminals. When motor neurons in culture extend neurites, they assemble and transport synaptic vesicles, some of which form aggregates similar to those found in nerve terminals. When the neurites contact muscle cells, new vesicle clusters form opposite the muscle membrane, and most of the preexisting clusters disperse.

These studies also revealed a second feature of neuromuscular development: that motor neurons and muscle cells can synthesize and arrange most synaptic components without each other's help. Uninnervated myotubes can synthesize functional ACh receptors and gather them into high-density aggregates. Likewise, motor axons can form synaptic vesicles and cluster them into varicosities in the absence of muscle. In fact, vesicles in growth cones can synthesize and release ACh in response to electrical stimulation, before the growth cone has reached its target cells. Thus, the developmental signals that pass between nerve and muscle do not induce wholesale changes in cell properties; rather, they assure that components of the pre- and postsynaptic machinery are organized at the correct time and in the right places. It is useful therefore to think of the intercellular signals that control synaptogenesis as organizers rather than inducers.

A third key feature of neuromuscular junction development is that new synaptic components are added in several distinct steps. The newly formed synapse is not simply a prototype of a fully developed synapse. Although nerve and muscle membrane form close contacts at early stages of synaptogenesis, only later does the synaptic cleft widen and the basal lamina appear. Similarly, ACh receptors accumulate in the postsynaptic membrane before acetylcholinesterase accumulates in the synaptic cleft, and the postsynaptic membrane acquires junctional folds only after the nerve terminal has matured. Several different axons innervate each myotube around the time of birth, but during early postnatal life, all but one axon withdraws.

This elaborate sequence is not orchestrated by the simple act of contact between nerve and muscle. Instead, multiple signals pass between the cells—the nerve sends a signal to the muscle that triggers the first steps in postsynaptic differentiation, at which point the muscle sends a signal that triggers the initial steps of nerve terminal differentiation. The nerve then sends further signals to the muscle, and this interaction continues.

We now consider retrograde (from muscle to nerve) and anterograde (from nerve to muscle) organizers in more detail.

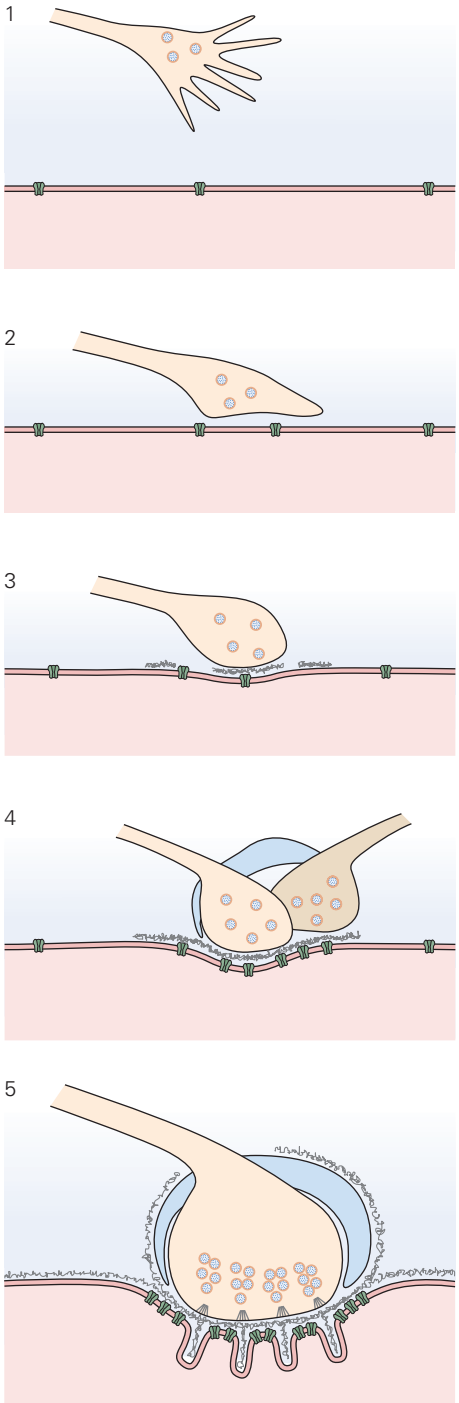
Differentiation of Motor Nerve Terminals Is Organized by Muscle Fibers

Soon after the growth cone of a motor axon contacts a developing myotube, a rudimentary form of neurotransmission begins. The axon releases ACh in vesicular packets, the transmitter binds to receptors, and the myotube responds with depolarization and weak contraction.

The onset of transmission at the new synapse reflects the intrinsic capabilities of each synaptic partner. Nevertheless, these intrinsic capabilities cannot readily explain the marked increase in the rate of transmitter release that occurs after nerve-muscle contact is made, nor can they explain the accumulation of synaptic vesicles and the assembly of active zones in the small portion of the motor axon that contacts the muscle surface. These developmental steps require signals from muscle to nerve.

A clue to the source of these signals came from studies on the reinnervation of adult muscle. Although axotomy leaves muscle fibers denervated and leads to insertion of ACh receptors in nonsynaptic regions, the postsynaptic apparatus remains largely intact. It is still recognizable by its synaptic nuclei, junctional folds, and the ACh receptors, which remain far more densely

A Development stages



B Mature neuromuscular junction

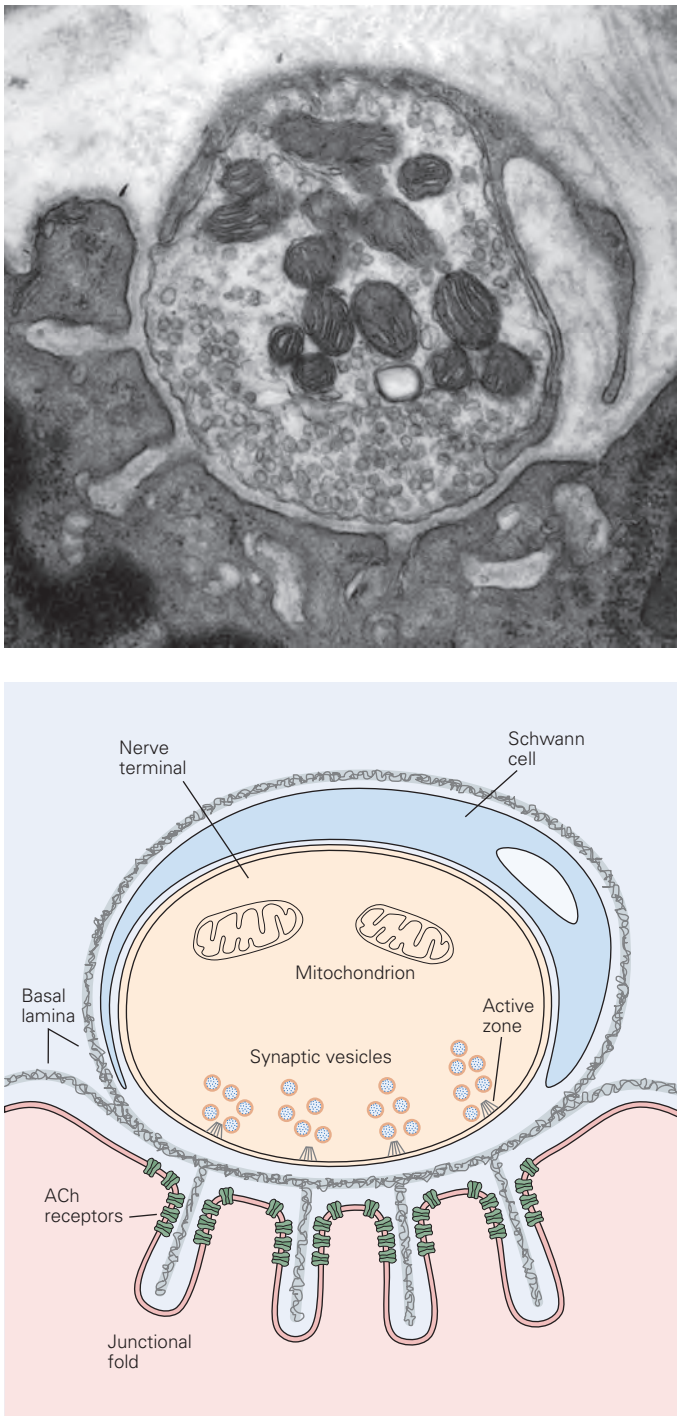


Figure 48–8 The neuromuscular junction develops in sequential stages.

A. A growth cone approaches a newly fused myotube (**1**) and forms a morphologically unspecialized but functional contact (**2**). The nerve terminal accumulates synaptic vesicles and a basal lamina forms in the synaptic cleft (**3**). As the muscle matures, multiple axons converge on a single site (**4**). Finally, all axons but one are eliminated and the surviving terminal matures (**5**). As the synapse matures, acetylcholine (**ACh**) receptors become concentrated in the postsynaptic membrane and depleted from the extrasynaptic membrane. (Adapted, with permission, from Hall and Sanes 1993.)

B. At the mature neuromuscular junction, pre- and postsynaptic membranes are separated by a synaptic cleft that contains basal lamina and extracellular matrix proteins. Vesicles are clustered at presynaptic release sites, transmitter receptors are clustered in the postsynaptic membrane, and nerve terminals are coated by Schwann cell processes. (Micrograph reproduced, with permission, from T. Gillingwater.)

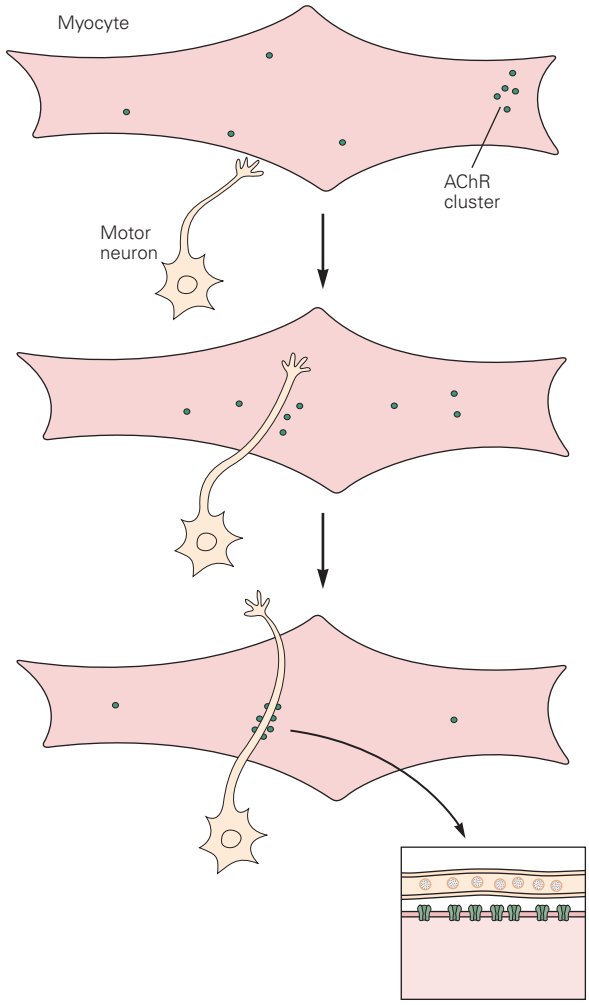

Figure 48–9 Nerve and muscle cells express synaptic components, but synaptic organization requires cell interactions. Acetylcholine receptors (AChR) are synthesized by muscle cells cultured without neurons. Many receptors are diffusely distributed, but some form high-density aggregates similar to those found in the postsynaptic membrane of the neuromuscular junction. When neurons first contact muscle, they do not restrict themselves to the receptor-rich aggregates. Instead, new receptor aggregates form at sites of neurite-muscle contact, and many of the preexisting clusters disperse. Similarly, motor axons contain synaptic vesicles that cluster at sites of neurite contact with muscle cells. (Adapted, with permission, from Anderson and Cohen 1977; Lupa, Gordon, and Hall 1990.)

packed in synaptic areas than in extrasynaptic areas of the cell. Damaged peripheral axons regenerate readily (unlike those in the central nervous system) and form new neuromuscular junctions that look and perform much like the original ones.

A century ago, Fernando Tello-Muñóz, a student of Santiago Ramón y Cajal, noted that the new junctions form at preexisting synaptic sites on the denervated muscle fibers even though the postsynaptic specializations occupy only 0.1% of the muscle fiber surface (Figure 48–10A). Later, electron microscopy showed that specialization in the axon occurs only in the terminals that contact the muscle. For example, active zones form directly opposite the mouths of the postsynaptic junctional folds. This striking example of subcellular specificity implies that motor axons recognize signals associated with the postsynaptic apparatus.

When regenerating axons reach a muscle fiber, they encounter the basal lamina of the synaptic cleft. To explore the significance of this association, muscles were damaged in vivo in a way that killed the muscle fibers but left their basal lamina intact. The necrotic fibers were phagocytized, leaving behind basal lamina sheaths on which synaptic sites were readily recognizable. At the same time that the muscle was damaged, the nerve was cut and allowed to regenerate. Under these conditions, motor axons reinnervated the empty basal lamina sheaths, contacting synaptic sites as precisely as they would have if muscle fibers were present. Moreover, nerve terminals developed at these sites and active zones even formed opposite struts of basal lamina that once lined junctional folds. These observations implied that components of the basal lamina organize presynaptic specialization (Figure 48–10B).

Several such molecular organizers have now been identified. Among the best studied are isoforms of the protein laminin. Laminins are major components of all basal laminae and promote axon outgrowth in many neuronal types. They are heterotrimers of α, β, and γ chains, comprising a family of five α, four β, and three γ chains (Chapter 47). Muscle fibers synthesize multiple laminin isoforms and incorporate them into the basal lamina. Laminin-211, a heterotrimer containing the $\alpha 2$, $\beta 1$, and $\gamma 1$ chains, is the major laminin in the basal lamina, and its absence leads to severe muscular dystrophy. In the synaptic cleft, however, isoforms bearing the $\beta 2$ chain predominate (Figure 48–11A), and nerve terminals fail to differentiate fully in mutant mice that lack the $\beta 2$ laminin (Figure 48–11B). The $\beta 2$ laminins appear to act by binding to voltage-sensitive calcium channels that reside in the axon terminal membrane, where they couple activity to transmitter release. Laminins act on the extracellular domain of the channels, whereas the intracellular segment recruits or stabilizes other components of the release apparatus.

The finding that presynaptic differentiation is only partially compromised in the absence of laminins indicated that additional muscle-derived organizers of axonal specialization must exist. Several have now been identified, including members of the fibroblast

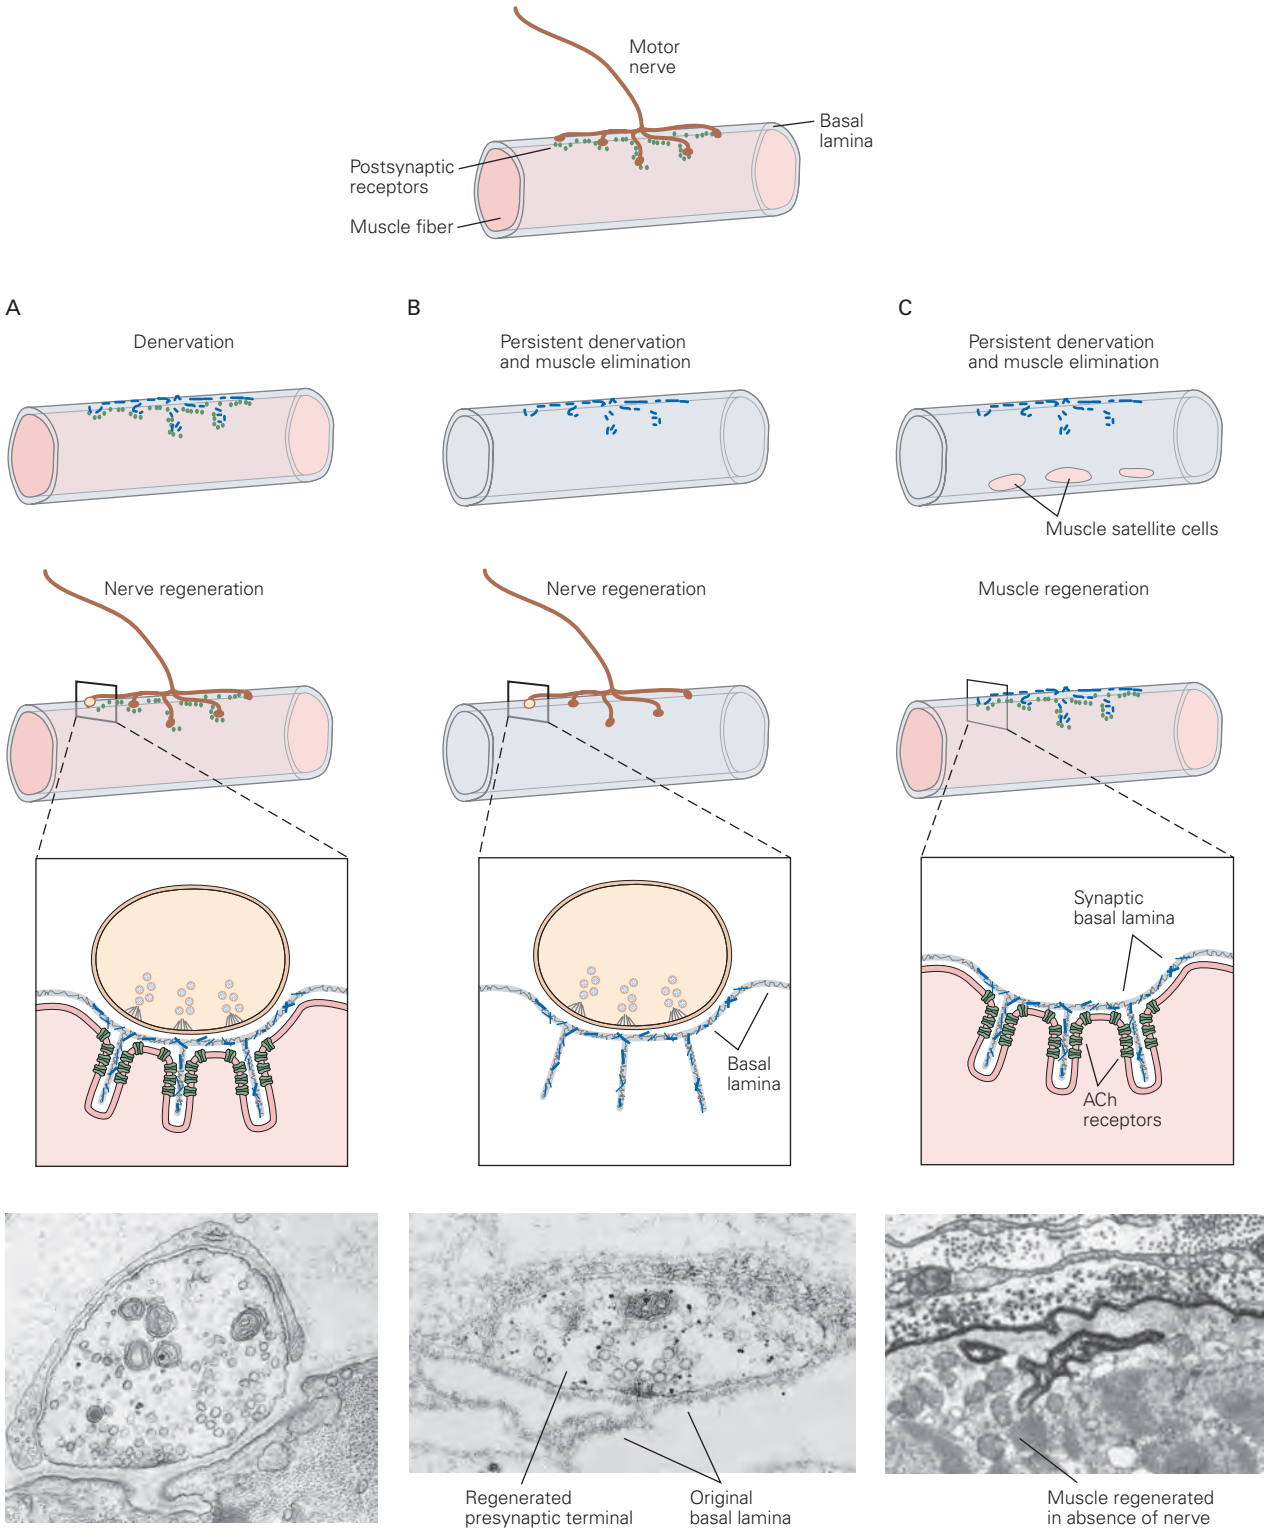

Figure 48–10 Synaptic portions of basal lamina contain proteins that organize developing and regenerating nerve terminals.

A. Damaged motor axons regenerate and form new neuromuscular junctions. Nearly all of the new synapses form at the original synaptic sites. (Micrograph reproduced, with permission, from Glicksman and Sanes 1983.)

B. A strong preference for innervation at original synaptic sites persists even after the muscle fibers have been removed, leaving behind basal lamina "ghosts." Regenerated axons develop synaptic specialization on contact with the original synaptic sites on the basal lamina. (Micrograph reproduced, with permission, from Glicksman and Sanes 1983.)

C. Following denervation of a skeletal muscle fiber and elimination of mature muscle fibers, muscle satellite cells proliferate and differentiate to form new myofibers. The expression of acetylcholine (ACh) receptors on the regenerated myofiber surface is concentrated in the synaptic areas of basal lamina, even when reinnervation is prevented. (Micrograph reproduced, with permission, from Burden, Sargent, and McMahan 1979.)

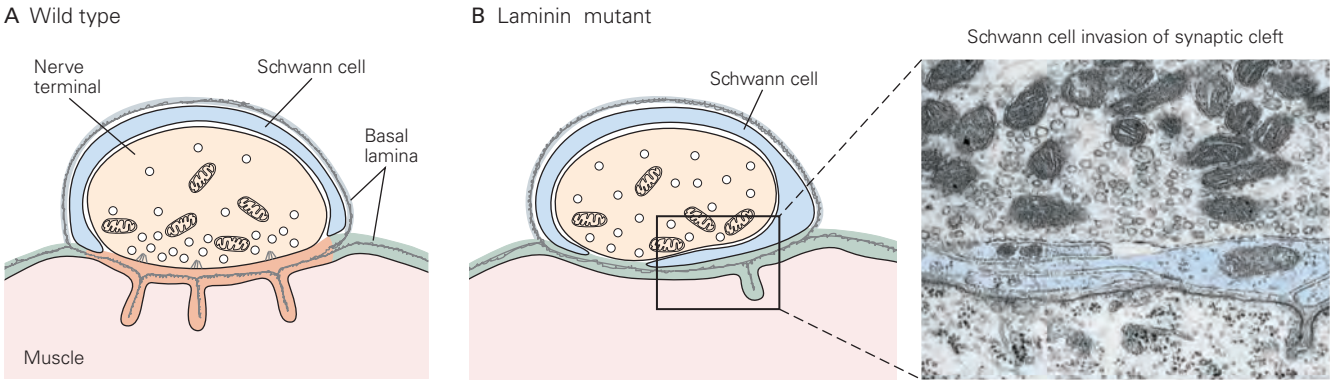

Figure 48–11 Different laminin isoforms are localized at synaptic and extrasynaptic areas of the basal lamina.

A. Different laminin isoforms are found in synaptic (**brown**) and extrasynaptic (**green**) areas of basal lamina. Isoforms, containing the β2 chain, are concentrated in the synaptic areas.

B. Maturation of neuromuscular junctions is impaired in mice lacking β2 laminins. These mutants have few active zones, and the synaptic cleft is invaded by Schwann cell processes (**blue**). (Micrograph reproduced, with permission, from Noakes et al. 1995.)

growth factor and collagen IV families, as well as a muscle membrane-associated protein, LRP4, that we will soon encounter again in the context of postsynaptic differentiation. Thus target-derived proteins from multiple families collaborate to organize the presynaptic nerve terminal.

Differentiation of the Postsynaptic Muscle Membrane Is Organized by the Motor Nerve

Soon after myoblasts fuse to form myotubes, the genes that encode ACh receptor subunits are activated. Receptor subunits are synthesized, assembled into pentamers in the endoplasmic reticulum, and inserted into the plasma membrane. As noted above, some receptors spontaneously form aggregates, but the majority are distributed throughout the membrane at a low density, approximately 1,000 per μm^2.

Once synapse formation is complete, however, the distribution of the receptors changes drastically. The receptors become concentrated at the synaptic sites of the membrane (to a density up to 10,000 per μm^2) and depleted in the nonsynaptic membrane (reduced to 10 per μm^2 or less). This thousand-fold difference in ACh receptor density occurs within a few tens of micrometers from the edge of the nerve terminal.

Appreciation of the critical role of the nerve in the redistribution of ACh receptors inspired a search for factors that might promote their clustering. This quest led to the discovery of a proteoglycan, agrin. Agrin is synthesized by motor neurons, transported down the axon, released from nerve terminals, and incorporated into the synaptic cleft (Figure 48–12A,B). Some agrin isoforms are also made by muscle cells, but the neuronal isoforms are about a thousand-fold more active in aggregating ACh receptors.

The phenotype of mutant mice lacking agrin shows that agrin has a central role in the organization of ACh receptors. Agrin mutants have grossly perturbed neuromuscular junctions and die at birth. The number, size, and density of ACh receptor aggregates are severely reduced in these mice (Figure 48–12C). Other components of the postsynaptic apparatus—including cytoskeletal, membrane, and basal lamina proteins—are also reduced. Interestingly, the differentiation of presynaptic elements is also perturbed. However, the defects in the presynaptic element do not result directly from lack of agrin in the motor neuron, but rather indirectly from the failure of the disorganized postsynaptic apparatus to generate signals for presynaptic specialization.

How does agrin work? Agrin's major receptor is a complex of a muscle-specific tyrosine kinase called MuSK (muscle-specific trk-related receptor with a kringle domain) and a coreceptor subunit called LRP4 (Figure 48–12A). MuSK and LRP4 are normally concentrated at synaptic sites in the muscle membrane, and muscles of mutant mice lacking MuSK or LRP4 do not have ACh receptor clusters (Figure 48–12C). Myotubes generated in vitro from these mutants express normal levels of ACh receptors, but these receptors cannot be clustered by agrin. Binding of agrin to the MuSK/LRP4 complex initiates a chain of events that ends in receptor clustering. Key events are agrin-induced activation of MuSK's kinase activity; autophosphorylation of the MuSK intracellular domain; recruitment of

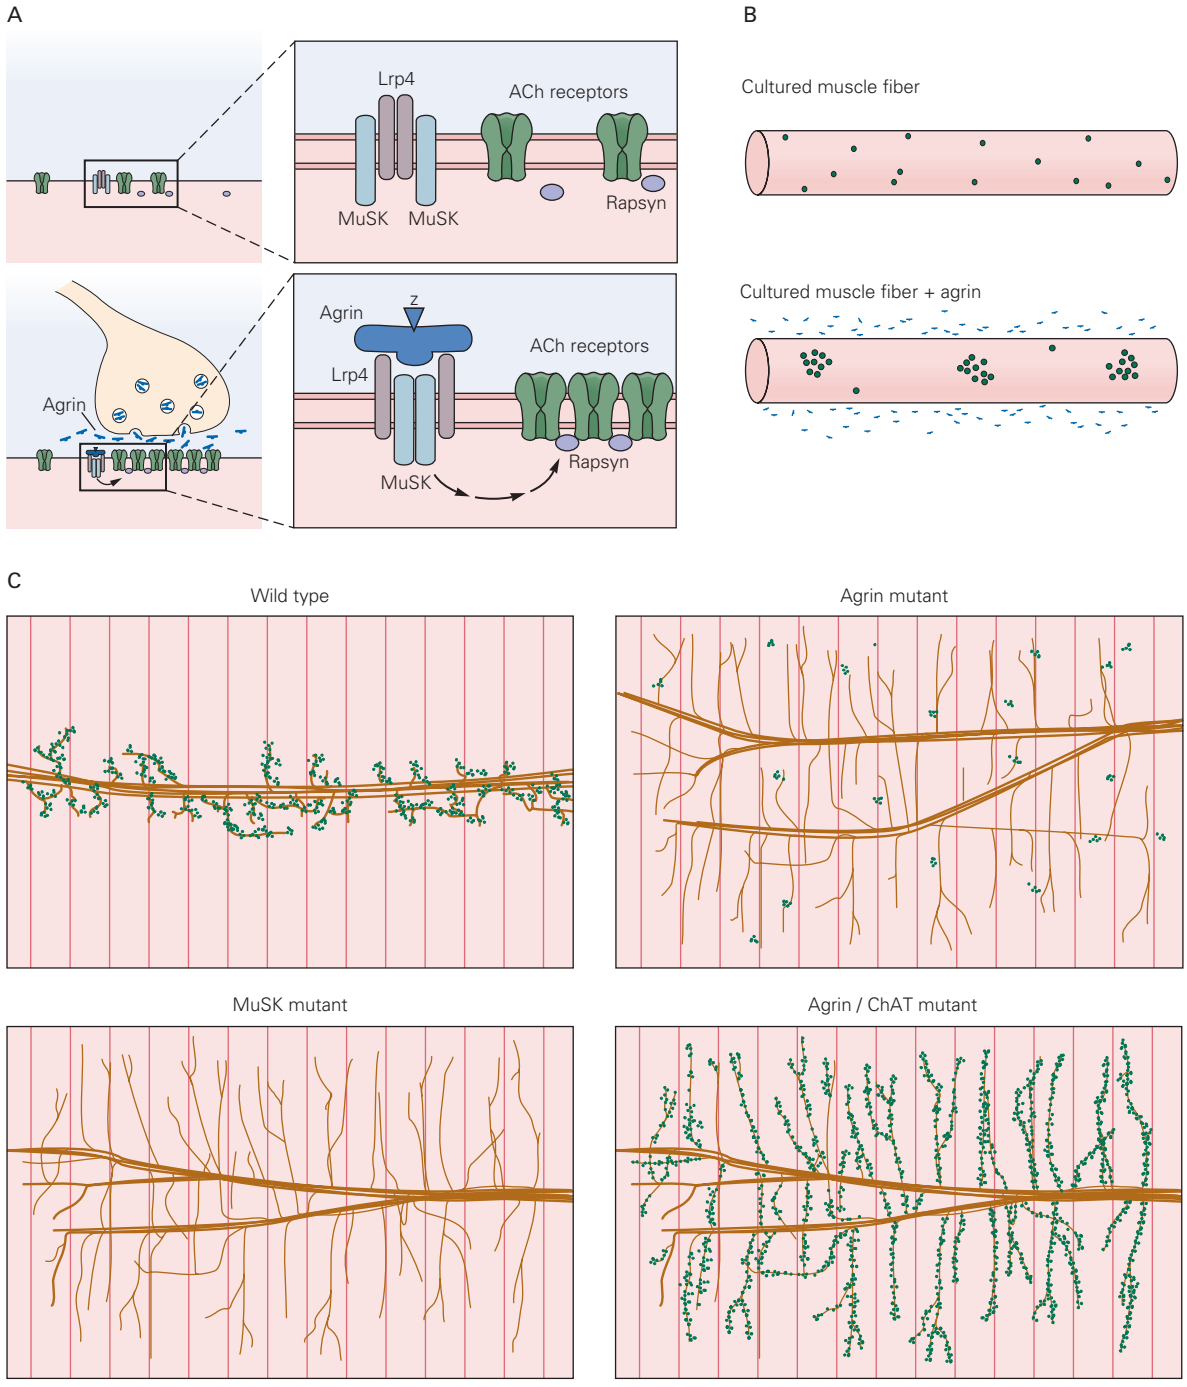

Figure 48–12 Agrin induces aggregation of acetylcholine (ACh) receptors at synaptic sites.

A. Agrin is a large (~400 kDa) extracellular matrix proteoglycan. Alternative splicing includes a "z" exon that confers the ability to cluster ACh receptors. When released by a nerve terminal, agrin binds Lrp4 on the muscle membrane, activating the membrane-associated receptor tyrosine kinase MuSK and triggering an intracellular cascade that results in ACh receptor clustering. Key intracellular signaling molecules are Dok7, Crk, and CrkL. These signal to rapsyn, a cytoplasmic ACh receptor–associated protein, which physically interacts with and clusters the ACh receptors. (Adapted, with permission, from DeChiara et al. 1996.)

B. Few ACh receptor clusters form on myofibers grown in culture under control conditions, but addition of agrin induces ACh receptor clustering. (Adapted, with permission, from Misgeld et al. 2005.)

C. Muscles from wild-type neonatal mice and from three mutant types. Muscles were labeled for ACh receptors (**green**) and motor axons (**brown**). In wild-type mice, ACh receptor clusters have formed under each nerve terminal by birth, whereas in agrin mutants, most clusters have dispersed. ACh receptor clusters are also absent in MuSK, Dok7, and rapsyn mutant mice. When the genes for agrin and **ChAT** (choline acetyltransferase) are mutated, clusters of ACh receptors remain, indicating that agrin works by counteracting receptor dispersion mediated by ACh. All mutant conditions also show axonal abnormalities, reflecting defects in retrograde signaling to the motor axon. (Abbreviation: **MuSK**, muscle-specific trk-related receptor with a kringle domain.) (Adapted, with permission, from Gautam et al. 1996.)

adaptor proteins Dok-7, Crk, and CrkL; and strengthening of an interaction between a cytoplasmic protein rapsyn and the ACh receptors. Rapsyn may be the final element in the sequence: It binds directly to the ACh receptors and can induce their aggregation in vitro. In mice lacking rapsyn, muscles form normally and ACh receptors accumulate in normal numbers but fail to aggregate at the synaptic sites on the membrane. Accordingly, muscles of mutant mice lacking Dok7 or rapsyn resemble those lacking MuSK or LRP4: They synthesize ACh receptors but do not have ACh receptor clusters.

Thus, an extracellular protein (agrin), transmembrane proteins (MuSK and LRP4), adaptor proteins (Dok-7, Crk, and CrkL), and a cytoskeletal protein (rapsyn) form a chain that links commands from the motor axon to ACh receptor clustering in the muscle membrane.

Nevertheless, postsynaptic differentiation can occur in the absence of agrin signaling. This capacity was apparent in early studies on cultured muscle (see Figure 48–9) and is also seen in vivo: ACh receptor clusters form initially but then disperse in agrin mutants (Figure 48–12C). Clustering also occurs in muscles that lack innervation entirely. Thus, the signaling pathway that initiates postsynaptic differentiation can be activated without agrin, but agrin is required to maintain clustering of ACh receptors.

The role of agrin is perhaps best understood in terms of the requirement that pre- and postsynaptic specializations be perfectly aligned. ACh receptor aggregates persist in uninnervated muscles but disappear in agrin mutant muscles, suggesting that axons sculpt the postsynaptic membrane through the combined action of agrin and a dispersal factor. One major dispersal factor is ACh itself; clustering persists in mutants that lack both agrin and ACh (Figure 48–12C). Thus, agrin may render ACh receptors immune to the declustering effects of ACh. Through a combination of positive and negative factors, the motor neuron ensures that the patches of postsynaptic membrane contacted by axon branches are rich in ACh receptors.

The Nerve Regulates Transcription of Acetylcholine Receptor Genes

Along with redistribution of ACh receptors in the plane of the membrane, the motor nerve orchestrates the transcriptional program responsible for expression of ACh receptor genes in muscle. To understand this aspect of transcriptional control, it is important to appreciate the geometry of the muscle.

Individual muscle fibers are often more than a centimeter long and contain hundreds of nuclei along their length. Most nuclei are far from the synapse, but a few are clustered beneath the synaptic membrane, so that their transcribed and translated products do not have far to go to reach the synapse. In newly formed myotubes, most nuclei express genes encoding ACh receptor subunits. In adult muscles, however, only synaptic nuclei express ACh receptor genes; nonsynaptic nuclei do not. Two processes contribute to this transformation.

First, as synapses begin to form, expression of the ACh receptor subunit genes is increased in synaptic nuclei (Figure 48–13). Signals acting through MuSK are needed for this specialization. Second, around the time of birth, ACh receptor gene expression shuts down in nonsynaptic nuclei. This change reflects a repressive effect of the nerve, as originally shown by studies of denervated muscle. When muscle fibers are denervated, as happens when the motor nerve is damaged, the density of ACh receptors in the postsynaptic membrane increases markedly, a phenomenon termed *denervation supersensitivity.*

This repressive effect of the nerve is mediated by electrical activation of the muscle. Under normal conditions, the nerve keeps the muscle electrically active, and fewer ACh receptors are synthesized in active muscle than in inactive muscle. Indeed, direct stimulation of denervated muscle through implanted electrodes decreases ACh receptor expression, preventing or reversing the effect of denervation (Figure 48–13B). Conversely, when nerve activity is blocked by application of a local anesthetic, the number of ACh receptors throughout the muscle fiber increases, even though the synapse is intact.

In essence, then, the nerve uses ACh to repress expression of ACh receptor genes extrasynaptically. Current that passes through the channel of the receptor leads to an action potential that propagates along the entire muscle fiber. This depolarization opens voltage-dependent Ca^{2+} channels, leading to an influx of Ca^{2+}, which activates a signal transduction cascade that reaches nonsynaptic nuclei and regulates transcription of ACh receptor genes. Thus, the same voltage changes that produce muscle contraction over a period of milliseconds also regulate transcription of ACh receptor genes over a period of days.

The increase in transcription of ACh receptor genes in nuclei beneath the synapse, along with the decrease in nuclei distant from synapses, leads to localization of ACh receptor mRNA and thus preferential synthesis and insertion of ACh receptors near synaptic sites. This local synthesis is reminiscent of that seen

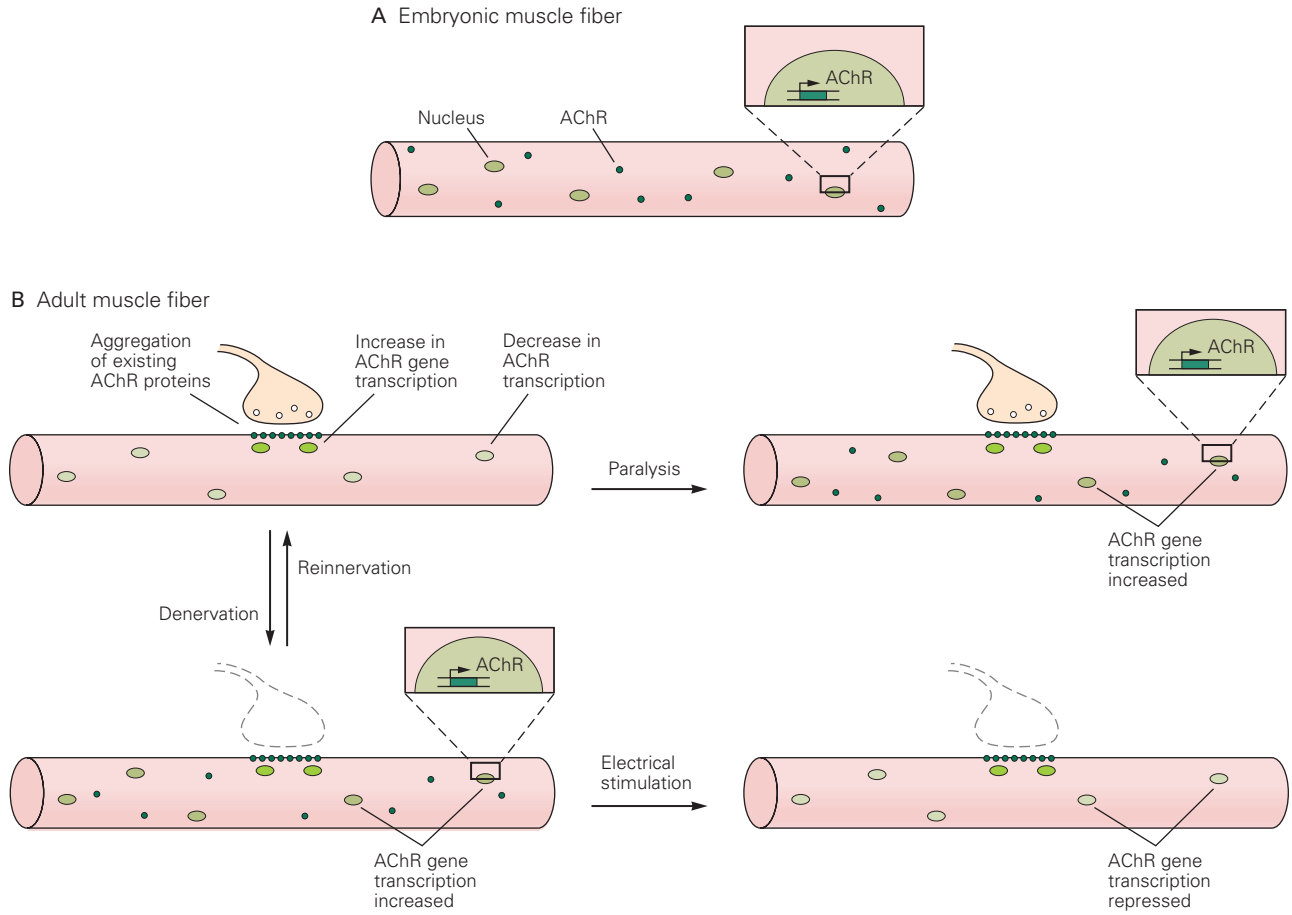

Figure 48–13 Clustering of acetylcholine (ACh) receptors at the neuromuscular junction results from transcriptional regulation and local protein trafficking.

A. ACh receptors (**AChR**) are distributed diffusely on the surface of embryonic myotubes.

B. After the muscle is innervated by a motor axon, the number of receptors in extrasynaptic regions decreases, whereas receptor density at the synapse increases. This reflects the aggregation of preexisting receptors and enhanced expression of ACh receptor genes in nuclei that lie directly beneath the nerve terminal. In addition, the transcription of receptor genes is repressed in nuclei in extrasynaptic regions. Electrical activity in muscle represses ACh gene expression in nonsynaptic nuclei, leading to a lower density of ACh receptors in these regions. The nuclei at synaptic sites are immune to this repressive effect. Following denervation, ACh receptor gene expression is upregulated in extrasynaptic nuclei, although not to the high level attained by synaptic nuclei. Paralysis mimics the effect of denervation, whereas electrical stimulation of denervated muscle mimics the influence of the nerve and decreases the density of ACh receptors in the extrasynaptic membrane.

at postsynaptic sites on dendritic spines in the brain. Local synthesis in muscle is advantageous since ACh receptors synthesized near the ends of fibers would never reach the synapse without degradation.

Many components of the postsynaptic apparatus are regulated in ways similar to those we have described for ACh receptors—their aggregation depends on agrin and MuSK, and their transcription is enhanced in synaptic nuclei and repressed in extrasynaptic nuclei by electrical activity. Thus, synaptic components have tailor-made regulatory mechanisms, but many of these components are regulated in parallel.

The Neuromuscular Junction Matures in a Series of Steps

The adult neuromuscular junction is dramatically different in its molecular architecture, shape, size, and functional properties from the simple nerve-muscle contact that initiates neurotransmission in the embryo. Maturation of the nerve terminal, the postsynaptic membrane, and the intervening synaptic cleft occurs in a complex series of steps. We illustrate this stepwise synaptic construction with a continued focus on the development of ACh receptors.

As we have seen, ACh receptors aggregate in the plane of the membrane as the neuromuscular junction begins to form, and receptor gene transcription is enhanced in postsynaptic nuclei. A few days later, activity begins to decrease the level of extrasynaptic receptors. These transcriptional changes are soon followed by changes in the stability of the receptors. In embryonic muscle, ACh receptors are turned over rapidly (with a half-life of approximately 1 day) in both synaptic and extrasynaptic regions. In contrast, in adult muscle, the receptors are relatively stable (with a half-life of approximately 2 weeks). The metabolic stabilization of ACh receptors helps concentrate them at synaptic sites and stabilize the postsynaptic apparatus.

Yet another alteration is in the composition of the ACh receptors. In the embryo, ACh receptors are composed of α-, β-, δ-, and γ-subunits. During the first few postnatal days, the γ gene is turned off and a closely related gene called ε is activated. As a result, new ACh receptors inserted in the membrane are composed of α-, β-, δ-, and ε-subunits. This altered subunit composition tunes the receptor in a way that is suited to its mature function. However, although it occurs at the same time as the metabolic stabilization, the two changes are not causally linked.

These molecular changes in the ACh receptors are accompanied by changes in their distribution (Figure 48–14). Soon after birth, junctional folds begin to form in the postsynaptic membrane and ACh receptors become concentrated at the crests of the folds, along with rapsyn, whereas other membrane and cytoskeletal proteins are localized in the depths of the folds. The initial aggregate of ACh receptors appears to have a plaque-like appearance. Perforations that undergo fusion and fission eventually transform the dense plaque into a pretzel shape that follows the branches of the nerve ending. New receptor-associated cytoskeletal proteins are added to the aggregate, presumably to drive the geometric changes. Finally, the postsynaptic membrane enlarges and eventually contains many more ACh receptors than were present in the initial cluster. Each of these changes occurs while the synapse is functional, suggesting that ongoing activity plays an important role in synaptic maturation.

Central Synapses and Neuromuscular Junctions Develop in Similar Ways

Synapses in the central nervous system are structurally and functionally similar to neuromuscular junctions in many ways. Presynaptically, most of the major protein components of synaptic vesicles are identical at both types of synapses. Likewise, the mechanisms of transmitter release differ only quantitatively, not qualitatively. Postsynaptically, neurotransmitter receptors are concentrated beneath the nerve terminal and associated with "clustering" proteins.

These parallels extend to synaptic development. Studies of cultured neurons have shown that the cellular logic of synapse formation is conserved between neuromuscular junctions and central synapses. At both synaptic types, pre- and postsynaptic elements regulate each other's differentiation by organizing synaptic components rather than by inducing their expression, and synapses develop in a progressive series of steps (Figure 48–15). The molecular details differ, however. Neuromuscular organizing molecules such as agrin and laminins do not play key roles at central synapses, suggesting that other synaptic organizers are involved. Recently, some of these organizing molecules have been identified.

Neurotransmitter Receptors Become Localized at Central Synapses

The concentration of neurotransmitter receptors in the postsynaptic membrane is a feature shared by many synapses. In the brain, receptors for glutamate, glycine, γ-aminobutyric acid (GABA), and other neurotransmitters are concentrated in patches of membrane aligned with nerve terminals that contain the corresponding transmitter.

The processes by which these receptors become localized may be similar to those at the neuromuscular junction. In cultures of dissociated hippocampal neurons, for example, both glutamatergic and GABAergic nerve terminals appear to stimulate clustering of appropriate receptors in the postsynaptic membrane. Moreover, nerves can induce expression of genes encoding glutamate receptors in central neurons, much as occurs for ACh receptors in muscle. Finally, electrical activity also regulates expression of neurotransmitter receptors in neurons.

In forming receptor clusters, central neurons face an obvious challenge that myotubes do not: They are contacted by axon terminals from distinct classes of neurons that use different neurotransmitters (Figure 48–16A). Thus, the nerve terminal probably has an instructive role in the clustering of receptors. In cultures of hippocampal neurons, glutamatergic and GABAergic axons terminate on adjacent regions of the same dendrite. Initially, glutamate and GABA receptors are dispersed, but soon, each type becomes selectively clustered beneath terminals that release that neurotransmitter. This observation implies the existence of multiple clustering signals with parallel pathways of signal transduction.

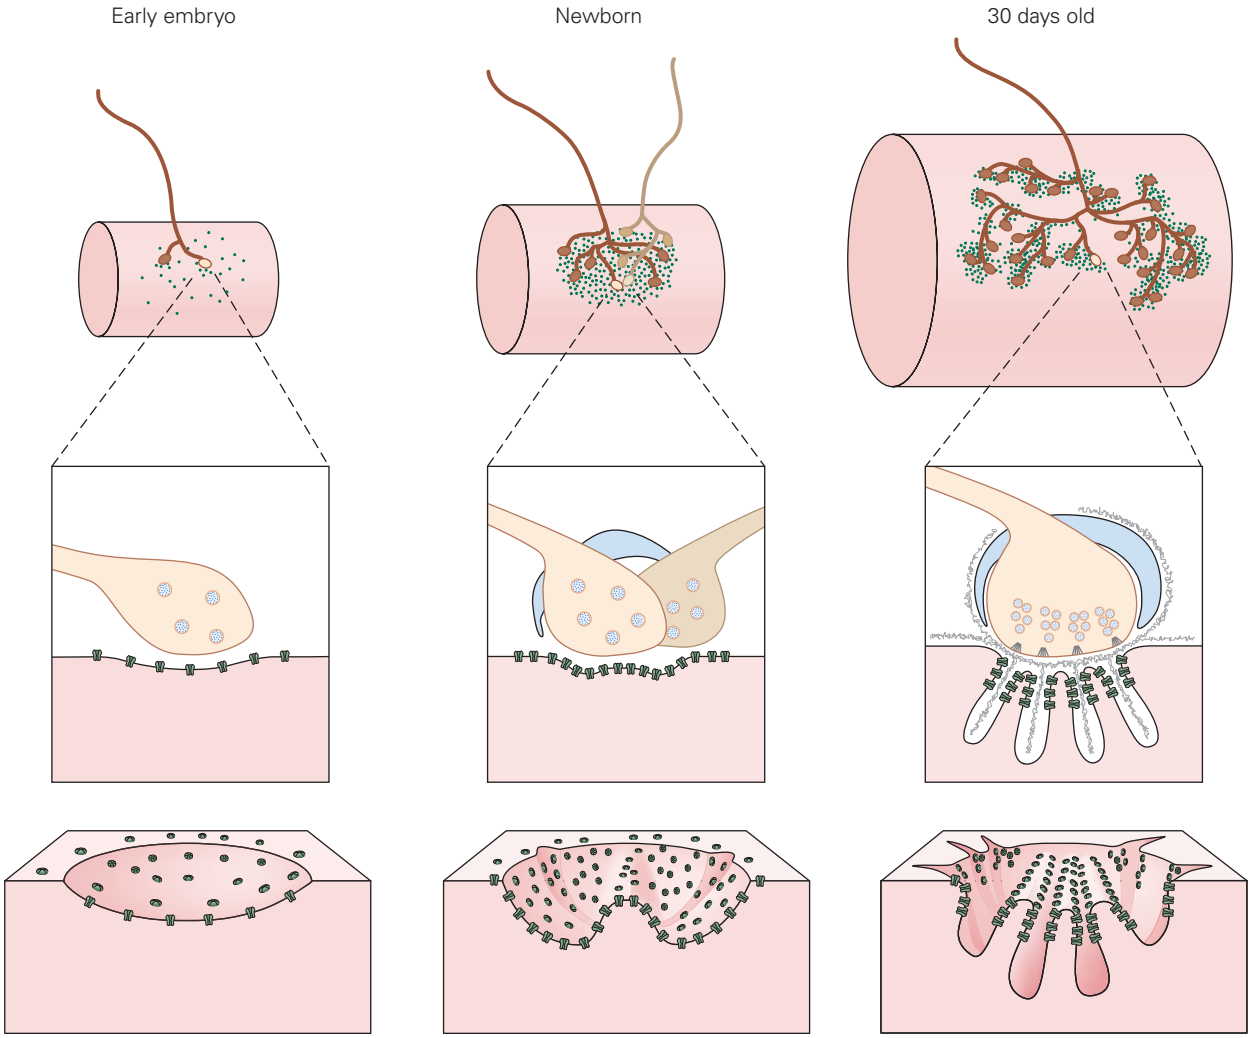

Figure 48–14 **The postsynaptic membrane at the neuromuscular junction matures in stages.** During early embryogenesis, ACh receptors exist as loose aggregates. Later, these aggregates condense into a plaque-like structure. After birth, the dense cluster opens up as the nerve develops multiple terminals. These axon branches expand in an intercalary fashion as the muscle grows, and the plaque indents to form a gutter, which then invaginates to form folds. Receptors are concentrated at the crests of the folds. (Adapted, with permission, from Sanes and Lichtman 2001.)

At the neuromuscular junction, rapsyn binds to the intracellular domain of ACh receptors and clusters them. Several proteins have been found to play similar roles at central synapses. One, gephyrin, is highly concentrated in the synaptic densities at glycinergic and some GABAergic synapses (Figure 48–16A). Gephyrin is not structurally related to rapsyn but has the same function: It links the receptors to the underlying cytoskeleton. In nonneural cells, glycine receptors cluster when gephyrin is co-expressed; conversely, clusters fail to form at inhibitory synapses in gephyrin-deficient mutant mice (Figure 48–16B). Similarly, a class of proteins that share conserved segments called PDZ domains—the prototypes being PSD-95 or SAP-90—facilitate clustering of *N*-methyl-D-aspartate (NMDA)-type glutamate receptors and their associated proteins. Other PDZ-containing proteins interact with α-amino-3-hydroxy-5-methylisoxazole-4-propionate acid (AMPA), kainate, and metabotropic types of glutamate receptors.

Synaptic Organizing Molecules Pattern Central Nerve Terminals

Although central synapses and neuromuscular junctions share many features, their synaptic clefts differ

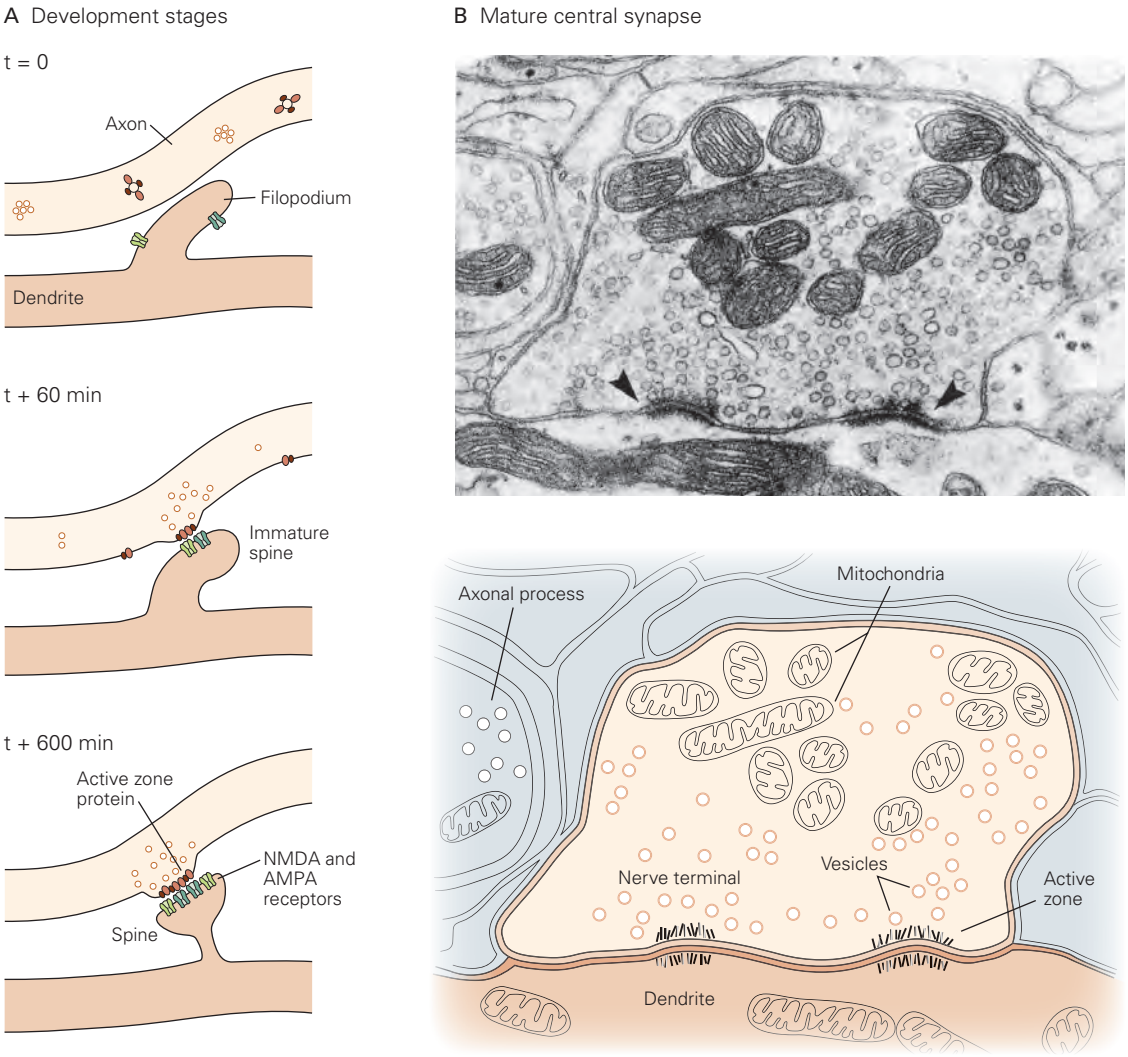

Figure 48–15 Ultrastructure of a synapse in the mammalian central nervous system.

A. Initial contact between an axon and a filopodium on a developing dendrite leads to a stable dendritic spine and an axodendritic synapse. This entire process can take as little as 60 minutes. (Abbreviations: **AMPA**, α-amino-3-hydroxy-5-methylisoxazole-4-propionate acid; **NMDA**, *N*-methyl-D-aspartate.)

B. In a mature interneuron synapse in the cerebellum, synaptic vesicles in the nerve terminal are clustered at active zones (**arrows**) directly opposite receptor-rich patches of postsynaptic membrane. (Reproduced, with permission, from J.E. Heuser and T.S. Reese.)

dramatically. Whereas muscle fibers are ensheathed by a basal lamina that has a distinctive molecular structure at the neuromuscular junction, central neurons do not have a prominent basal lamina. Instead, formation of central synapses is regulated in large part by molecules embedded in the pre- and postsynaptic membranes.

Several interacting pairs of membrane proteins have now been found that link the pre- and postsynaptic membranes and also organize synaptic differentiation as synapses form. Perhaps the best studied are a set of proteins called neurexins, which are enriched in presynaptic membranes, and their partners, the neuroligins, which are concentrated in postsynaptic membranes (Figure 48–17A). There are three neurexin and four neuroligin genes in the mammalian genome. The ability of neurexins and neuroligins to promote synaptic differentiation was first revealed by culturing neurons

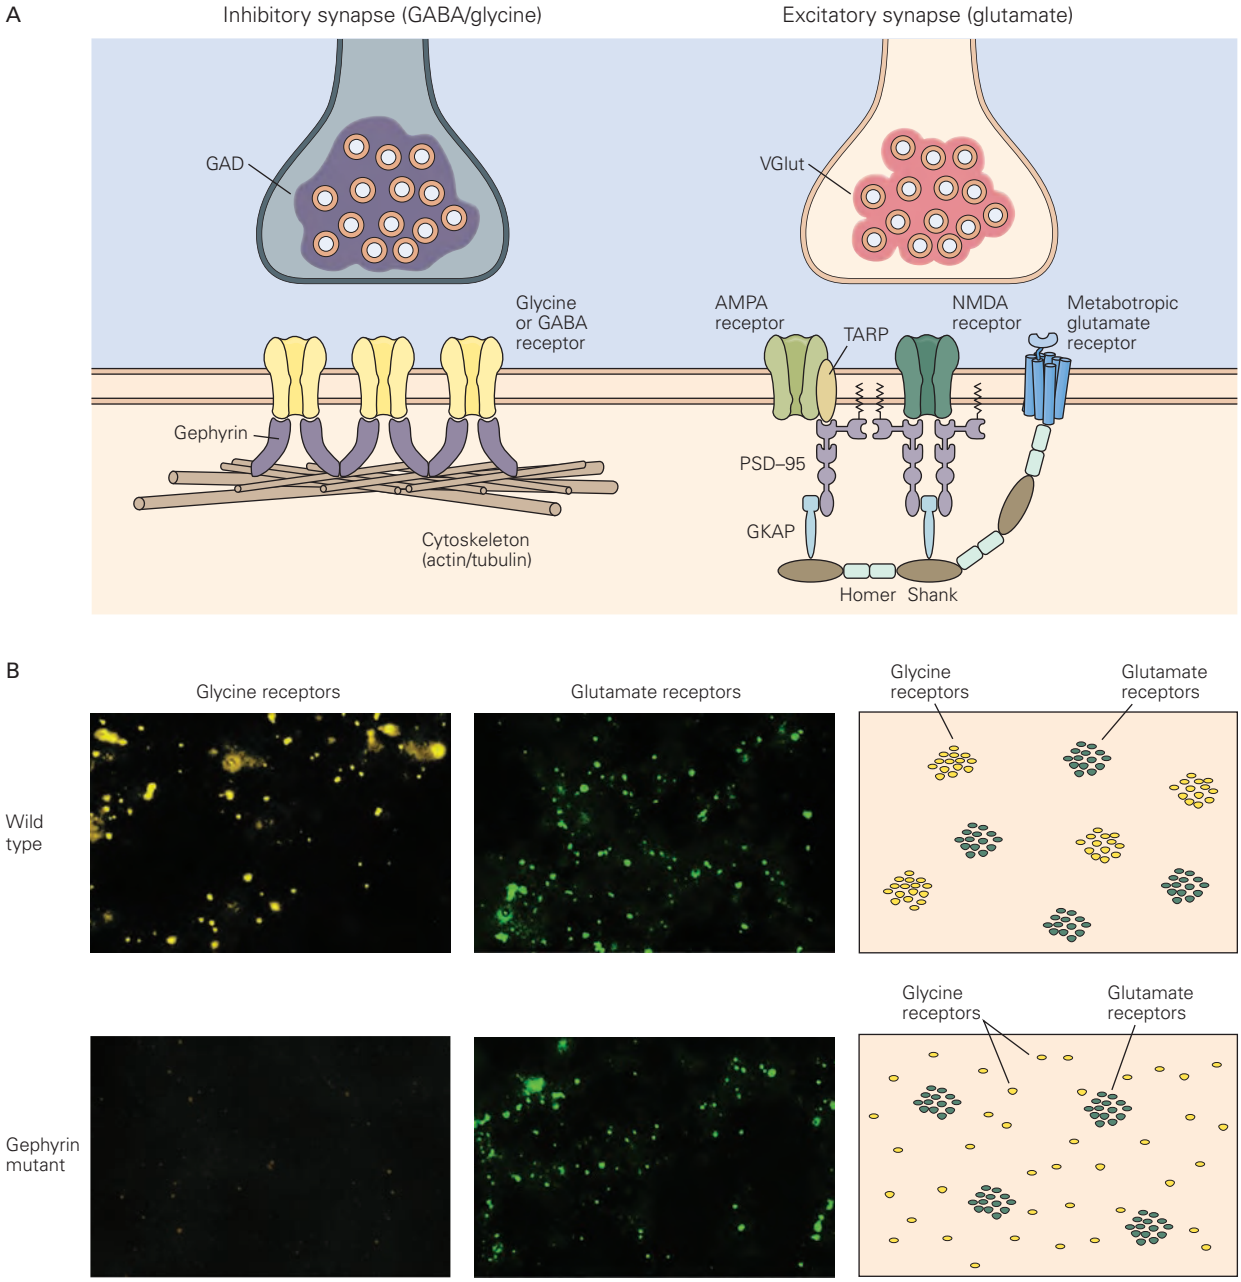

Figure 48–16 Localization of neurotransmitter receptors in central neurons.

A. Glutamate receptors are localized at excitatory synapses, and γ-aminobutyric acid (**GABA**) and glycine receptors are localized at inhibitory synapses. The receptors are linked to the cytoskeleton by adaptor proteins. Glycine receptors are linked to microtubules by gephyrin (*left*), and *N*-methyl-D-aspartate (**NMDA**)-type glutamate receptors are linked to each other and to the cytoskeleton by PSD-95–related molecules (*right*). The PSD family of molecules contains PDZ domains that interact with a variety of synaptic proteins to assemble signaling complexes. Other PDZ-containing proteins interact with α-amino-3-hydroxy-5-methylisoxazole-4-propionate acid (**AMPA**)-type and metabotropic glutamate receptors (see Chapter 13). (Abbreviations: **GAD**, glutamate decarboxylase; **GKAP**, Guanylate-kinase-associated protein; **TARP**, transmembrane AMPA receptor regulatory proteins; **VGlut**, vesicular glutamate transporter.)

B. In gephyrin mutant mice, glycine receptors do not cluster at synaptic sites on spinal motor neurons, and the animals show spasticity and hyperreflexia. In the same neurons, glutamate receptor clusters are unaffected. (Adapted, with permission, from Feng et al. 1998.)

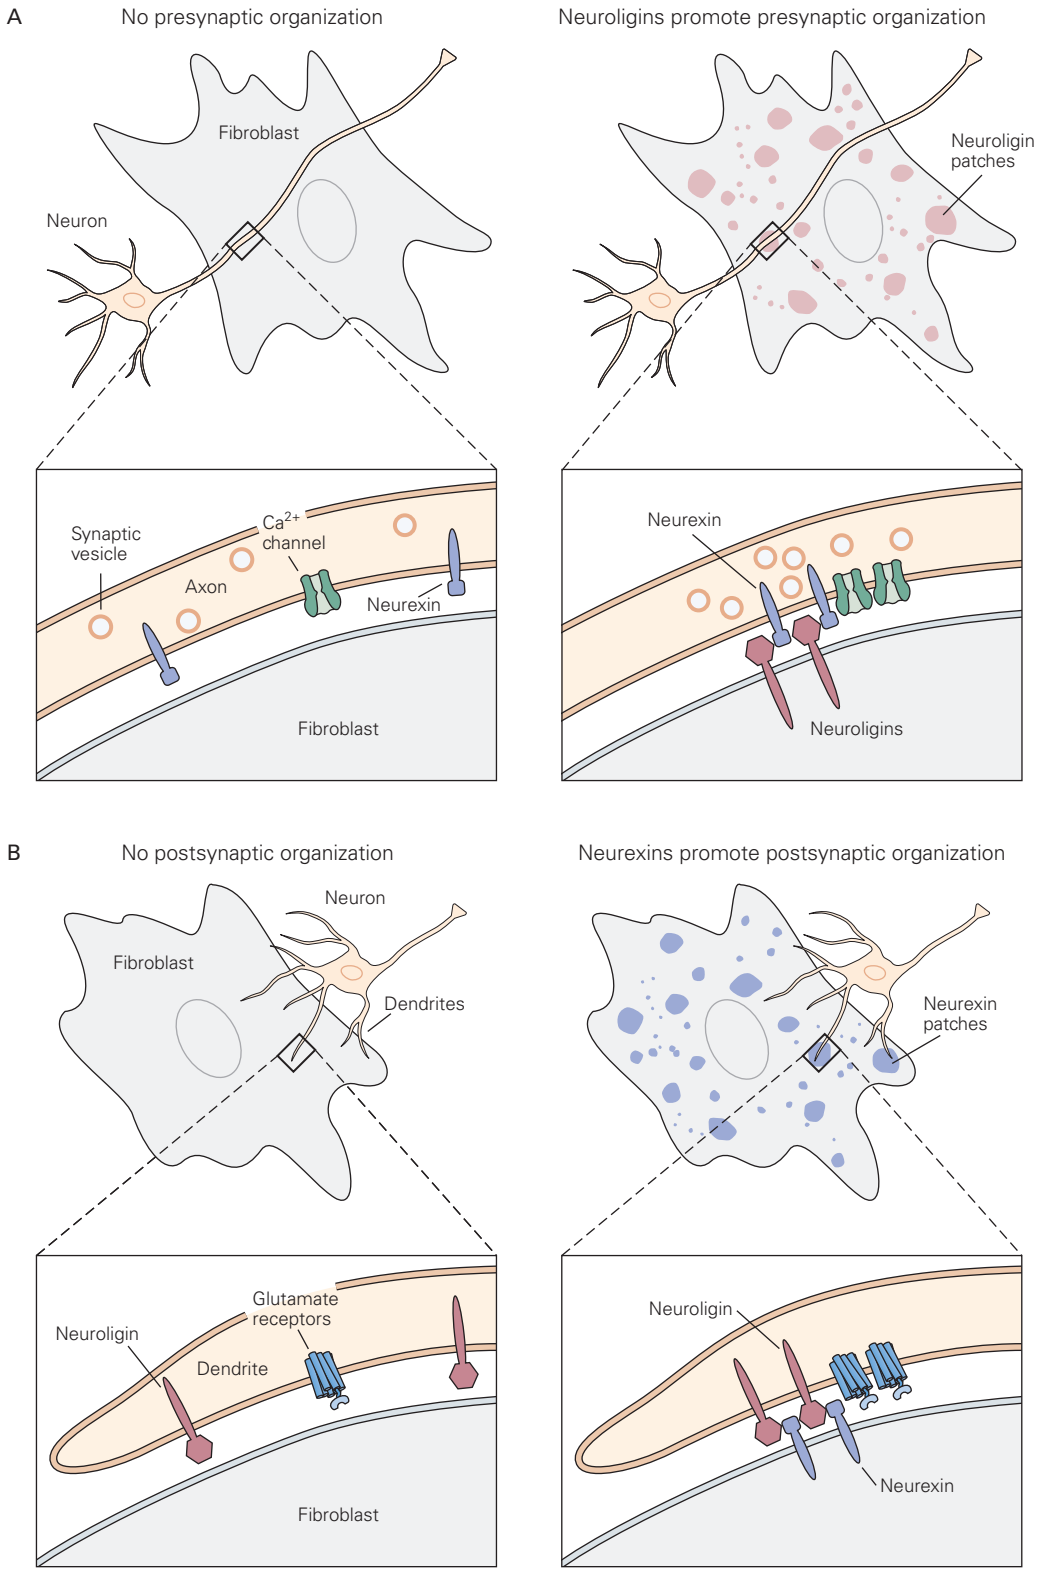

Figure 48–17 Synaptic organizers such as neurexins and neuroligins promote differentiation of central synapses.

A. When brain neurons are cultured with fibroblast cells that express neuroligin, those segments of the axon that contact these cells form presynaptic specializations, marked by clustered neurexin, Ca^{2+} channels, and synaptic vesicles.

B. Similarly, when neurons are cultured with cells that express neurexin, dendrites that contact these cells accumulate aggregates of glutamate receptors, accompanied by scaffolding molecules (not shown) and clustered neuroligins. Neurons grown with control cells fail to form such pre- and postsynaptic specializations.

with nonneural cells engineered to express one or the other. In culture, synaptic vesicles form clusters at sites of contact with the neuroligin-expressing cells, and they are capable of releasing neurotransmitter when stimulated (Figure 48–17A). Conversely, neurotransmitter receptors in dendrites aggregate at sites that contact nonneural cells engineered to express neurexins (Figure 48–17B). Thus, neurexin–neuroligin interactions facilitate precise apposition of pre- and postsynaptic specializations.

How do neurexins and neuroligins work? Part of the answer is that their carboxy terminal tails bind to PDZ domains in proteins such as PSD-95 (Figure 48–16). Indeed, a remarkable number of proteins in both pre- and postsynaptic membranes have PDZ domain-binding motifs, notably adhesion molecules, neurotransmitter receptors, and ion channels. Moreover, many cytoplasmic proteins that possess PDZ domains are present in nerve terminals and beneath the postsynaptic membrane. Thus, PDZ-containing proteins can serve as scaffolding molecules that link key components on both sides of the synapse. Interactions of proteins such as neurexins and neuroligins may provide a means of coupling the intercellular interactions required for synaptic recognition to the intracellular interactions required to cluster synaptic components within the cell membrane.

Although neurexin–neuroligin interactions promote synaptic differentiation in culture, mice lacking neurexins or neuroligins form synapses in vivo. However, the synapses that form in the mutants are defective, with the nature and severity of the defects varying among synaptic types. Thus, the primary role of these synaptic organizers may be to specify the properties of particular synapses. For example, neuroligin1 is concentrated in the postsynaptic membrane of excitatory synapses, and levels of glutamate receptors are reduced at excitatory synapses in neuroligin1 mutants. Conversely, neuroligin2 is concentrated at inhibitory synapses and plays a critical role in patterning the inhibitory postsynaptic membrane.

Additional complexity in the tuning of central synapses by neurexins arises from the fact that they bind to multiple postsynaptic organizing molecules in addition to the neuroligins (Figure 48–18). Moreover, thousands of neurexin isoforms are generated from each neurexin gene as a result of differences in promoter choice (generating α and β forms) and alternative splicing at multiple sites. Different neurexin isoforms are differentially expressed by neurons and have different affinities for the various neurexin ligands. Neuroligins are also alternatively spliced and differentially expressed and thus are likely to have multiple presynaptic partners.

More recently, other synaptic organizing molecules have been found; they include protein tyrosine phosphatases and leucine-rich repeat proteins as well as members of the fibroblast growth factor (FGF) and

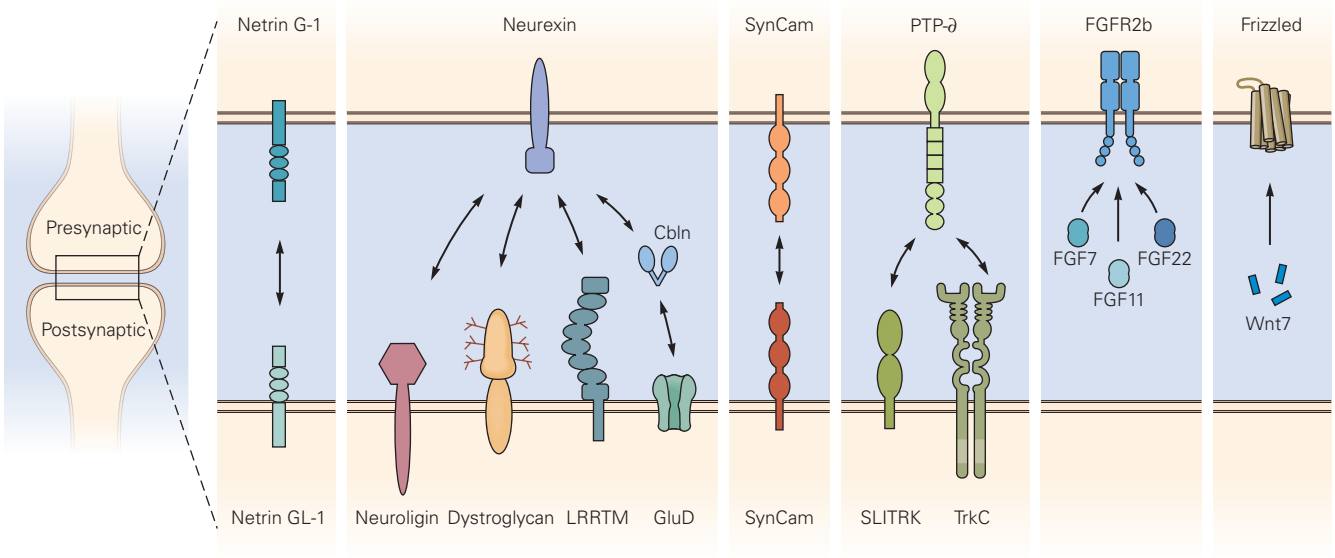

Figure 48–18 **Numerous macromolecular complexes link pre- and postsynaptic membranes at central synapses.** The figure shows some of the many transsynaptic proteins that interact at synaptic sites. Some bias synapse formation in favor of appropriate partners, whereas others act to regulate the properties of the synapse; some may do both.

Wnt families of secreted morphogens and their receptors (Figure 48–18). They are present at specific subsets of synapses and play distinct roles. For example, similar to neuroligin1 and neuroligin2, FGF22 and FGF7 are localized to and promote differentiation of excitatory and inhibitory synapses, respectively. Some of these organizing proteins may act in parallel with neurexins, while others may act as initial organizers, with neuroligins and neurexins consolidating the synapses at a later time and specifying their particular properties.

Together, these results suggest that central synapses are not patterned by master organizers akin to agrin, MuSK, LRP4, and laminins. Indeed, loss of no single central organizer studied to date is lethal in the manner observed for agrin, MuSK, LRP4, and laminin mutants. Instead, the enormous variety of neuronal and synaptic types in the central nervous system and their wide range of functional properties arise from a multitude of organizers that act combinatorially and in cell type–specific ways. Consistent with this view, genetic variation in many central organizers and synaptic recognition molecules, including neurexins, neuroligins, cadherins, and contactins, has been associated with behavioral perturbations in experimental animals and with behavioral disorders, including autism, in humans (Chapter 62).

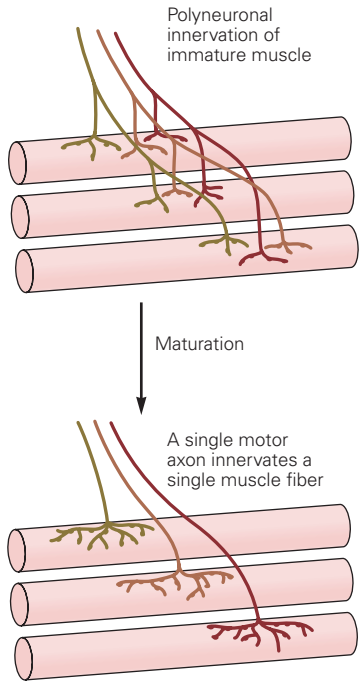

Figure 48–19 Some neuromuscular synapses are eliminated after birth. Early in the development of the neuromuscular junction, each muscle fiber is innervated by several motor axons. After birth, all motor axons but one withdraw from each fiber, and the surviving axon becomes more elaborate. Synapse elimination occurs without any overall loss of axons—axons that "lose" at some muscle fibers "win" at others. Central synapses are also subject to elimination.

Some Synapses Are Eliminated After Birth

In adult mammals, each muscle fiber bears only a single synapse. However, this is not the case in the embryo. At intermediate stages of development, several axons converge on each myotube and form synapses at a common site. Soon after birth, all inputs but one are eliminated.

The process of synapse elimination is not a manifestation of neuronal death. Indeed, it generally occurs long after the period of naturally occurring cell death (Chapter 46). Each motor axon withdraws branches from some muscle fibers but strengthens its connections with others, thus focusing its increasing capacity for transmitter release on a decreasing number of targets. Moreover, axonal elimination is not targeted to defective synapses; all inputs to a neonatal myotube are morphologically and electrically similar, and each can activate the postsynaptic cell (Figure 48–19).

What is the purpose of the transient stage of polyneuronal innervation? One possibility is that it ensures that each muscle fiber is innervated. A second is that it allows all axons to capture an appropriate set of target cells. A third, intriguing idea is that synapse elimination provides a means by which activity can change the strength of specific synaptic connections. We will explore this idea in Chapter 49.

Like synapse formation, synapse elimination results from intercellular interactions. Every muscle fiber ends up with exactly one input: None have zero, and very few have more than one. It is difficult to imagine how this could occur without feedback from the muscle cell. Moreover, the axons that remain after partial denervation at birth have a larger number of synapses than they did initially. Thus, synapse elimination appears to be a competitive process.

What drives the competition, and what is the reward? There is good evidence that neural activity plays a role: Paralysis of muscle reduces synapse elimination, whereas direct stimulation enhances it. These findings showed that activity was involved but did not reveal how the outcome was determined, because all axons were stimulated or paralyzed together. Because the essence of the competitive process is that some synapses gain territory at the expense of others, differential activity among axons may be a determinant

of axon winners and losers. Changing the activity of only a subset of axons in a living animal has been a technical challenge, but genetic approaches have made this possible in mice. In fact, when the activity of one of the inputs to a muscle fiber is decreased, that axon is highly likely to withdraw.

If the more active axon wins the competition, there is a new problem. Because all synapses made by an axon have the same activity pattern, one might predict that the least active axon in the muscle would eventually lose all of its synapses and the most active would retain all of its synapses. Yet this does not happen. Instead, all axons win at some sites and lose at others, so that every axon ends up innervating a substantial number of muscle fibers.

One possible resolution to this paradox is that the outcome of competition may not depend on the number of synaptic potentials from the winning axon at a synapse but rather on the total amount of synaptic input that the axon provides to the muscle—a product of the number of impulses and the amount of transmitter released per impulse. In this case, an axon that loses at several synapses might redistribute its resources (eg, synaptic vesicles) so that the remaining terminals would be strengthened and more likely to win at their synapses. Conversely, an axon that wins many competitions might find itself with insufficient vesicles to generate large synaptic potentials and thus would eventually lose to competitors at some synapses. Accordingly, the number of muscle fibers innervated by individual axons would vary much more among axons than is actually observed.

If activity drives the competition, what is the object of the competition? One idea is that the mechanisms are similar to those that determine whether neurons live or die. The muscle might produce limited amounts of a trophic substance for which the axons compete. As the winner grows, it either deprives the loser of its sustenance or gains enough strength to mount an attack that results in removal of its competitor. Alternatively, the muscle might release a toxic or punitive factor. In these scenarios, although the muscle does contribute a factor in the competition, the outcome is entirely dependent on differences between axons. These differences could be related to activity. The more active axon might be better able to take up trophic factor or resist a toxin. Such positive and negative competitive interactions have been demonstrated at nerve-muscle synapses in culture, although not in vivo.

Nevertheless, the muscle could play a selective role in synapse elimination rather than just providing a broadly distributed signal. For example, the more active axon might trigger a signal from the muscle fiber that strengthens its adhesive interactions with the synaptic cleft, whereas the less active axon might elicit a signal that weakens those interactions.

The complexity of the brain makes direct demonstration of synapse elimination problematic, but electrophysiological evidence from many parts of the central nervous system indicates that synapse elimination is widespread. In autonomic ganglia and cerebellar Purkinje cells, synapse elimination has been documented directly and its rules seem similar to those found at neuromuscular junctions. Individual axons withdraw from some postsynaptic cells while simultaneously increasing the size of the synapses they form with other neurons.

Glial Cells Regulate Both Formation and Elimination of Synapses

Classical studies of synapse formation and maturation focused, logically enough, on the pre- and postsynaptic partners. More recently, however, there has been a growing appreciation of the role played by a third type of cell: the glial cells that cap nerve terminals. Schwann cells are the glia at neuromuscular junctions, and astrocytes are the glia at central synapses. Both have been implicated in synapse formation and maturation.

The most penetrating analyses were performed by the late Ben Barres and his colleagues. They devised methods to culture neurons in defined media and in the complete absence of nonneuronal cells. Using this system, they found that neurons formed few synapses when cultured in isolation but many when astrocytes were present (Figure 48–20). The astrocytes provide multiple signals to neurons. Some, such as thrombospondin, promote postsynaptic maturation, whereas others, such as cholesterol, promote presynaptic maturation.

Another glial type, the microglial cell, also plays critical roles. Microglia are relatives of macrophages and monocytes in other tissues, sharing their ability to eliminate dead cells or debris. Initially thought to be primarily involved in the brain's response to damage, they have now been found to phagocytose synaptic terminals during the period of synapse elimination. True to their phagocytic origins, they use the complex system of complement factors, initially studied in the context of immunity, to target terminals; the targeting is activity dependent, providing a possible mechanism for the activity dependence of synapse elimination (Figure 48–21). An intriguing possibility is that dysregulation of microglial pruning contributes to synaptic loss in neurodegenerative diseases such as Alzheimer disease and schizophrenia (see Chapters 60 and 64).

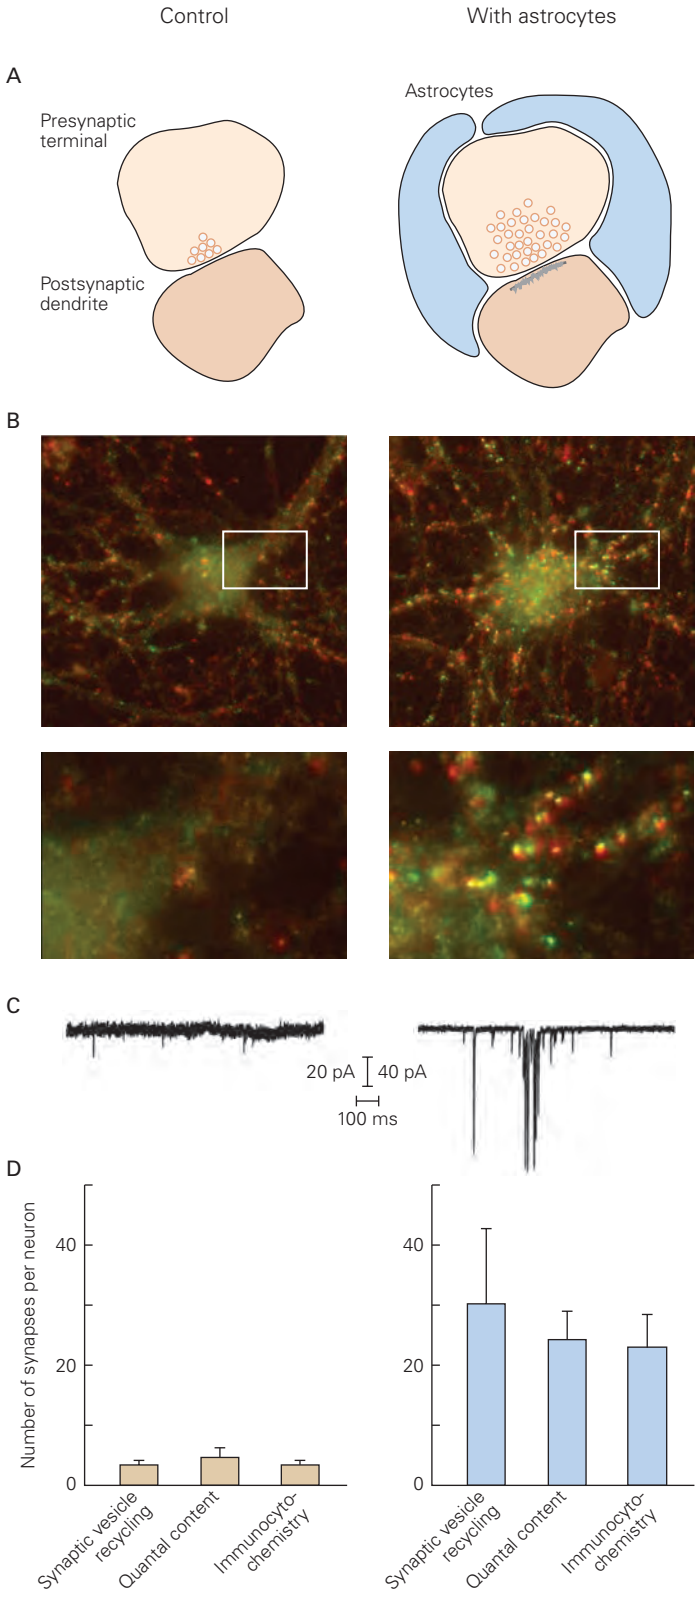

Figure 48–20 Signals from astrocytes promote synapse formation.

A. Astrocytes promote the maturation of both pre- and postsynaptic elements of the synapse.

B. Neurons cultured with astrocytes form more synapses, as assessed by expression of synaptic proteins (**yellow dots**). (Reproduced, with permission, from Ben A. Barres.)

C. Retinal neurons cultured with astrocytes form a greater number of synapses, as shown by increased transmitter release.

D. Synapse formation is enhanced in the presence of astrocytes by three measures.

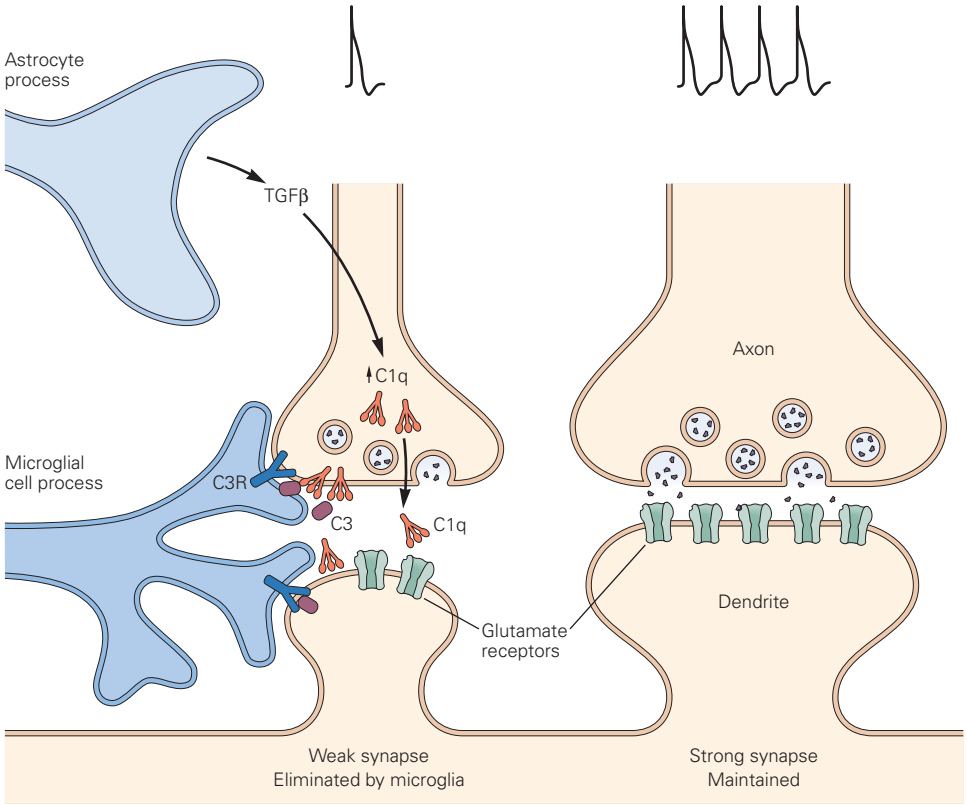

Figure 48–21 Microglia prune synapses, contributing to synapse elimination. Microglia engulf weak synapses. The engulfment is stimulated by complement components such as C1q, which tags the inactive terminal and marks it for removal by a process involving interaction of C3 with the complement receptor C3R on the microglia. Astrocytes play a role by secreting transforming growth factor β (TGFβ), which promotes production of C1q. (Adapted, with permission, from Allen 2014. Permission conveyed through Copyright Clearance Center, Inc.)

The roles of glia in synaptic development are only beginning to be worked out, and the assignments of astrocytes and microglia to synapse formation and elimination are clearly oversimplifications. Both glial types are involved in both processes, and Schwann cells may play both roles at the neuromuscular junction. Moreover, a complex set of signals passes between astrocytes and microglia, and between neurons and glia, all of which contribute to development and are at risk of going awry in brain disorders.

Highlights

1. Elaborate guidance mechanisms bring axons to appropriate target areas, but within those areas they still need to choose synaptic partners, often from among many neuronal types. Multiple mechanisms guide these choices.
2. Matching cell-surface recognition molecules on pre- and postsynaptic partners provide one prevalent mechanism for synaptic specificity. They include members of the cadherin, immunoglobulin, and leucine-rich repeat protein superfamilies. Individual members are selectively expressed by subsets of neurons and exhibit selective binding. Often, the binding is homophilic, biasing connectivity in favor of partners expressing the same molecule.
3. Other mechanisms promoting specificity include selective interactions among axons, the ability of some axons to convert their targets to the appropriate types, and selective elimination of inappropriate contacts.
4. At present, it remains unknown how many molecular species are required to wire up neural circuits in the mammalian brain. At one time, it seemed that molecular complexity might need to approach the complexity of circuits, but it is more likely that a few hundred recognition molecules will suffice, given their combinatorial use, as well as deployment of the same gene at multiple times and in multiple regions.

5. Spatial constraints that enhance specificity include restriction of axons and dendrites to particular laminae within a target region—thereby restricting their choice of partners—and restriction of synapses of particular types to defined domains on the target cell surface.
6. Some specificity mechanisms do not require the partners to be electrically active, but in many cases, activity-dependent mechanisms sharpen specificity. Activity can be spontaneous, early in development, or driven by experience at later stages.
7. The skeletal neuromuscular junction, at which the axon of a motor neuron synapses on a muscle fiber, has been a favored preparation for working out principles of synaptic development. A key finding is that multiple interactions between the synaptic partners are required for the formation, maturation, and maintenance of the synapse.
8. Motor neurons and muscle fibers can express genes encoding pre- and postsynaptic components, respectively, in each other's absence, but they exert profound influences on the levels and distribution of these components in their partners. Thus, signals between synaptic partners are best viewed as organizers rather than inducers.
9. At the neuromuscular junction, a layer of basal lamina occupies the synaptic cleft between the motor nerve terminal and the postsynaptic membrane. Nerve and muscle secrete signaling molecules into the cleft, where they become stabilized and organize differentiation.
10. A key nerve-derived organizer of postsynaptic differentiation is agrin. It acts through the receptors MuSK and LRP4 to cluster acetylcholine receptors and other postsynaptic components beneath the nerve terminal. Nerve-evoked activity also affects postsynaptic differentiation by modulating expression of postsynaptic components. Key muscle-derived organizers of presynaptic differentiation include members of the laminin and fibroblast growth factor families.
11. Central synapses develop in ways similar to those discovered at the neuromuscular junction. Many central synaptic organizers have now been discovered, including neuroligins, neurexins, protein tyrosine phosphatases, leucine-rich repeat proteins, and numerous others.
12. Many of the synapses that form initially in both the peripheral and central nervous systems are subsequently eliminated, generally by competitive, activity-dependent mechanisms. The consequence is that as circuits mature, the number of inputs a neuron receives may decrease dramatically, but the size and strength of the remaining inputs increase even more dramatically.
13. Along with pre- and postsynaptic partners, glial cells play key roles at the synapse. In particular, both astrocytes and microglial cells receive signals from and send signals to developing synaptic partners, with these signals contributing to synapse formation, maturation, maintenance, and elimination.

Experience and the Refinement of Synaptic Connections

The human nervous system is functional at birth—newborn babies can see, hear, breathe, and suckle. However, the capabilities of human infants are quite rudimentary compared to those of other species. Wildebeest calves can stand and run within minutes of birth, and many birds can fly shortly after they hatch from their eggs. In contrast, a human baby cannot lift its head until it is 2 months old, cannot bring food to its mouth until it is 6 months old, and cannot survive without parental care for a decade.

What accounts for the delayed maturation of our motor, perceptual, and cognitive abilities? One main factor is that the embryonic connectivity of the nervous system, discussed in Chapters 45 through 48, is only a "rough draft" of the neural circuits that exist in our adult selves. Embryonic circuits are refined by sensory stimulation—our experiences. This two-part sequence—genetically determined connectivity followed by experience-dependent reorganization—is a common feature of mammalian neural development, but in humans, the second phase is especially prolonged.

At first glance, this delay in human neural development might seem dysfunctional. It does exact a toll,

but it also provides an advantage. Because our mental abilities are shaped largely by experience, we gain the ability to custom fit our nervous systems to our individual bodies and unique environments. It has been argued that it is not just the large size of the human brain but also its experience-dependent maturation that makes our mental capabilities superior to those of other species.

The plasticity of the nervous system in response to experience endures throughout life. Nevertheless, periods of heightened susceptibility to modification, known as *sensitive periods*, occur at particular times in development. In some cases, the adverse effects of deprivation or atypical experience during circumscribed periods in early life cannot easily be reversed by providing appropriate experience at a later age. Such periods are referred to as *critical periods*. As we shall see, new discoveries are blurring the distinction between sensitive and critical periods, so we will use the term "critical periods" to refer to both.

Behavioral observations have helped us appreciate critical periods. Imprinting, a form of learning in birds, is one of the most striking illustrations of a lifelong behavior established during a critical period. Just after hatching, birds become indelibly attached, or imprinted, to a prominent moving object in their environment and follow it around. This is typically their mother, but it could be an experimenter who is near the newborn chick. The process of imprinting is important for the protection of the hatchling. Although the attachment is acquired rapidly and persists, imprinting can only occur during a critical period soon after hatching—in some species, only a few hours.

In humans, critical periods are evident in the ways children acquire the capacities to perceive the world around them, learn a language, or form social relationships. A 5-year-old child can quickly and effortlessly learn a second language, whereas a 15-year-old adolescent may become fluent but is likely to speak with an accent, even if he lives to be 90 years old. Likewise, deaf children fitted with a cochlear implant during the first 3 to 4 years of life generally acquire and understand spoken language well, whereas neither production nor understanding may ever be normal following implantation at later ages. Such critical periods demonstrate that experience-dependent neural development is concentrated in, although certainly not confined to, early postnatal life.

We begin this chapter by examining the evidence that early experience shapes a range of human mental capacities, from our ability to make sense of what we see to our ability to engage in appropriate social interactions. The neural basis of these experiential effects has been analyzed in numerous parts of the brains of experimental animals, including the auditory, somatosensory, motor, and visual systems. Here, rather than surveying multiple systems, we will focus primarily on the visual system because research on this system has provided a particularly rich understanding of how experience shapes neural circuitry. We will see that experience is needed to refine patterns of synaptic connections and to stabilize these patterns once they have formed. Finally, we will consider recent evidence that critical periods in many systems are less restrictive than once thought and, in some cases, can be extended or even "reopened."

Understanding critical periods in childhood and the extent to which they can be reopened in adulthood has many important practical consequences. First, much educational policy is based on the idea that early experience is crucial, so it is important to know exactly when a particular form of enrichment will be optimally beneficial. Second, medical treatment of many childhood conditions, such as congenital cataracts or deafness, is now predicated on the idea that early intervention is imperative if long-lasting deficits are to be avoided. Third, there is increasing suspicion that some behavioral disorders, such as autism, may be caused by impairment of reorganization of neural circuits during critical periods. Finally, the possibility of reopening critical periods in adulthood is leading to new therapeutic approaches to neural insults, such as stroke, that previously were thought to have irreversible consequences.

Development of Human Mental Function Is Influenced by Early Experience

Early Experience Has Lifelong Effects on Social Behaviors

One of the first indications that early social and perceptual experiences have irreversible consequences for human development came from studies of children who had been deprived of these experiences early in life. In rare cases, children abandoned in the wild and later returned to human society have also been studied. As might be expected, these children were socially maladjusted, but surprisingly, the defects proved to persist throughout life.

In the 1940s, the psychoanalyst René Spitz provided more systematic evidence that early interactions with other humans are essential for normal social development. Spitz compared the development of infants raised in a foundling home with the development

of infants raised in a nursing home attached to a women's prison. Both institutions were clean and both provided adequate food and medical care. The babies in the prison nursing home were all cared for by their mothers, who, although in prison and away from their families, tended to shower affection on their infants in the limited time allotted to them each day. In contrast, infants in the foundling home were cared for by nurses, each of whom was responsible for several babies. As a result, children in the foundling home had far less contact with other humans than did those in the prison's nursing home.

The two institutions also differed in another respect. In the prison nursing home, the cribs were open, so that the infants could readily watch other activities in the ward; they could see other babies play and observe the staff go about their business. In the foundling home, the bars of the cribs were covered by sheets that prevented the infants from seeing outside. In reality, the babies in the foundling home were living under conditions of severe sensory and social deprivation.

Infants at the two institutions were followed through their early years. At the end of the first 4 months, the infants in the foundling home fared better on several developmental tests than those in the prison nursing home, suggesting that intrinsic factors did not favor the infants in the prison nursing home. But by the end of the first year, the motor and intellectual performance of the children in the foundling home had fallen far below that of children in the prison nursing home. Many of the children in the foundling home had developed a syndrome that Spitz called *hospitalism* and is now sometimes called *anaclitic depression*. These children were withdrawn and displayed little curiosity or gaiety. Moreover, their defects extended beyond emotional and cognitive signs. They were especially prone to infection, implying that the brain exerts complex controls over the immune system as well as behavior. By their second and third years, children in the prison nursing home were similar to children raised in normal families at home—they were agile, had a vocabulary of hundreds of words, and spoke in sentences. In contrast, the development of children in the foundling home was still further delayed—many were unable to walk or to speak more than a few words.

More recent studies of other similarly deprived children have confirmed these conclusions and shown that the defects are long-lasting. Longitudinal studies of orphans who were raised for several years in large impersonal institutions with little or no personal care, then adopted by caring families, have been especially revealing. Despite every effort of the adoptive parents, many of the children were never able to develop appropriate, caring relationships with family members or peers (Figure 49–1A). More recent imaging studies have revealed defects in brain structure correlated with, and presumably due to, this deprivation (Figure 49–1B).

As compelling as these observations are, it is difficult to derive definitive conclusions from them. An influential set of studies that extended the analysis of social behavior to monkeys was carried out in the 1960s by two psychologists, Harry and Margaret Harlow. The Harlows reared newborn monkeys in isolation for 6 to 12 months, depriving them of contact with their mothers, other monkeys, or people. At the end of this period, the monkeys were physically healthy but behaviorally devastated. They crouched in a corner of their cage and rocked back and forth like autistic children (Figure 49–1C). They did not interact with other monkeys, nor did they fight, play, or show any sexual interest. Thus, a 6-month period of social isolation during the first 18 months of life produced persistent and serious disturbances in behavior. By comparison, isolation of an older animal for a comparable period was found to be without such drastic consequences. These results confirmed, under controlled conditions, the critical influence of early experience on later behavior. For ethical reasons, these studies would not be possible today.

Development of Visual Perception Requires Visual Experience

The dramatic dependence of the brain on experience and the ability of that experience to shape perception is evident in people born with cataracts. Cataracts are opacities of the lens that interfere with the optics of the eye but not directly with the nervous system; they are easily removed surgically. In the 1930s, it became apparent that patients who had congenital binocular cataracts removed after the age of 10 years experienced permanent deficits in visual acuity and had difficulties perceiving shape and form. In contrast, when cataracts that develop in adults are removed decades after they form, normal vision returns immediately.

Likewise, children with *strabismus* (crossed eyes) do not have normal depth perception (*stereopsis*), an ability that requires the two eyes to focus on the same location at the same time. They can acquire this ability if their eyes are aligned surgically during the first few years of life, but not if surgery occurs later in adolescence. As a result of these observations, congenital cataracts are now usually removed, and strabismus is corrected surgically, in early childhood. Over the

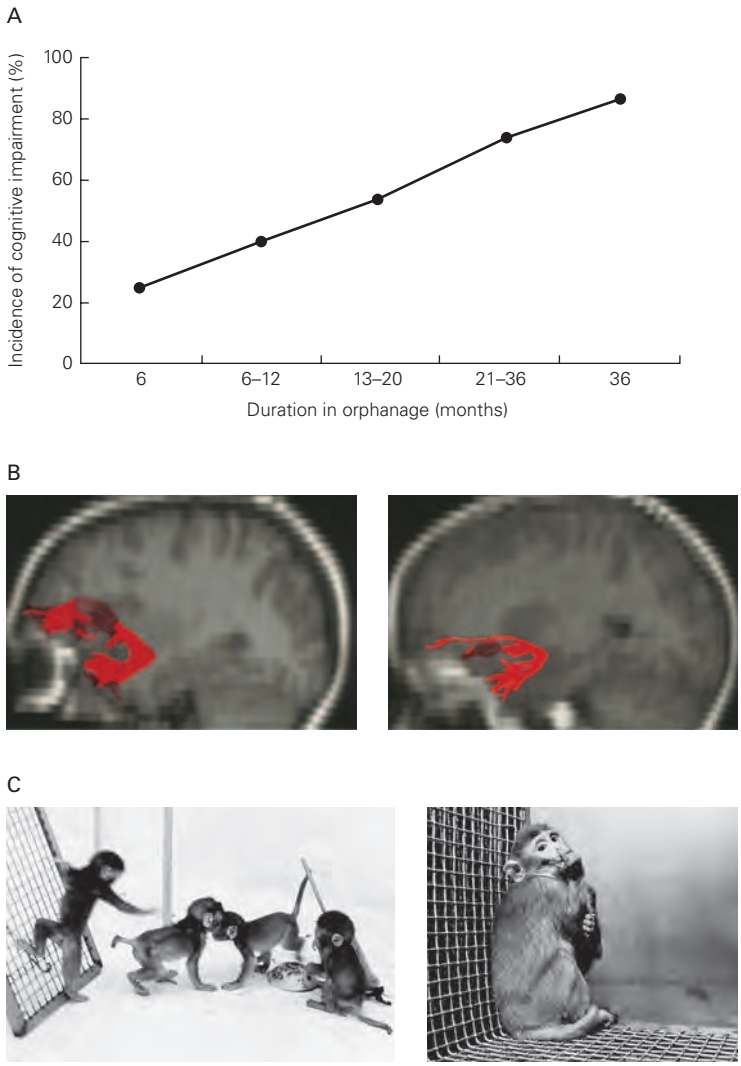

Figure 49–1 Early social deprivation has a profound impact on later brain structure and behavior.

A. Neurocognitive dysfunction is evident in children raised under conditions of social deprivation in orphanages. The incidence of cognitive impairment increases with the duration of stay in the orphanage. (Adapted from Behen et al. 2008.)

B. Diffusion tensor magnetic resonance imaging (MRI) scans show a well-developed and robust uncinate fasciculus (**red region**) in a normal child (*left*), whereas in a socially deprived child (*right*), it is thin and poorly organized. C. Early social interactions impact later social behavior patterns. Monkeys reared in the presence of their siblings acquire social skills that permit effective interactions in later life (*left*). A monkey reared in isolation never acquires the capacity to interact with others and remains secluded and isolated in later life (*right*). (Source: Harry F. Harlow. Used with permission.)

past five decades, researchers have elucidated structural and physiological underpinnings of these critical periods.

Development of Binocular Circuits in the Visual Cortex Depends on Postnatal Activity

Because sensory experience of the world is transformed into patterns of electrical activity in the brain, one might imagine that electrical signals in neural circuits affect the brain's circuitry. But is this true? And if it is true, what changes occur, and how does activity trigger them?

Our most detailed understanding of these links comes from studies of the neural circuits that mediate binocular vision. The key figures in the early phases of this work were David Hubel and Torsten Wiesel. Following their pioneering studies on the structural and functional organization of the visual cortex in cats and monkeys (Chapter 23), they undertook another set of studies on how experience affects the circuits they had delineated.

Visual Experience Affects the Structure and Function of the Visual Cortex

In one influential study, Hubel and Wiesel raised a monkey from birth to 6 months of age with one eyelid sutured shut, thus depriving the animal of vision in that eye. When the sutures were removed, it became clear that the animal was blind in the deprived eye, a condition called *amblyopia*. They then performed electrophysiological recordings from cells along the visual

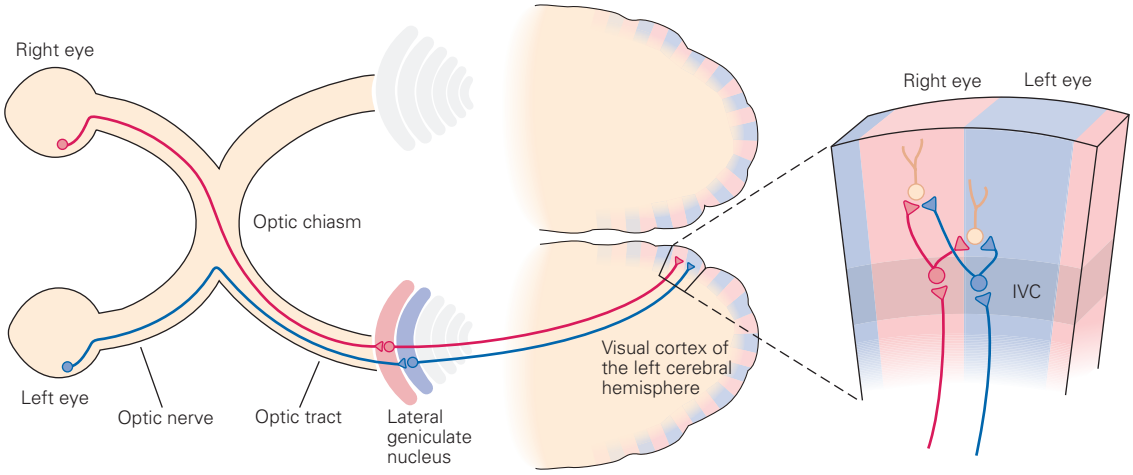

Figure 49–2 Afferent pathways from the two eyes project to discrete columns of neurons in the visual cortex. Retinal ganglion neurons from each eye send axons to separate layers of the lateral geniculate nucleus. The axons of neurons in this nucleus project to neurons in layer IVC of the primary visual cortex, which is organized in alternating sets of ocular dominance columns; each column receives input from only one eye. The axons of the neurons in layer IVC project to neurons in adjacent columns as well as to neurons in the upper and lower layers of the same column. As a result, most neurons in the upper and lower layers of the cortex receive information from both eyes.

pathway to determine where the defect arose (Figure 49–2). They found that retinal ganglion cells in the deprived eye, as well as neurons in the lateral geniculate nucleus that receive input from the deprived eye, responded well to visual stimuli and had essentially normal receptive fields.

In contrast, cells in the visual cortex were fundamentally altered. In the cortex of normal animals, most neurons are responsive to binocular input. In animals that had been monocularly deprived for the first 6 months, most cortical neurons did not respond to signals from the deprived eye (Figure 49–3). The few cortical cells that were responsive were not sufficient for visual perception. Not only had the deprived eye lost its ability to drive most cortical neurons, but little recovery ever occurred: The loss was permanent and irreversible.

Hubel and Wiesel went on to test the effects of visual deprivation imposed for shorter periods and at different ages. They obtained three types of results, depending on the timing and duration of the deprivation. First, monocular deprivation for a few weeks shortly after birth led to loss of cortical responses from the deprived eye that was reversible after the eye had been opened, especially if the opposite eye was then closed to encourage use of the initially deprived eye. Second, monocular deprivation for a few weeks during the next several weeks also resulted in a substantial loss of cortical responsiveness to signals from the deprived eye, but in this case, the effects were irreversible. Finally, deprivation in adults, even for periods of many months, had no effect on the responses of cortical cells to signals from the deprived eye or on visual perception. These results demonstrated that the cortical connections that control visual perception are established within a critical period of early development.

Are there anatomical correlates of these functional defects? To address this question, we need to recall three basic facts about the anatomy of the visual cortex (Figure 49–2). First, inputs from the two eyes remain segregated in the lateral geniculate nucleus. Second, the geniculate inputs carrying information from the two eyes to the cortex terminate in alternating columns, termed *ocular dominance columns*. Third, lateral geniculate axons terminate on neurons in layer IVC of the primary visual cortex; convergence of input from the two eyes on a common target cell occurs at the next stage of the pathway, in cells above and below layer IVC.

To examine whether the architecture of ocular dominance columns depends on visual experience early in postnatal life, Hubel and Wiesel deprived newborn animals of vision in one eye and then injected a labeled amino acid into the normal eye. The injected label was incorporated into proteins in retinal ganglion cell bodies, transported along the retinal axons to the lateral geniculate nucleus, transferred to geniculate neurons, and then transported to the synaptic terminals of these axons in the primary visual cortex. After closure of one eye, the columnar array of synaptic terminals relaying input from the deprived eye was reduced, whereas the columnar array of terminals relaying input from the

normal eye was expanded (Figure 49–4). Thus, sensory deprivation early in life alters the structure of the cerebral cortex.

How are these striking anatomical changes brought about? Does sensory deprivation alter ocular dominance columns after they have been established, or does it interfere with their formation? A columnar organization of the visual cortex is already evident by birth in monkeys, although the mature pattern is not achieved until several weeks after birth (Figure 49–5). Only at this time do the terminals of fibers from the lateral geniculate nucleus become completely segregated in the cortex. Because the inputs are partially but not completely segregated at the time visual deprivation exerts its effects, we can conclude that the deprivation perturbs the ability of the inputs to acquire their mature pattern. We shall return to the question of what leads to the initial, experience-independent phases of segregation in a later section of this chapter.

Patterns of Electrical Activity Organize Binocular Circuits

How does activity lead to maturation of ocular dominance columns? The crucial factor may be the

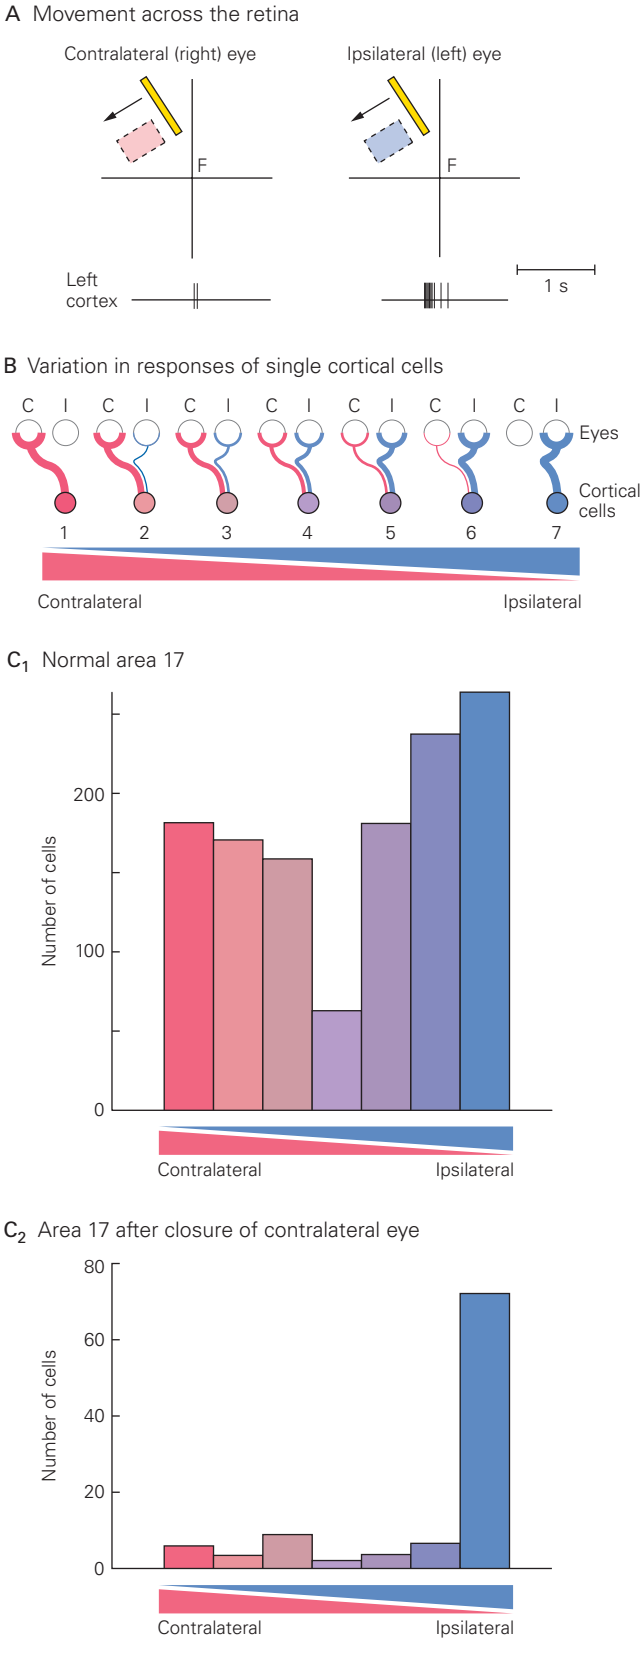

Figure 49–3 (Right) Responses of neurons in the primary visual cortex of a monkey to visual stimuli. (Adapted from Hubel and Wiesel 1977.)

A. A diagonal bar of light is moved leftward across the visual field, traversing the receptive fields of a binocularly responsive cell in area 17 of visual cortex. Receptive fields measured through the right and left eye are drawn separately. The receptive fields of the two cells are similar in orientation, position, shape, and size, and respond to the same form of stimulus. Recordings (below) show that the cortical neuron responds more effectively to input from the ipsilateral eye. (Abbreviation: **F**, fixation point.)

B. The responses of individual cortical neurons in area 17 can be classified into seven groups. Neurons receiving input only from the contralateral eye (**C**) fall into group 1, whereas neurons that receive input only from the ipsilateral eye (**I**) fall into group 7. Other neurons receive inputs from both eyes, but the input from one eye may influence the neuron much more than the other (groups 2 and 6), or the differences may be slight (groups 3 and 5). Some neurons respond equally to input from both eyes (group 4). According to these criteria, the cortical neuron shown in part A falls into group 6.

C. Responsiveness of neurons in area 17 to stimulation of one or the other eye. **1.** The responses of more than 1,000 neurons in area 17 in the left hemisphere of normal adult and juvenile monkeys. Neurons in layer IV that normally receive only monocular input have been excluded. **2.** The responses of neurons in the left hemisphere of a monkey in which the contralateral (right) eye was closed from the age of 2 weeks to 18 months and then reopened. Most neurons respond only to stimulation of the ipsilateral eye.

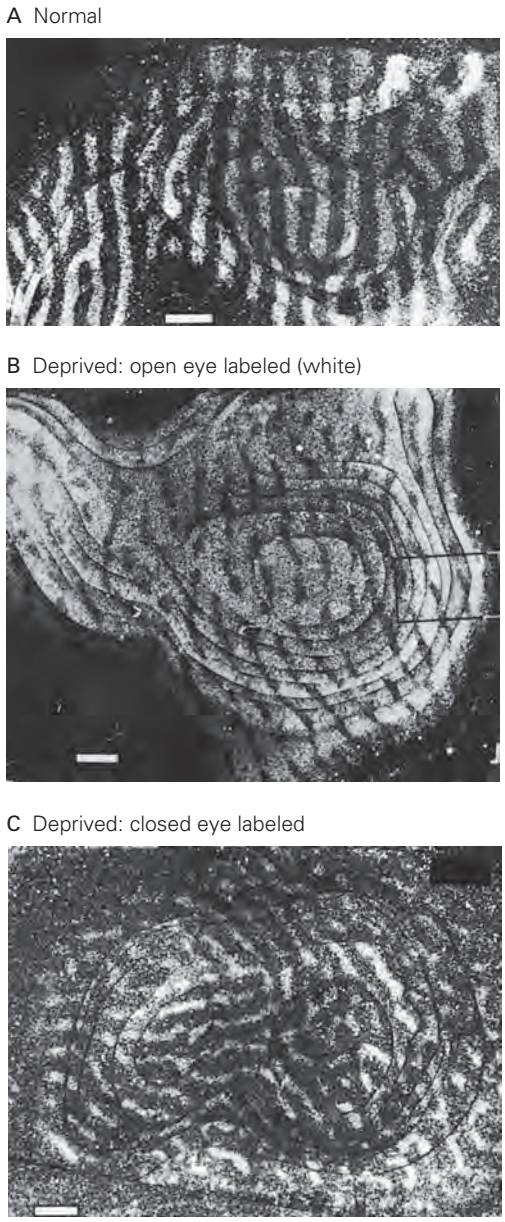

Figure 49–4 Visual deprivation of one eye during a critical period of development reduces the width of the ocular dominance columns for that eye. (Scale bars = 1 mm) (Adapted, with permission, from Hubel, Wiesel, and LeVay 1977.)

A. A tangential section through area 17 of the right hemisphere of a normal adult monkey, 10 days after one eye was injected with a radiolabeled amino acid. Radioactivity is localized in stripes (**white**) in layer IVC of the visual cortex, indicating sites of termination of the axons from the lateral geniculate nucleus that carry input from the injected eye. The alternating unlabeled (**dark**) stripes indicate sites of termination of the axons carrying signals from the uninjected eye. Labeled and unlabeled stripes are of equal width.

B. A comparable section through the visual cortex of an 18-month-old monkey whose right eye had been surgically closed at 2 weeks of age. Label was injected into the left (open) eye. The wider (**white**) stripes are the labeled terminals of afferent axons carrying signals from the open eye; the narrow (**dark**) stripes are terminals of axons with input from the closed eye.

C. A section comparable to that in part B from an 18-month-old animal whose right eye had been shut at 2 weeks. Label was injected into the closed eye, giving rise to narrow (**white**) stripes of labeled axon terminals and wide (**dark**) stripes of unlabeled terminals.

differences in the proportion of inputs from each eye that converge on common target cells at birth. If by chance the fibers conveying input from one eye are initially more numerous in one local region of cortex, those axons may have an advantage, leading to further segregation.

How might this occur? An attractive idea, based on a theory first proposed in the 1940s by Donald Hebb, is that synaptic connections are strengthened when pre- and postsynaptic elements are active together. In the case of binocular interactions, neighboring axons from the same eye tend to fire in synchrony because they are activated by the same visual stimulus at any instant. The synchronization of their firing means that they cooperate in the depolarization and excitation of a target cell. This cooperative action maintains the viability of those synaptic contacts at the expense of the noncooperating synapses.

Cooperative activity could also promote branching of axons and thus create the opportunity for the formation of additional synaptic connections with cells in the target region. At the same time, the strengthening of synaptic contacts made by the axons of one eye will impede the growth of synaptic inputs from the opposite eye. In this sense, fibers from the two eyes may be said to compete for a target cell. Together,

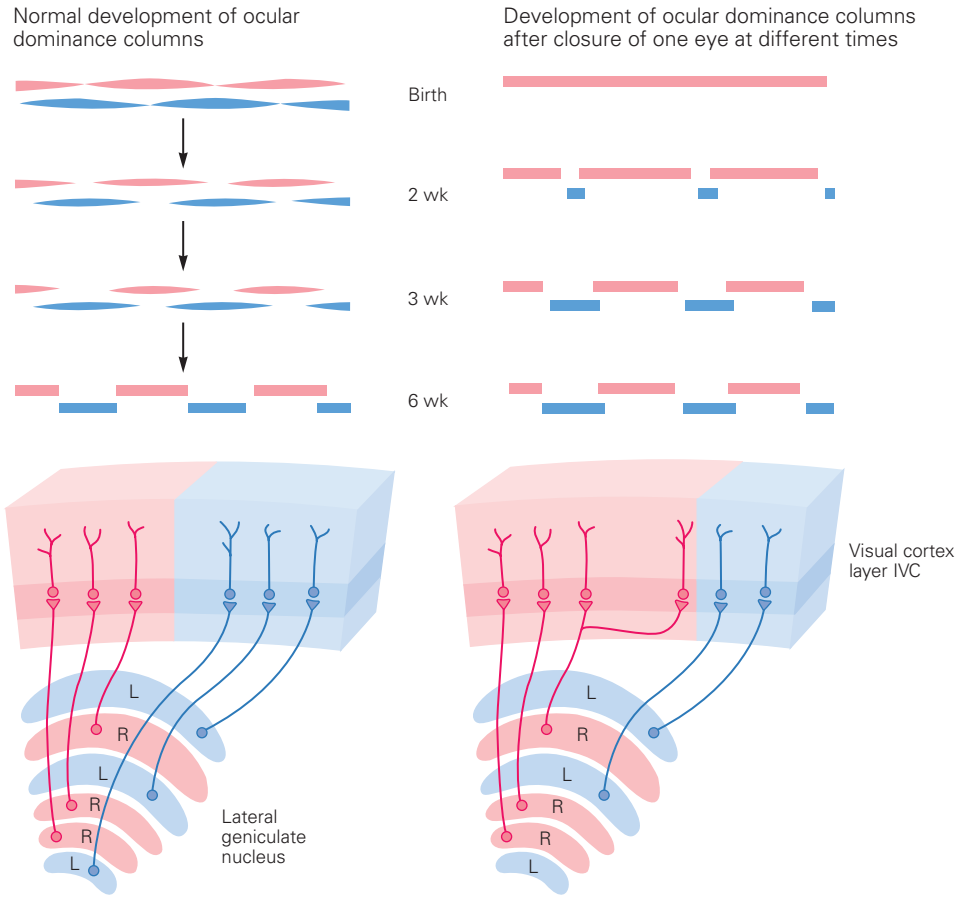

Figure 49–5 The effects of eye closure on the formation of ocular dominance columns. The top diagrams show the gradual segregation of the terminals of lateral geniculate afferents in layer IVC of the visual cortex under normal conditions (*left*) and when one eye is deprived of stimulation (*right*). **Blue domains** represent the areas of termination of inputs from one eye, **red domains** those of the other eye. The lengths of the domains represent the density of the terminals at each point along layer IVC. For clarity, the columns are shown here as one above the other, whereas in reality, they are side by side in the cortex. During normal development, layer IVC is gradually divided into alternating sites of input from each eye. The consequences of depriving sight in one eye depend on the timing of eye closure. Closure at birth leads to dominance by the open eye (**red**) because at this point little segregation has occurred. Closure at 2, 3, and 6 weeks has a progressively weaker effect on the formation of ocular dominance columns because the columns become more segregated with time. (Abbreviations: **L**, left; **R**, right.) (Adapted, with permission, from Hubel, Wiesel, and LeVay 1977.)

cooperation and competition between axons ensure that two populations of afferent fibers will eventually innervate distinct regions of the primary visual cortex with little local overlap.

Competition and cooperation are not simply the outcome of neural activity per se or of differences in absolute levels of activity among axons. Instead, they appear to depend on precise temporal patterns of activity in the competing (or cooperating) axons. The principle was dramatically illustrated by Hubel and Wiesel in a set of studies that examined stereoscopic vision—the perception of depth. The brain normally computes depth perception by comparing the disparity in retinal images between the two eyes. When the eyes are improperly aligned, this comparison cannot be made and stereoscopy is impossible. Such misalignments occur in children who are "cross-eyed," or strabismic. As noted above, this condition can be surgically repaired, but unless the surgery occurs during the first few years of life, the children forever remain incapable of stereoscopy.

Hubel and Wiesel examined the impact of strabismus on the organization of the visual system in cats. To render cats strabismic, the tendon of an extraocular muscle was severed in kittens. Both eyes remained fully functional but misaligned. Inputs from the two eyes that converged on a binocular cell in the visual cortex now carried information about different stimuli

in slightly different parts of the visual field. As a result, cortical cells became monocular, driven by input from one eye or the other but not both (Figure 49–6). Conversely, cortical neurons remained binocularly responsive following binocular visual deprivation, leading to a decrease but not an imbalance in activity arising from the two eyes. These findings suggested to Hubel and Wiesel that disruption of the synchrony of inputs led to competition rather than cooperation, so that cortical cells came to be dominated by one eye, presumably the one that had dominated at the outset.

These physiological studies led investigators to test whether pharmacological blockade of electrical activity in retinal ganglion cells could affect neural connectivity in the visual system. Activity was blocked by injecting both eyes with tetrodotoxin, a toxin that selectively blocks voltage-sensitive Na^+ channels. Signals from the two eyes were generated separately by direct electric stimulation of the bilateral optic nerves. In kittens, ocular dominance columns are not established if activity in retinal ganglion neurons is blocked before the critical period of development. When the two optic nerves were stimulated synchronously, ocular dominance columns still failed to form. Only when the optic nerves were stimulated asynchronously were ocular dominance columns established.

If the development of ocular dominance columns indeed depends on competition between fibers from the two eyes, might it be possible to induce the formation of columns where they normally are not present, simply by establishing competition between two sets of axons? This radical possibility was tested in frogs, where retinal ganglion neurons from each eye project only to the contralateral side of the brain. In normal frogs, afferent fibers from the two eyes do not compete for the same cells, so there is no columnar segregation of afferent inputs. To generate competition, a third eye was transplanted early in larval development into a region of the frog's head near one of the normal eyes. The retinal ganglion neurons of the extra eye extended axons to the contralateral optic tectum. Remarkably, axon terminals from the transplanted and normal eyes segregated, generating a pattern of alternating columns (Figure 49–7).

This finding provided dramatic support for the idea that competition between afferent axons for the same population of target neurons drives their segregation into distinct target territories. The columnar segregation of retinal inputs in the frog brain is dependent on synaptic activity, presumably at the synapses between retinal axons and tectal neurons. Thus, neural activity has powerful roles in fine-tuning visual circuits.

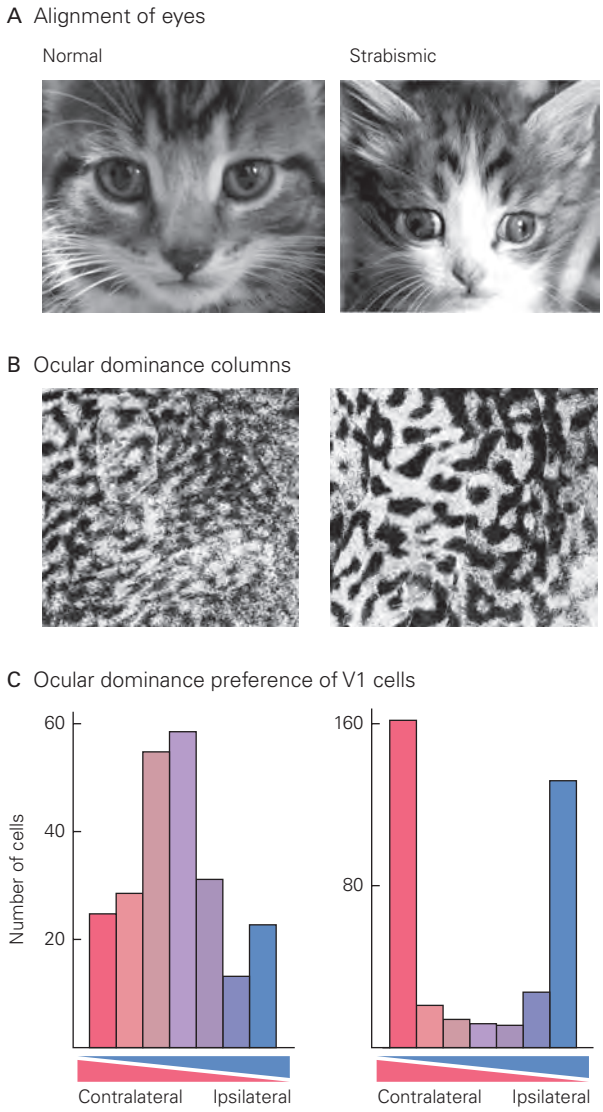

Figure 49–6 Inducing strabismus in kittens impairs the formation of binocular response regions in the primary visual cortex.

A. The eyes of strabismic cats are misaligned. (Photos [*left*] Steve Richardson/Alamy Stock Photo and [*right*] reproduced with permission from Van Sluyters and Levitt 1980.)

B. In strabismic animals, left and right eye domains are more sharply defined, an indication of the paucity of binocular regions. (Reproduced, with permission, from Löwel 1994. Copyright © 1994 Society for Neuroscience.)

C. Strabismic animals have fewer binocularly tuned neurons in the visual cortex. (Reproduced, with permission, from Hubel and Wiesel 1965.)

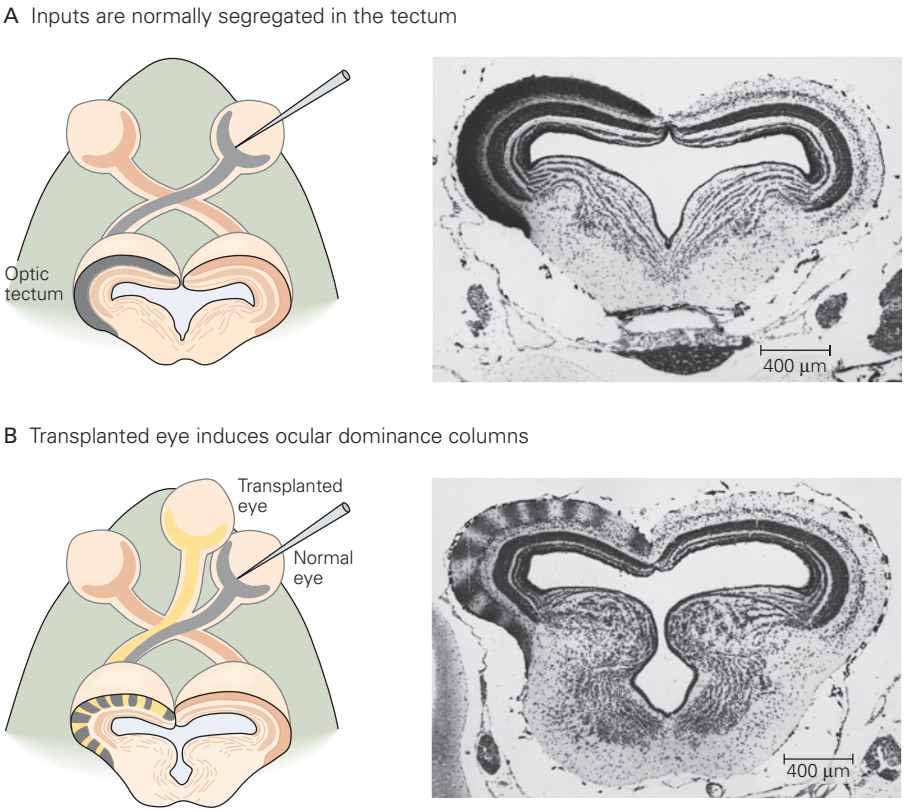

Figure 49–7 Ocular dominance columns can be experimentally induced in a frog by transplantation of a third eye. (Adapted, with permission, from Constantine-Paton and Law 1978. Copyright © 1978 AAAS.)

A. Three days before the transplant, the right eye was injected with a radiolabeled amino acid. The autoradiograph in a coronal section of the hindbrain shows the entire superficial neuropil of the left optic lobe filled with silver grains, indicating the region occupied by synaptic terminals from the labeled (contralateral) eye.

B. Some time after a third eye was transplanted near the normal right eye, the right eye was injected with a radiolabeled amino acid. The autoradiograph shows that the left optic lobe receives inputs from both the labeled eye and the transplanted eye. The normally continuous synaptic zone of the contralateral eye has become divided into alternating dark and light zones that indicate the sites of inputs from each eye.

Reorganization of Visual Circuits During a Critical Period Involves Alterations in Synaptic Connections

The pioneering work of Hubel, Wiesel, and their colleagues showed that early experience is required for the emergence of normal structure and function in the visual cortex. However, the cellular and molecular mechanisms that underlie the critical period remained mysterious. In recent years, many investigators have begun addressing these issues. Much of their work has involved the use of mice, because mice are more amenable to mechanistic analysis than the cats and monkeys studied by Hubel, Wiesel, and their disciples.

Cortical Reorganization Depends on Changes in Both Excitation and Inhibition

Unlike cats and monkeys, most of the mouse visual cortex receives only contralateral input and its binocular region is not divided into ocular dominance columns. Nonetheless, the small binocular region contains a mixture of monocularly and binocularly driven neurons, and closure of the contralateral eye during the critical period for ocular dominance markedly shifts the preference of binocular neurons to inputs from the ipsilateral eye (Figure 49–8).

What converts this early loss of input into a permanent alteration of functional capability? One idea is that thalamic axons carrying information from the deprived eye lose their ability to activate cortical neurons. However, although a decrease in efficacy of the thalamocortical synapse may contribute to this effect, this is not the whole story. Each thalamic axon carries input from only one eye (Figure 49–2). Because loss of responsiveness to the deprived eye occurs only if the other eye remains active, one might imagine that the earliest changes would occur at the first site where inputs from the two eyes have the opportunity to interact. Consistent with this idea, the first physiological changes are not observed in layer IV neurons, each of which receives input from only one eye. Rather, they occur in the binocular neurons of layers II/III and V, which receive convergent input from both right eye– and left eye– driven monocular layer IV neurons. This implies that the loss of cortical responsiveness to the deprived eye results from a circuit alteration rather than from a simple loss of input.

Several possible cellular mechanisms have been proposed to account for these changes in circuitry.

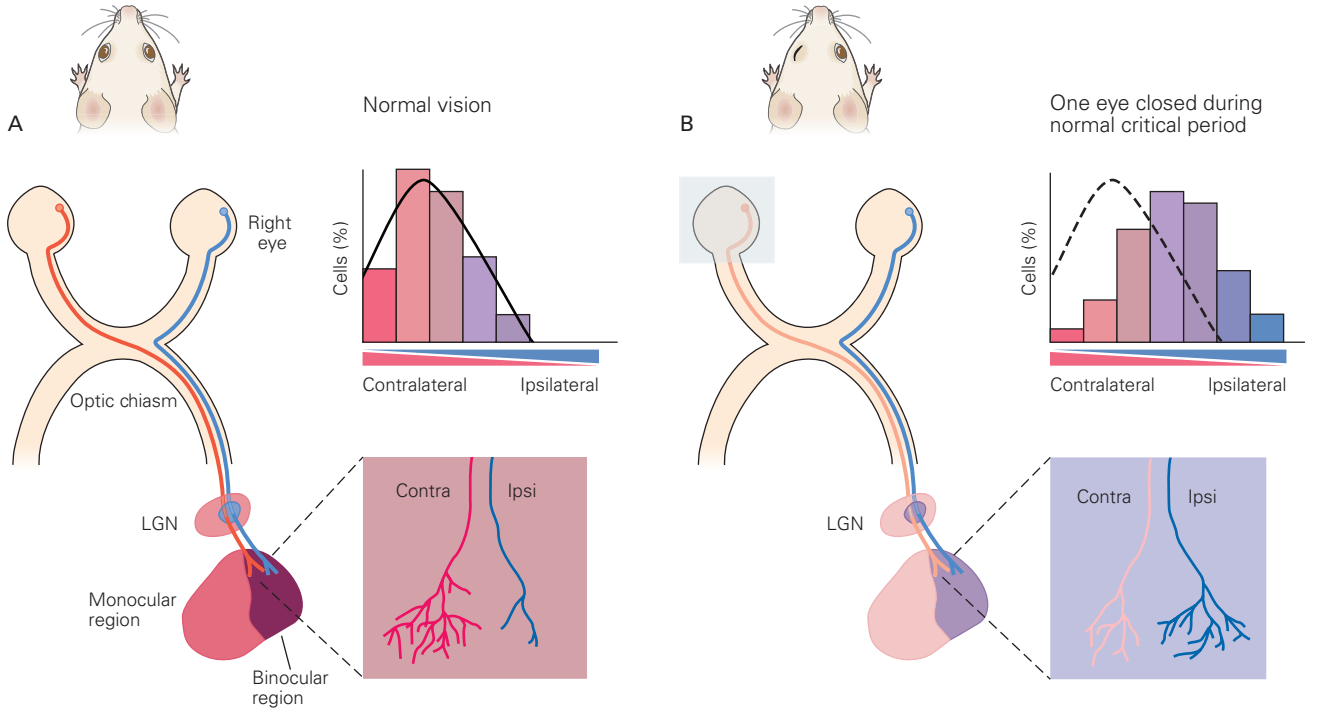

Figure 49–8 A critical period for ocular dominance plasticity is evident in mice. (Adapted, with permission, from Hensch 2005.)

A. The visual cortex in mice contains a small region that receives thalamic (lateral geniculate nucleus [**LGN**]) inputs from both eyes. In this binocular region, most neurons are predominantly responsive to contralateral eye input, fewer respond to binocular inputs, and very few respond to ipsilateral eye input only.

B. When the contralateral eye has been closed during the normal critical period and then reopened, inputs from that eye are underrepresented, and many more neurons respond to binocular or ipsilateral eye input. Eye closure before or after the time of the normal critical period does not elicit the same shift in responsiveness.

First, excitatory synapses within the primary visual cortex may weaken because of the decreased input from the closed eye, perhaps through long-term depression (LTD) (Chapter 53). Second, excitatory synapses carrying input from the open eye may become stronger. Third, the strength of inhibitory synapses may be altered, leading to a net decrease in the level of excitation of cortical neurons by inputs from the closed eye or a net increase in excitation from the open eye. Fourth, neuromodulation within the cortex may tune the circuit in more subtle ways, altering the balance between excitation and inhibition.

Careful analysis of neurons in mouse cortex has provided insight into roles played by some of these mechanisms. During the first few days after closing one eye, responses to input from the closed eye are greatly weakened, with no major effect on inputs from the open eye. The weakening results from a process like LTD or a closely related phenomenon called spike timing–dependent plasticity (STDP). Then, over the following few days, responses to inputs from the open eye become stronger. The increase results from a combination of synaptic changes called long-term potentiation and homeostatic plasticity. Homeostatic plasticity is a circuit mechanism that endeavors to maintain a steady level of input to neurons. In this case, loss of excitatory drive from the closed eye leads to a compensatory increase in excitatory drive from the open eye.

Further studies demonstrated that inhibitory interneurons have an important role in the timing of the critical period. Maturation of inhibitory input onto visual cortical neurons coincides with the beginning of the critical period. Moreover, manipulations that lead to earlier development of γ-aminobutyric acid (GABA) signaling result in advancing the critical period (Figure 49–9). Conversely, delaying GABA signaling delays the period in which monocular deprivation enhances the preference for ipsilateral eye input (Figure 49–9). Together these results and others suggest that a sufficient level of inhibitory input plays a critical role in "gating" the opening of the critical period, whereas excitatory mechanisms may play a more prominent role in enacting the alterations that occur during the critical period.

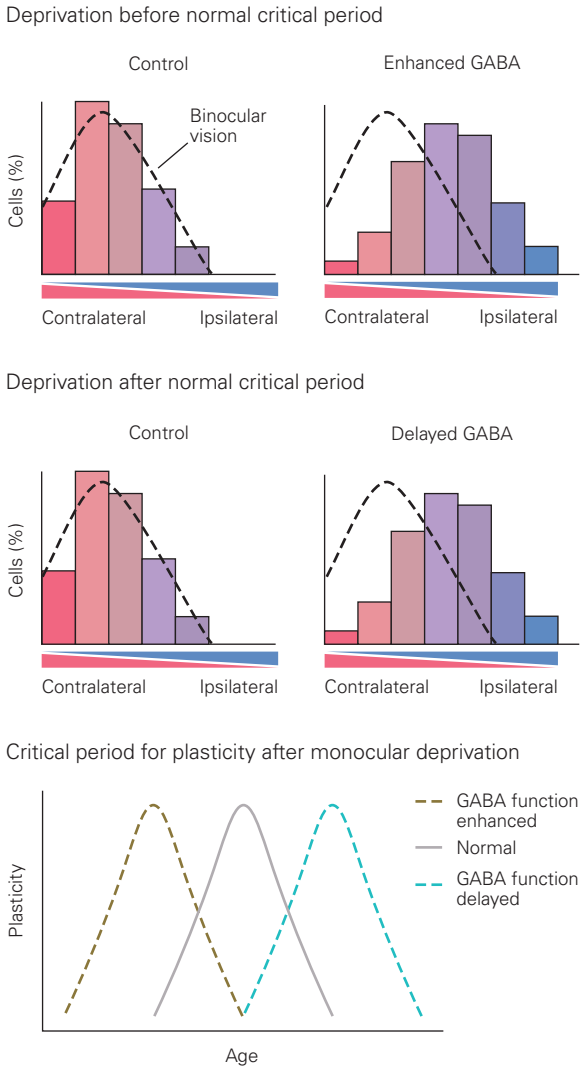

Figure 49–9 The timing of the critical period for ocular dominance plasticity in mice is sensitive to the level of GABAergic neurotransmission. Altering the status of γ-aminobutyric acid (GABA) synthesis and signaling shifts the period in which monocular deprivation can change the response properties of neurons in the visual cortex. Enhancing GABA signaling (through administration of benzodiazepines) shifts the critical period for monocular deprivation to an earlier developmental time. In contrast, delaying GABA signaling (by reducing GABA synthesis genetically and then administering benzodiazepines at a later time) shifts the critical period for monocular deprivation to a later developmental time. (Adapted from Hensch et al. 1998.)

Synaptic Structures Are Altered During the Critical Period

Many studies have sought structural changes that correlate with the altered responsiveness of the visual cortex to input from the closed and open eyes. Particular attention has been paid to dendritic spines as potential sites of plasticity.

Spines are small protrusions from the dendrites of many cortical neurons on which excitatory synapses form. They are dynamic structures, and their appearance and loss are thought to reflect the formation and elimination of synapses. Spine motility is especially marked during early postnatal development, and increases in spine dynamics and number have been associated with changes in behavior.

Striking alterations in the motility and number of dendritic spines on neurons in the mouse visual cortex are observed following closure of one eye. Two days after eye closure in young mice, the motility and turnover of dendritic spines on neurons in the visual cortex increases, suggesting that synaptic connections are beginning to rearrange (Figure 49–10). A few days later, the number of spines begins to change; the number of spines on the apical dendrites of pyramidal neurons decreases initially, but after longer periods of deprivation increases again.

These alterations in spine motility and number can be correlated with three known features of the critical period. First, rather than occurring in layer IV, the changes occur primarily in superficial and deep layers of the cortex, where binocular cells lie. Second, they occur only in the portion of the visual cortex that normally receives binocular input. Third, they fail to occur following eye closure in adult mice (Figure 49–10).

Together, these results support a linkage of spine dynamics with critical period plasticity. According to one model, spine motility may result from the imbalance of inputs to binocular neurons from the open and closed eyes, and it may reflect the first stages in synaptic rearrangement. In turn, the loss of spines, and presumably of synapses, corresponds in time and space to the loss of input from the closed eye and may provide a structural basis for the permanence of this loss. The later growth of new spines occurs as or after responsiveness to the open eye increases and may underlie the adaptive rearrangement that permits the cortex to make the best use of the input available to it.

Thalamic Inputs Are Remodeled During the Critical Period

How are local changes in spines related to the large-scale structural changes in ocular dominance columns

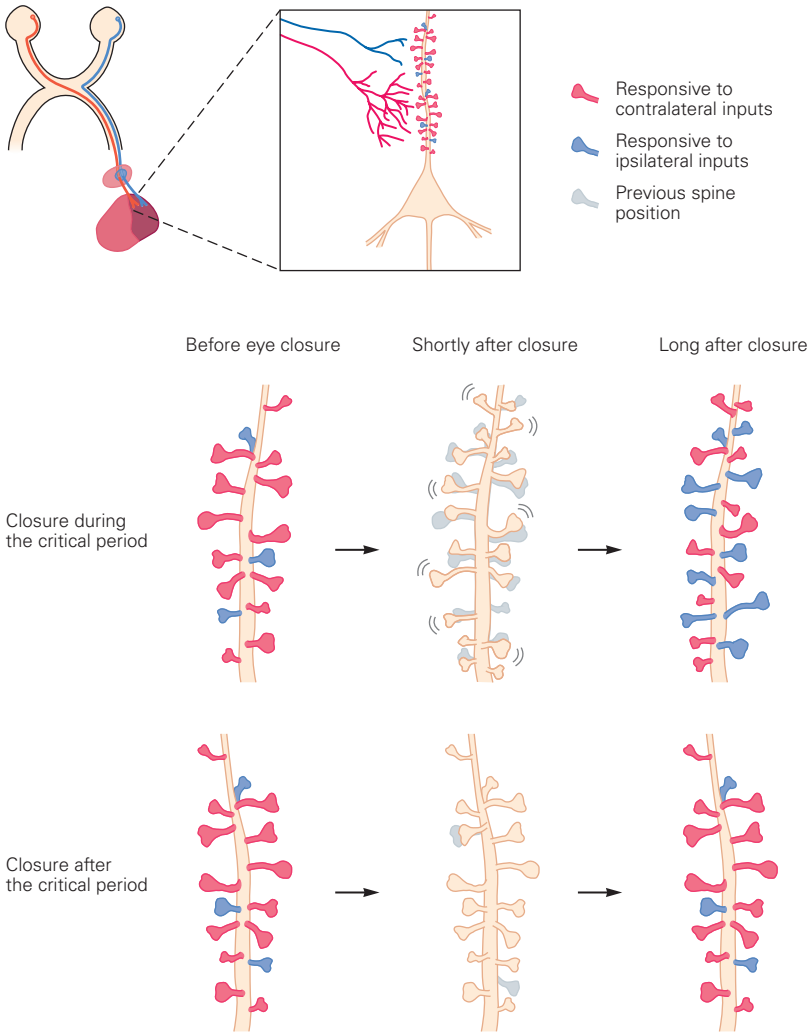

Figure 49–10 The motility of dendritic spines in the mouse visual cortex changes after one eye is closed. The dendrites of pyramidal neurons in the visual cortex have many spines, the density of which remains comparatively constant under normal conditions. Closure of one eye (contralateral in this example) during the critical period for binocular development enhances the motility of dendritic spines and, over time, results in an increase in the proportion of spines that receive synaptic input from the open eye. Similar changes in spine motility are not observed if the eye is closed after the critical period. (Adapted from Oray, Majewska, and Sur 2004.)

shown in Figure 49–4? When developing axons from the lateral geniculate nucleus first reach the cortex, the terminal endings of several neurons overlap extensively. Each fiber extends a few branches over an area of the visual cortex that spans several future ocular dominance columns. As the cortex matures, axons retract some branches, expand others, and even form new branches (Figure 49–11A).

With time, each geniculate neuron becomes connected almost exclusively to a group of neighboring cortical neurons within a single column. The arbors become segregated into columns through the pruning or retraction of certain axons and the sprouting of others. This dual process of axon retraction and sprouting occurs widely throughout the nervous system during development.

What happens after one eye is closed? Axons from a closed eye are at a disadvantage, and a greater than normal proportion retract. At the same time, axons from the open eye sprout new terminals at sites vacated by fibers that would otherwise convey input from the closed eye (Figure 49–11B). If an animal is deprived of the use of one eye early during the critical period of axonal segregation, the normal processes of axon retraction and outgrowth are perturbed. In contrast, if an animal is deprived of the use of one eye after the ocular dominance columns are almost fully segregated, axons conveying input from the open eye actually sprout collaterals in regions of the cortex that they had vacated earlier (see Figure 49–5).

Initially, it was believed that rearrangements of thalamocortical axons in monocularly deprived animals caused the changes in cortical responsiveness to the open and closed eyes. We now know, through electrophysiological recording and imaging of spines, that physiological changes and synaptic alterations

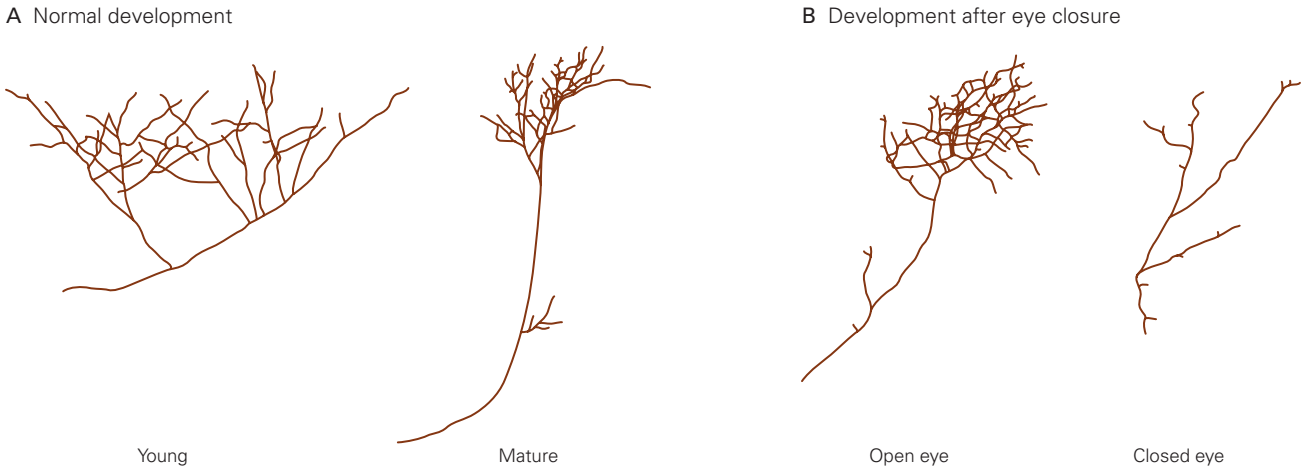

Figure 49–11 The branching of thalamocortical fibers in the visual cortex of kittens changes after the closure of an eye. (Adapted, with permission, from Antonini and Stryker 1993. Copyright © 1993 AAAS.)

A. During normal postnatal development, the axons of lateral geniculate nucleus cells branch widely in the visual cortex. The branching eventually becomes confined to a small region.

B. After one eye is closed, the terminal arbors of neurons in the pathway from that eye are dramatically smaller compared to those of the open eye.

precede the large-scale axonal rearrangements. So rather than causing the physiological changes, axonal remodeling may contribute to making these changes enduring and irreversible. The question then becomes: How do alterations in synaptic structure and function within the cortex lead to alterations in the input?

One idea is that synaptic activity regulates the secretion of neurotrophic factors by cortical neurons. Such factors may then regulate survival of some neurons at the expense of others (Chapter 46) or promote the expansion of some axonal arbors at the expense of others. One such factor, brain-derived neurotrophic factor (BDNF) is synthesized and secreted by cortical neurons, and administering excess BDNF or interfering with its receptor trkB modifies the formation of ocular dominance columns. Nevertheless, interpreting the actions of BDNF is not straightforward. BDNF and trkB signaling affect the cortex in many ways, including enhancing the growth of thalamocortical axons. BDNF can also speed the maturation of inhibitory circuits, which, as noted above, can influence plasticity. It remains unclear whether BDNF is a specific catalyst of the competition that preferentially promotes expansion of some arbors.

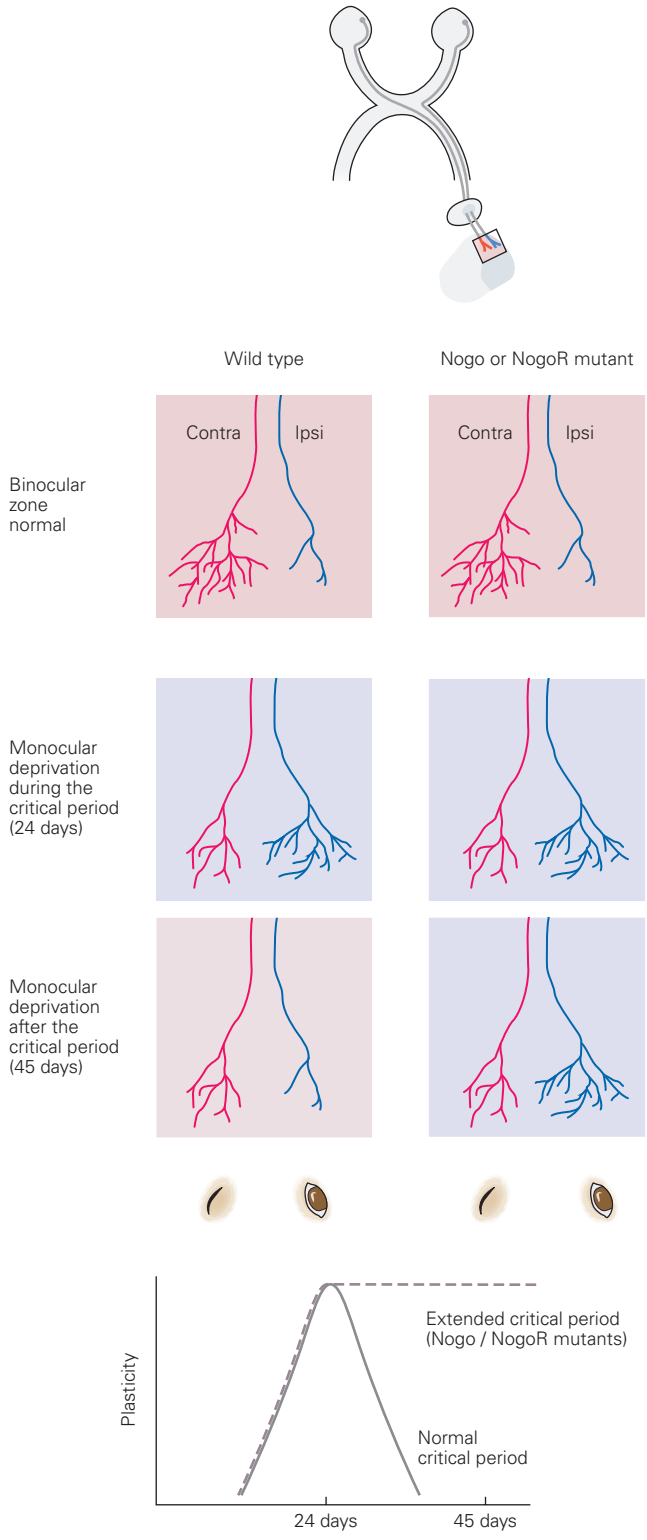
Synaptic Stabilization Contributes to Closing the Critical Period

A hallmark of critical periods is that the interval in which experience affects the development of neural circuits is limited. What brings this period of heightened plasticity to a close?

Since synapses and circuits are labile during critical periods, investigators have sought developmental changes in cortex that could lead to stabilization. One parameter is the state of myelination of axons, which occurs around the time the critical period closes. Formation of myelin creates physical barriers to sprouting and axonal growth. Moreover, as discussed in detail in Chapter 50, myelin contains factors such as Nogo and myelin-associated glycoprotein that actively inhibit growth of axons. In mutant mice lacking Nogo or one of its receptors, NogoR, the critical period remains open into adulthood, suggesting that the appearance of these receptors normally contributes to closing the critical period (Figure 49–12).

Another possible agent of closure is the perineuronal net, a web of glycosaminoglycans that wraps certain classes of inhibitory neurons. These nets form around the time that the critical period closes. Infusion of the enzyme chondroitinase, which digests perineuronal nets, maintains plasticity. Thus, critical periods may close once molecular barriers to synaptic growth and rearrangement come into play.

Additional agents of closure may be intrinsic to the neurons. In Chapter 50, we will see that neuronal growth programs decrease with age, and in Chapter 51, we will describe epigenetic mechanisms that "lock in" experience-dependent patterns of gene expression established in early postnatal life.



Why should there be an end to critical periods? Would it not be advantageous for the brain to maintain its ability to remodel into adulthood? Perhaps not—the ability of our brain to adapt to variations in sensory input, to gradual physical growth (eg, increases in the distance between the eyes affecting binocular correspondence), and to various congenital disorders is a valuable asset. At an extreme, if one eye is lost, it is advantageous to devote all available cortical real estate to the remaining eye. However, one would not want wholesale reorganization, possibly accompanied by loss of skills and memories, if vision through one eye were lost temporarily in adulthood due to disease or injury. So, enhancing plasticity during a critical period may represent an adaptive compromise between flexibility and stability.

Experience-Independent Spontaneous Neural Activity Leads to Early Circuit Refinement

As noted above, the segregation of visual cortex into ocular dominance columns in cats and monkeys begins before the onset of visual experience. What drives this early phase of segregation? One possibility is that axons from the ipsilateral and contralateral eyes bear different molecular labels that lead to their association. A similar mechanism occurs in the formation of the olfactory projection (Chapter 48). However, no such molecule or mechanism has yet been discovered in the visual projection. Instead segregation appears to rely on spontaneous activity, which not only occurs prior to sensory input but also exhibits striking patterning. This mechanism was initially discovered in studies of the lateral geniculate nucleus, whose neurons provide visual input to the visual cortex.

The arbors of retinal ganglion cells from the two eyes are segregated into alternating layers in the lateral geniculate nucleus, much as the projections from this nucleus are segregated in alternating ocular dominance

Figure 49–12 (Left) The critical period for monocular deprivation is extended in mice lacking Nogo signaling. The drawings show arborization patterns of thalamocortical axons carrying signals from contralateral and ipsilateral eyes to the binocular zone in visual cortex. Monocular deprivation during the critical period results in a shift in ocular preference in neurons in the binocular zone in both wild-type mice and mice mutant for Nogo or the Nogo receptor (**NogoR**). After the normal critical period (at 45 days), the shift in ocular preference continues in mice with mutant Nogo-A or the Nogo receptor but not in wild-type mice. The plot shows that elimination of Nogo signaling prevents closure of the critical period. (Adapted from McGee et al. 2005.)

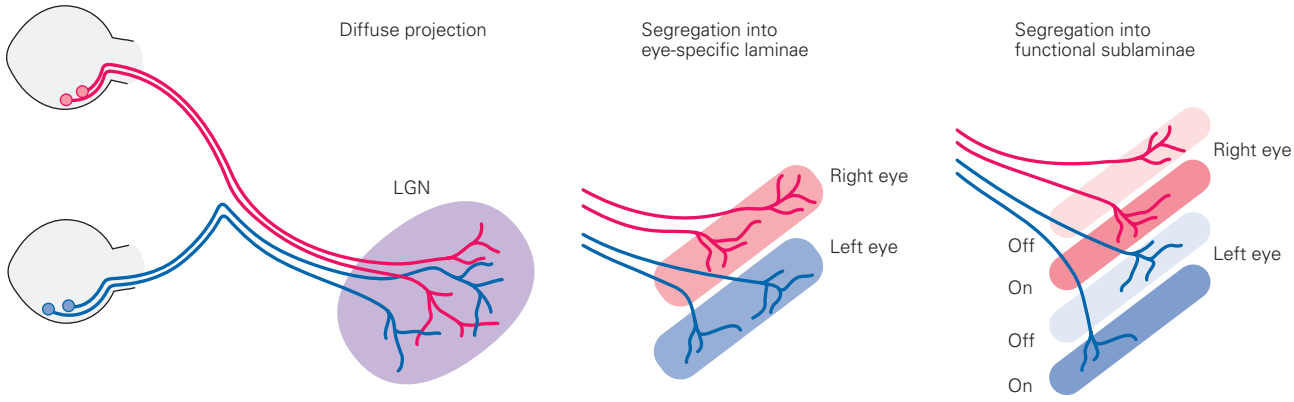


Figure 49–13 **The terminals of retinal ganglion cells in the lateral geniculate nucleus (LGN) become segregated during normal development.** At early stages of development, the terminals of axons from each eye intermingle, but at later stages, they segregate into separate layers of the nucleus. In some species, axons from one eye even segregate into functionally specialized sublayers (on and off layers in ferrets). (Adapted, with permission, from Sanes and Yamagata 1999.)

columns in the visual cortex (Figure 49–13). In both structures, individual axons at first form terminals in multiple domains (layers in the geniculate nucleus, columns in the cortex). Later, the terminals become segregated by a process of refinement. The refinement involves both growth of terminal arbors in the "appropriate" layer and elimination of terminals from the inappropriate layer (Chapter 48).

As in the cortex, application of tetrodotoxin to the optic nerves disrupts the segregation of the inputs from each eye, indicating that activity is essential for segregation. In contrast to cortex, however, segregation of inputs is complete before the onset of visual experience—prior to birth in monkeys and postnatally but prior to eye opening in mice. Thus, vision cannot drive the neural activity essential for segregation.

It turns out that the axons of retinal ganglion neurons are spontaneously active in utero, well before the eyes open. Neighboring ganglion cells fire in synchronous bursts that last a few seconds, followed by silent periods that may last for minutes. Sampling the activity of retinal ganglion neurons across the entire retina revealed that these bursts propagate across much of the retina in a wave-like manner (Figure 49–14). This pattern of ganglion cell activity appears to be coordinated by excitatory inputs from amacrine cells in the overlying layer of the retina (Chapter 22).

The spontaneous, synchronous firing of a select group of ganglion neurons excites a local group of neurons in the lateral geniculate nucleus. Such synchronized activity appears to strengthen these synapses at the expense of other nearby synapses, perhaps by a Hebbian mechanism similar to that posited for experience-dependent refinement. This does not mean that visually evoked activity has no role in sculpting the retinogeniculate pathway. At a later stage, other aspects of refinement, such as spatial rearrangement of synapses along the axon, are regulated by visual experience.

The discovery that spontaneous activity can lead to circuit refinement provides a likely explanation for the initial segregation of inputs to the visual cortex. More generally, the parsing of activity-dependent circuit refinement into two phases, the first dependent on spontaneous activity and the second on sensory input, now appears to be a general theme in the development of brain circuits that begin refinement before they have the chance to respond to environmental stimulation.

Activity-Dependent Refinement of Connections Is a General Feature of Brain Circuitry

We have seen that neural activity is critical for segregating axons from the two retinas into distinct layers in the lateral geniculate nucleus and then into distinct columns in the visual cortex. Is this developmental role of activity a special case, or does activity also affect maturation elsewhere in the visual system, and even in other parts of the brain? Studies of many systems show that activity-dependent control of refinement is a general property of neural circuits in the mammalian brain.

Many Aspects of Visual System Development Are Activity-Dependent

One well-studied example of activity-dependent development in the visual system is the sharpening

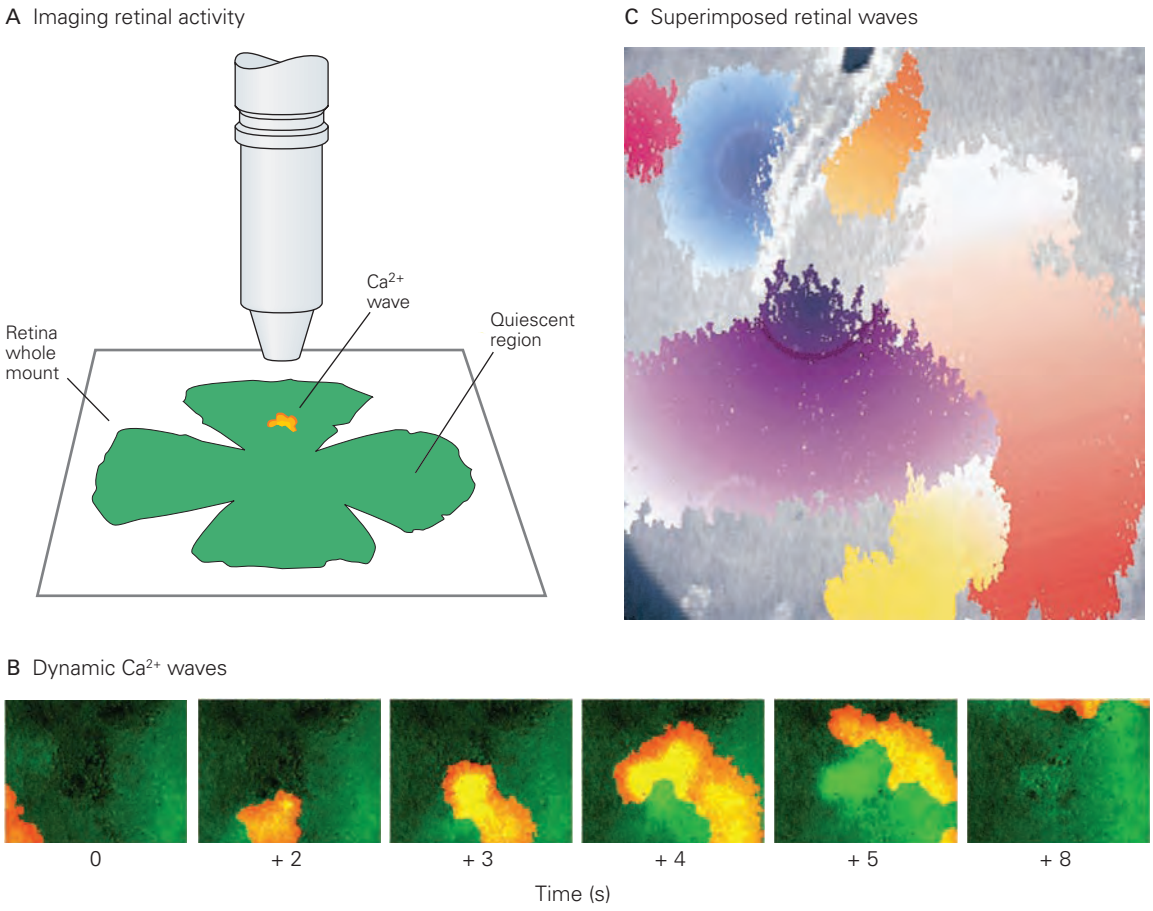

Figure 49–14 Correlated waves of neural activity in the developing retina.

A. Microscopic visualization of the activity of retinal ganglion neurons in a flat-mounted preparation of mammalian retina. Spontaneous waves of neural activity are visualized by monitoring Ca^{2+} transients (**yellow domain**) after loading of cells with dyes that change their fluorescent emission spectrum in response to changes in intracellular Ca^{2+} concentration.

B. These still images from a movie sequence show the propagation of one Ca^{2+} activity focus (**yellow domain**) across the retina. Images were taken 1 second apart. Many cells within the activity focus are activated synchronously. (Reproduced, with permission, from Blankenship et al. 2009. Copyright © 2009 Elsevier Inc.)

C. Retinal activity waves recorded over time are superimposed in this image. Discrete waves are indicated in different colors; the origin of a wave is indicated by a darker hue. These waves originate in different retinal foci and spread in distinct, unpredictable directions. (Reproduced, with permission, from Meister et al. 1991. Copyright © 1991 AAAS.)

of the topographic distribution of retinal ganglion cell axons onto their central targets, a topic we introduced in Chapter 47. In vertebrates, molecular cues such as ephrins guide axons from the retina to appropriate sites in the optic tectum (called the superior colliculus in mammals—see Figure 47–11), but they are not sufficient to form the refined visual map.

Histological and physiological studies have found that the map formed initially in the superior colliculus/optic tectum is coarse and that individual retinal ganglion cell axons have large, overlapping arbors. These axonal arbors are later pruned to their mature size, resulting in a more restricted and precise field of termination. If retinal activity is inhibited, only the initial coarse map forms.

Is it the pattern of activity or activity itself that is important in visual map formation? Put another way, is activity simply a precondition for refinement, or does it have an organizing role, determining exactly which axons win or lose the competition? Many experiments show that the latter idea is closer to the truth.

In one study, the accuracy of the retinotectal map was assessed in fish raised in a tank illuminated only by brief flashes from a strobe light. A control group was raised in a normal laboratory environment. The total light intensity presented to the fish was similar

under both conditions, but the resulting pattern was very different. In control fish, the images fell haphazardly on various parts of the retina as the fish swam around their tanks. This input produces local synchronous activity of the sort generated by the waves of spontaneous activity described above—neighboring ganglion cells tend to fire together, but there is little correlation with the firing patterns of distant ganglion cells. In these fish, the map becomes precise. In contrast, stroboscopic illumination synchronously activates nearly all of the ganglion cells, and in these fish, the retinotectal map remains coarse.

Presumably, the tectum determines which retinal axons are near neighbors by judging which ones fire in synchrony, much as activity patterns in the lateral geniculate nucleus or visual cortex determine which axons carry signals from the same eye. This information is then used to refine the topographic map, through mechanisms similar to those in the cortex. When all of the axons fire in synchrony, the tectum cannot determine which axons are neighbors; refinement fails, and the map remains coarse.

Sensory Modalities Are Coordinated During a Critical Period

Our experience of the world is shaped by synthesizing sensory input from multiple modalities. For example, our mental image of where an object is with respect to our body is the same whether we localize it by touch, sound, or sight. For each modality, information is mapped in an orderly way within relevant brain areas, much like the retinotopic maps in the optic tectum and visual cortex. Multimodal localization requires that these maps, which are formed independently during development, be brought into register. This aspect of refinement occurs during critical periods.

Studies on barn owls have provided insight into how auditory and visual maps are coordinated during a critical period. During the day, owls use vision to localize their prey—mice or other small rodents—but at night, they rely on auditory cues, and at dusk, both sensory channels are used. The localization of sound must be precise if owls are to succeed in finding prey, and it is intuitively obvious that the visual and auditory cues for the same location need to be consistent.

Auditory localization in owls, as in people, results from the presence of neurons that vary in their sensitivity to sounds sensed by the two ears. For example, sounds arising from a source to the left arrive slightly sooner at the left ear than at the right ear and are slightly louder in the left ear. These discrepancies help us determine the point in horizontal space from which a sound arises (Chapter 28). Computation of the temporal difference in the arrival of sounds at the two ears is particularly crucial. The difference is only a few tens of microseconds, as expected from calculations based upon the speed of sound and the width of the head. Remarkably, the auditory system is sensitive to these extremely short interaural time differences (ITDs) and can calculate prey position from them (Figure 49–15). Moreover, many auditory neurons in the optic tectum

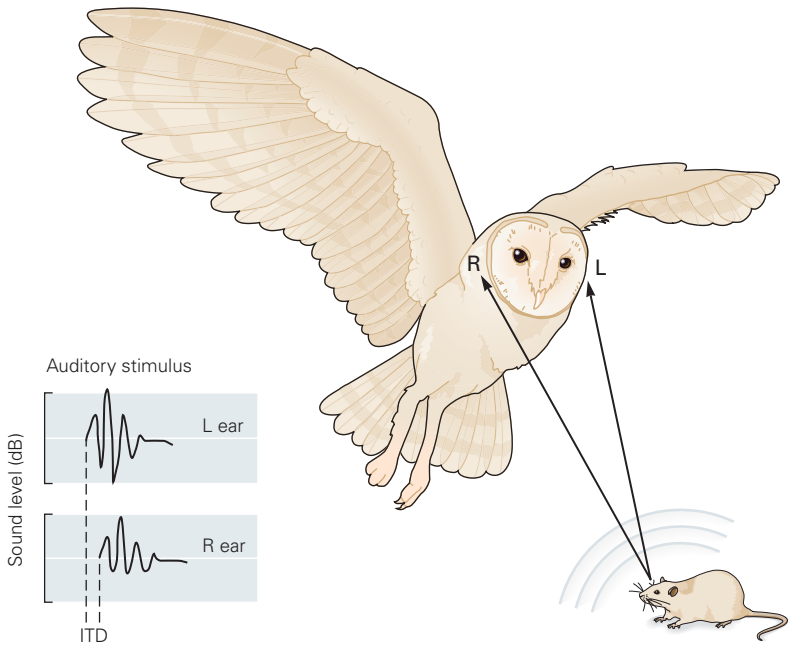

Figure 49–15 The barn owl uses interaural time differences to localize its prey. Sound waves generated by movements of a mouse are received by the owl's left and right ears. As the prey emits noise, the difference in the time of arrival of auditory stimuli at the two ears—the interaural time difference (ITD)—is used to calculate the precise position of the prey target. (Reproduced, with permission, from Knudsen 2002. Copyright © 2002 Springer Nature.)

with receptive fields centered on a particular location are also tuned to ITDs that correspond to sounds emitted from that same point in space. The registration is imprecise at early stages but becomes progressively more precise during early adolescence as a consequence of the animal's experience.

Crucial insight into how this registration occurs came from experiments in which prisms were mounted over the eyes of young owls. The prisms shifted the retinal image horizontally so that the visual map in the tectum reflected a world systematically displaced from its "actual" orientation. This change abruptly disrupted the correspondence between visual and auditory receptive fields. Over the next several weeks, however, the ITD to which tectal neurons responded optimally, ie, their auditory receptive field, changed until the visual and auditory maps came back into register (Figure 49–16). Thus, the visual map instructs the auditory map.

Further experiments showed that this reorganization resulted from rewiring of connections between two deeper auditory nuclei (Figure 49–17). When prism goggles were placed on young owls, changes in ITD tuning were fully adaptive in that the animals compensated completely for the effects of the prisms. In contrast, goggles placed on mature owls (older than 7 months of age) had little effect. Thus, reorganization of this auditory projection occurs optimally during a critical juvenile period.

Different Functions and Brain Regions Have Different Critical Periods of Development

Not all brain circuits are stabilized at the same time. Even within the visual cortex, the critical periods for organization of inputs differ among layers in both mice

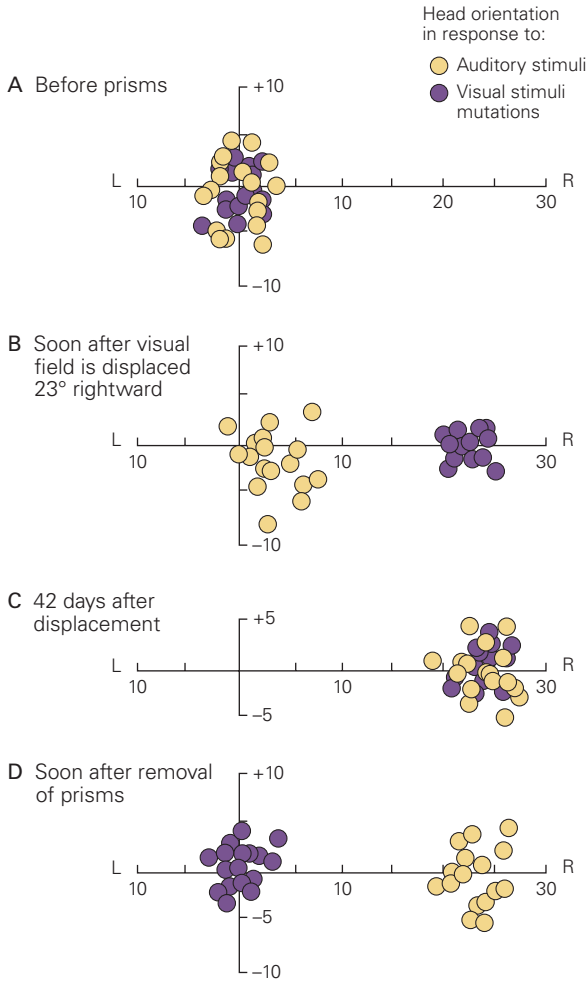

Figure 49–16 (Right) **Reorganization of sensory maps in the optic tectum of owls after systematic displacement of the retinal image.** The retinal image in adolescent owls can be displaced by prism goggles, which shift images from 5° to 30°. (Adapted, with permission, from Knudsen 2002. Copyright © 2002 Springer Nature.)

A. Before application of the prisms, the visual and auditory neural maps coincide.

B. The prism goggles displace the retinal image by 23°. Consequently, the neural and auditory maps are out of alignment.

C. The two brain maps are once again congruent 42 days after prism application because the auditory map has shifted to realign with the visual map.

D. Soon after the prisms are removed, the visual map reverts to its original position, but the auditory map remains in its shifted position.

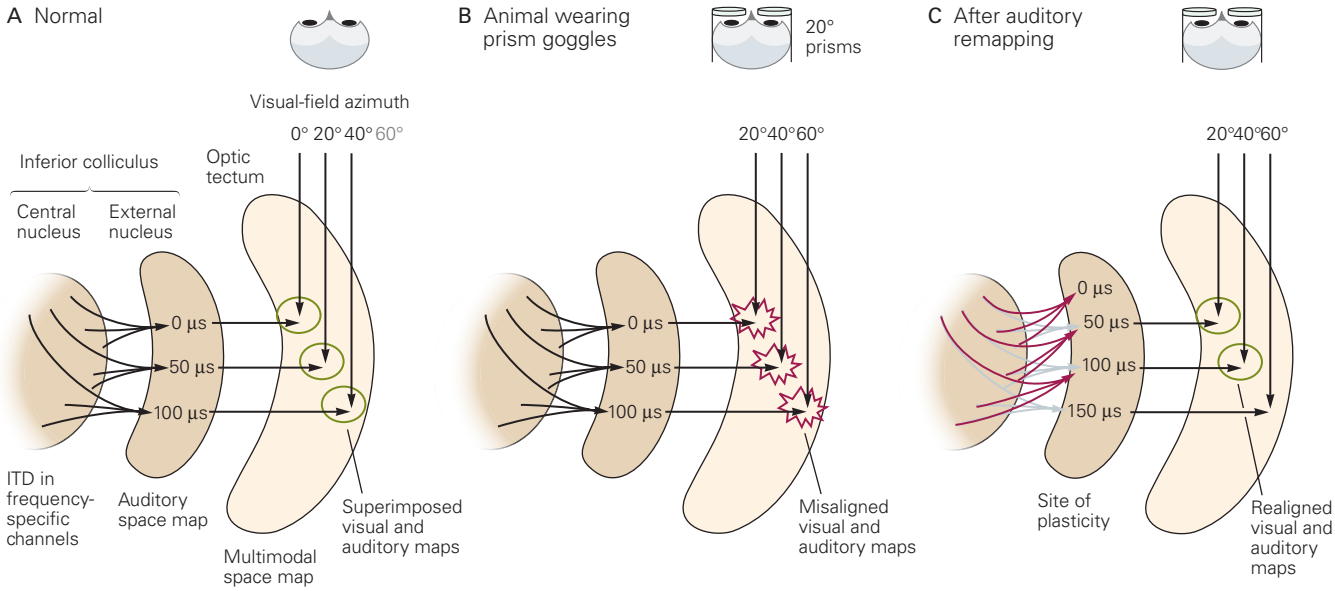

Figure 49–17 The effect of prism experience on information flow in the midbrain auditory localization pathway in the barn owl. (Adapted from Knudsen 2002.)

A. The auditory pathway in a normal owl. The interaural time difference (ITD) is measured and mapped in frequency-specific channels in the brain stem. This information ascends to the inferior colliculus, where a neural map of auditory space is created. The map is conveyed to the optic tectum where it merges with a map of visual space.

B. After an owl is fitted with prism goggles, the visual and auditory space maps in the optic tectum become misaligned.

C. After reorganization of auditory maps, the visual and auditory maps are once again in alignment.

and monkeys. As an example, the neural connections in layer IVC of the visual cortex of the monkey are not affected by monocular deprivation by the time the animal is 2 months old. In contrast, connections in the upper and lower layers continue to be influenced by sensory experience (or lack of it) for almost the entire first year after birth. Critical periods for other features of the visual system, such as orientation tuning, occur at different developmental stages (Figure 49–18A).

The timing of critical periods also varies between brain regions (Figure 49–18B). The adverse consequences of sensory deprivation for the primary sensory regions of the brain are generally fully realized early in postnatal development. In contrast, social experience can affect the intracortical connections over a much longer period. These differences may explain why certain types of learning are optimal at particular stages of development. For example, certain cognitive capacities—language, music, and mathematics—usually must be acquired well before puberty if they are to develop at all. In addition, insults to the brain at specific early stages of postnatal life may selectively affect the development of certain perceptual abilities and behavior.

Critical Periods Can Be Reopened in Adulthood

By definition, critical periods are limited in time. Nevertheless, they are less sharply defined than originally thought. Extending or reopening critical periods in adulthood could increase brain plasticity and make it possible to facilitate recovery from strokes and other insults that impair discrete regions of the nervous system.

Some of the first evidence for plasticity in the adult cortex came from studies by Merzenich and colleagues on the representation of the fingers of monkeys in the somatosensory cortex. Recordings of neuronal receptive fields in normal adult animals showed that each digit is mapped in an orderly way on the cortical surface, with abrupt discontinuities between areas responding to different digits (Figure 49–19A). Amputation of a digit left the cortical representation of that digit initially unresponsive, but after several months, areas serving the neighboring digits filled in the gap (Figure 49–19B). Much as happens in the visual cortex following monocular deprivation, the somatosensory map was readjusted so that the cortex could devote

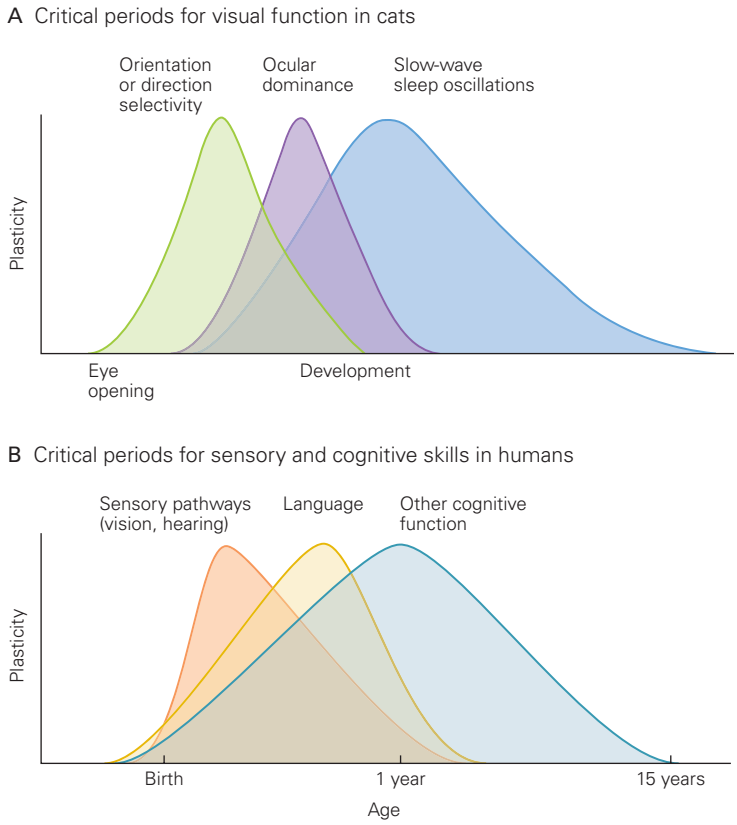

Figure 49–18 The timing of critical periods varies with brain function. (Reproduced, with permission, from Hensch 2005. Copyright © 2005 Springer Nature.)

A. In cats, the critical periods for development of orientation or direction selectivity in visual neurons occur earlier than those for establishment of ocular dominance and slow-wave sleep oscillation.

B. In humans, the timing of periods for development of sensory processing, language, and cognitive functions varies.

most of its resources to useful inputs. Conversely, when two fingers were sutured together so they received coincident input, a swath of cortex on both sides of the border between the two digit areas eventually became responsive to both areas (Figure 49–19C). This result suggests that, as in the visual system, borders may result from competition and can be blurred when competition declines. What was most surprising was that these effects occurred in adulthood, long after all known critical periods had closed.

In the years since Merzenich's studies, evidence has accumulated that critical periods can be reopened in many systems. We illustrate this principle by returning to two areas in which critical periods have been well mapped, the optic tectum in the owl and the visual cortex in the mouse.

Visual and Auditory Maps Can Be Aligned in Adults

In initial studies of the matching of auditory and visual maps in owls, realignment following displacement of the visual field with prism goggles was largely restricted to an early sensitive period (Figures 49–16 and 49–17). However, three strategies dramatically enhance binaural tuning plasticity in adult owls.

First, when adult owls that had worn goggles as adolescents are refitted with the goggles, the auditory map again shifts to align with the new visual map (Figure 49–20A). In contrast, in adult owls that had not worn the goggles as adolescents, the use of goggles has little effect on the organization of the auditory map. Thus, the events of map rearrangement during the normal critical period must leave a neural trace that permits rearrangement later in life. In fact, in the owls that wore prisms in early life, axons to auditory nuclei that were normally pruned were maintained, providing a structural basis for the reorganization in adulthood.

A second method for inducing late plasticity is to displace the retinal image in small steps by having the owl wear a series of prism spectacles of progressively increasing strength. Under these conditions, adjustment of the auditory map is typically three- to fourfold greater than the response to a single large displacement of the retinal image (Figure 49–20B).

The third technique is to allow owls to hunt live prey. In earlier experiments, animals were housed and fed under standard laboratory conditions. However, when adult prism-wearing owls are allowed to capture live mice under low light conditions for 10 weeks, they exhibit far greater plasticity of binaural tuning

than owls fed dead mice (Figure 49–19C), albeit less than that exhibited by juvenile owls that did not hunt. The finding that hunting increases the plasticity of binaural tuning in adult owls dramatically demonstrates that behavioral context affects the ability of the nervous system to reorganize. Whether this effect results from increased sensory information, attention, arousal, motivation, or reward needs to be resolved.

Binocular Circuits Can Be Remodeled in Adults

As the body of observations on monocular deprivation grew, it became apparent that some plasticity persisted beyond the classical critical period in cats, rats, and mice. In mice, for example, modest shifts in ocular dominance occur even when one eye is deprived of vision at 2 or 3 months of age. By 4 months of age, however, monocular deprivation has no detectable effect.

Over the past decade, several interventions have been discovered that enhance the extent of ocular dominance plasticity in young adults and even enable substantial plasticity in older animals. Some are noninvasive: Environmental enrichment, social interaction (via group housing), visual stimulation, and exercise all increase the magnitude and speed of changes that occur following monocular deprivation in adults. A second group of interventions targets mechanisms that appear to affect the timing of the normal critical period. As noted above, treating the cortex with chondroitinase to disrupt perineuronal nets or interference with the inhibitory effects of myelin on axonal growth can both extend and reopen the critical period. Remarkably, transplantation of immature inhibitory interneurons into the visual cortex also reopens the critical period even in 6-month-old mice.

How can we reconcile the strong evidence for critical periods with the newer evidence for reorganization

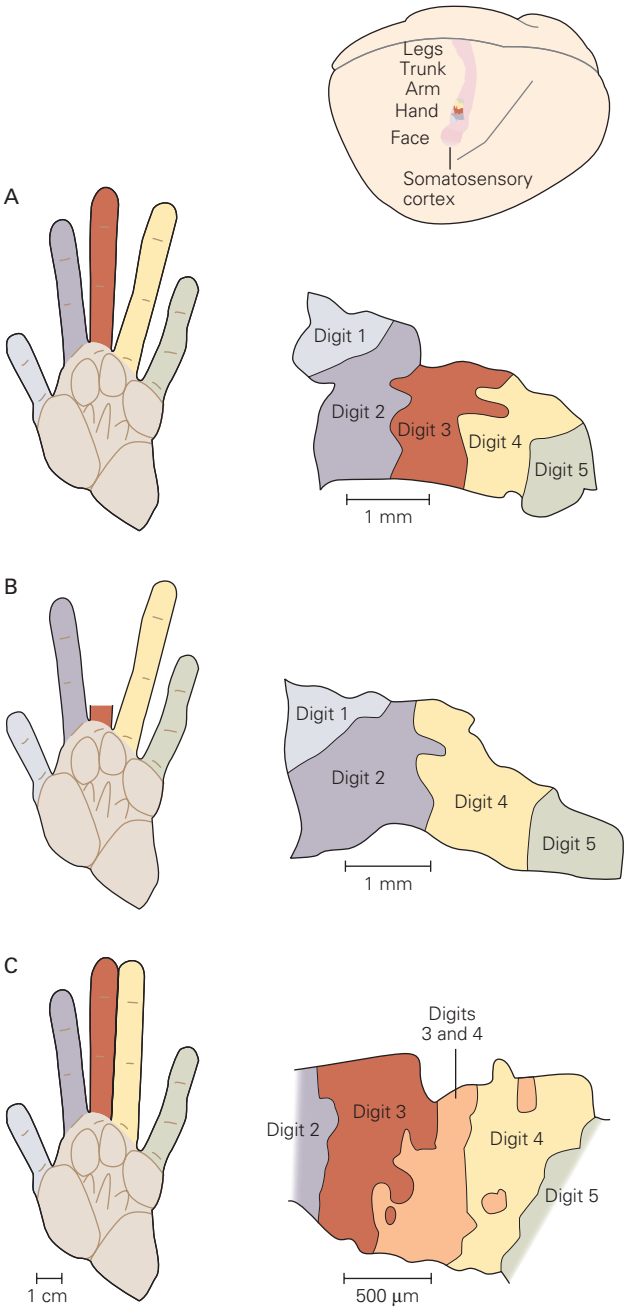

Figure 49–19 (Left) Representation of digits in somatosensory cortex can be remapped in adult monkeys. (Adapted, with permission, from Merzenich et al. 1984 and Allard et al. 1991.)

A. Lightly touching specific spots on the digits (*left*) elicits responses from neurons in somatosensory cortex (*right*), revealing orderly topographic maps of each digit on the cortical surface. Abrupt discontinuities distinguish regions serving adjacent digits.

B. Following amputation of a digit, the cortical region it previously supplied is left unresponsive. Several months later, axons from the adjacent digits (2 and 4) have formed synaptic connections in the unresponsive area.

C. After digits 3 and 4 have been sutured together, they received simultaneous sensory stimulation, and cortical regions at the border between areas representing the digits become responsive to both.

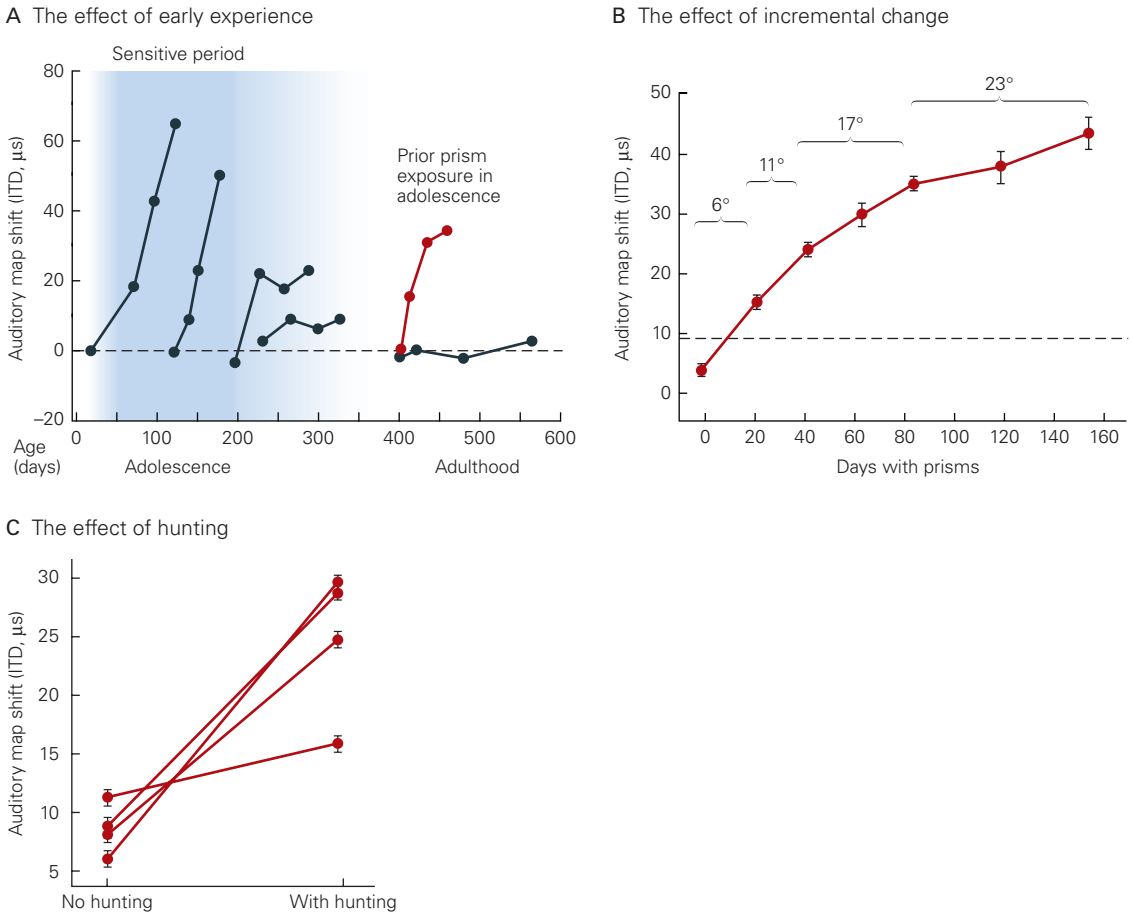

Figure 49–20 Different behavioral conditions have different effects on the realignment of visual and auditory neural maps in the mature barn owl.

A. The remodeling of the auditory maps that results from wearing prism goggles for a brief period during adolescence leaves a neural trace that can be reactivated in the adult. When these birds are fitted with the goggles as adults, the auditory map is still able to realign with the visual map. (Abbreviation: ITD, interaural time difference.) (Reproduced, with permission, from Knudsen 2002. Copyright © 2002 Springer Nature.)

B. When an animal is fitted with a series of prisms, each of which produces a small displacement in the visual image, the auditory map is successfully brought into alignment. The dotted line shows the extent of realignment if the animal is fitted with a 23° prism on day 0. (Reproduced, with permission, from Linkenhoker and Knudsen 2002. Copyright © 2002 Springer Nature.)

C. If an adult owl has the opportunity to hunt live prey while wearing prism goggles, auditory remapping occurs, perhaps because of enhanced motivation to sharpen perception. (Reproduced, with permission, from Bergan et al. 2005. Copyright © 2005 Society for Neuroscience.)

of circuitry in adults? The plasticity observed in adults is modest and slow compared to that seen during the critical period, and its mechanisms differ in some respects from those for earlier deprivation. These differences result from two factors. First, from early postnatal life into adolescence, the molecular environment in the brain is conducive to axonal growth, and cellular mechanisms are optimal for promoting the formation, strengthening, weakening, and elimination of synapses. Under these conditions, circuits can readily change in response to experience. Conversely, in mature circuits, molecular and structural elements promote stability and impede plasticity. Second, in a developing circuit, no particular pattern of connectivity is firmly entrenched, so there is less to overcome. The connections specified by genetic determinants are less precise, and the connections themselves are relatively weak. The patterns of neural activity that result from experience sharpen and even realign these patterns of connectivity.

In sum, experience during critical periods has a potent effect on circuits because the cellular and molecular conditions are optimal for plasticity and because the instructed pattern of connectivity does not have

to compete with a long-existing pattern. These differences help explain the special behavioral, pharmacological, or genetic interventions needed to stimulate plasticity in adults.

Highlights

1. Although the nervous system is malleable throughout life, plasticity is particularly great during restricted intervals in early postnatal life called critical periods. Alterations that occur during these periods are nearly irreversible.
2. Critical periods vary in time among brain areas and tasks. For example, children with strabismus (crossed eyes) will never have good stereoscopic vision unless their eyes are brought into alignment during the first few postnatal years, and people cannot learn a new language without an accent after their early teens.
3. The richest understanding of critical periods comes from studies initiated by Hubel and Wiesel on how input from the two eyes is integrated in the cortex. They deprived one eye of vision for varying periods in young cats or monkeys. In normal animals, most neurons in visual cortex are binocularly responsive, but following monocular deprivation for a brief period in early postnatal life, most cortical cells permanently lost responsiveness to input from the once-closed eye. Responses in the eye itself and the lateral geniculate nucleus were nearly normal, pinpointing the cortex as the site of change. Much longer deprivation in adulthood had little effect.
4. A structural basis for the loss of binocularity was seen in the alternating pattern of ocular dominance columns, within which neurons are dominated by input from one eye or the other. Following monocular deprivation during the critical period, columns representing the open eye expanded at the expense of those representing the closed eye. This form of plasticity may be designed to optimize the use of cortical space for each individual at each time period—for example, subtly shifting binocular interactions as the head grows and the eyes become further apart.
5. The binocular interaction reflects competition between the two sets of inputs, since vision and symmetrical columns are retained following binocular deprivation. Many lines of evidence indicate that the competition depends on patterns of activity arising in the two eyes, with inputs from each eye being more synchronous with each other than with inputs from the other eye. Postnatally, synchrony is driven by visual experience. Prenatally or prior to eye opening, patterned spontaneous activity in the two eyes accounts for the synchrony.
6. Cellular mechanisms underlying the effects of monocular deprivation have been studied in greatest detail in mice. Following monocular deprivation, input from the closed eye is weakened rapidly by a process akin to long-term depression (LTD). Shortly thereafter, input from the other eye is strengthened, partly by a compensatory mechanism called homeostatic plasticity. Structural remodeling of thalamic axons and cortical dendrites occurs later.
7. Maturation of inhibitory interneurons is a main determinant of when the critical period opens. The end of the critical period is marked by the formation of myelin and proteoglycan-rich perineuronal structures that hamper structural remodeling.
8. Although plasticity of binocular interactions was initially believed to be confined to early postnatal life, it is now apparent that critical periods can be "reopened" to some extent in adults. In some cases, this can be done by altering the animal's environment or the way in which the altered experience is delivered. Critical periods can also be reopened by manipulating some of the factors that normally close them in adolescence.
9. Plasticity in adulthood is modest in magnitude and difficult to trigger compared to early postnatal critical periods. Nonetheless, reopening of critical periods could, if properly controlled, enable reorganization to compensate for losses incurred from injuries, disease, and early maladaptive experience.
10. Critical periods occur during development of numerous systems, such as formation of orderly maps of auditory, somatosensory, and visual input onto relevant sensory cortices. Many of the principles and mechanisms that characterize the plasticity of binocular interactions also regulate these critical periods, including roles of spontaneous and experience-dependent activity, competition, alterations in excitatory and inhibitory synapses, and selective growth and pruning of inputs to achieve appropriate patterns of adult connectivity.
11. The existence of critical periods demonstrates that the brain's ability to remodel declines precipitously in adulthood. This seems disadvantageous but may represent a useful adaptation, allowing each brain to adapt to its environment

as it develops, but then buffering it against excessive change later, perhaps even enabling skills and memories to persist. If this is the case, therapies based on reopening critical periods in adults may come at a cost.

Repairing the Damaged Brain

For much of its history, neurology has been a discipline of outstanding diagnostic rigor but little therapeutic efficacy. Simply put, neurologists have been renowned for their ability to localize lesions with great precision but until recently have had little to offer in terms of treatment. This situation is now changing.

Advances in our understanding of the structure, function, and chemistry of the brain's neurons, glial cells, and synapses have led to new ideas for treatment. Many of these are now in clinical trials, and some are already available to patients. Developmental neuroscience is emerging as a major contributor to this sea change for three main reasons. First, efforts to preserve or replace neurons lost to damage or disease rely on recent advances in our understanding of the mechanisms that control the generation and death of nerve cells in embryos (Chapters 45 and 46). Second, efforts to improve the regeneration of neural pathways following injury draw heavily on what we have learned about the growth of axons and the formation of synapses (Chapters 47 and 48). Third, there is increasing evidence that some devastating brain disorders, such as autism and schizophrenia, are the result of disturbances in the formation of neural circuits in embryonic or early postnatal life. Accordingly, studies of normal development provide an essential foundation for discovering precisely what has gone wrong in disease.

In this chapter, we focus on the first two of these issues: how neuroscientists hope to augment the limited ability of neurons to recover normal function. We shall begin by describing how axons degenerate following the separation of the axon and its terminals from the cell body. The regeneration of severed axons is robust in the peripheral nervous system of mammals and in the central nervous system of lower vertebrates, but very poor in the central nervous system of

mammals. Many investigators have sought the reasons for these differences in the hope that understanding them will lead to methods for augmenting recovery of the human brain and spinal cord following injury. Indeed, we shall see that several differences in regenerative capacity of mammalian neurons have been discovered, each of which has opened promising new approaches to therapy.

We shall then consider an even more dire consequence of neural injury: the death of neurons. The inability of the adult brain to form new neurons has been a central dogma of neuroscience since the pioneering neuroanatomist Santiago Ramón y Cajal asserted that in the injured central nervous system, "Everything may die, nothing may be regenerated." This pessimistic view dominated neurology for most of the last century despite the fact that Ramón y Cajal added, "It is for the science of the future to change, if possible, this harsh decree." Remarkably, in the past few decades, evidence has accumulated that neurogenesis does occur in certain regions of the adult mammalian brain. This discovery has helped accelerate the pace of research on ways to stimulate neurogenesis and to replace neurons following injury. More than a century later, neuroscientists are finally beginning to reverse Cajal's "harsh decree."

Damage to the Axon Affects Both the Neuron and Neighboring Cells

Because many neurons have very long axons and cell bodies of modest size, most injuries to the central or peripheral nervous system involve damage to axons. Transection of the axon, either by cutting or by crushing, is called *axotomy*, and its consequences are numerous.

Axon Degeneration Is an Active Process

Axotomy divides the axon in two: a proximal segment that remains attached to the cell body and a distal segment that has lost this crucial attachment. Axotomy dooms the distal segment of the axon because energy supplies dwindle during a short-lived latent period. Soon the alterations become irreversible. Synaptic transmission fails at severed nerve terminals, and calcium levels increase within the axon. The calcium activates proteases, initiating a program of cytoskeletal disassembly and degradation, and physical degeneration of the axon ensues. Once the denervation begins, its progression is relatively rapid and inexorably proceeds to completion (Figure 50–1). This degenerative response is the first step in an elaborate constellation

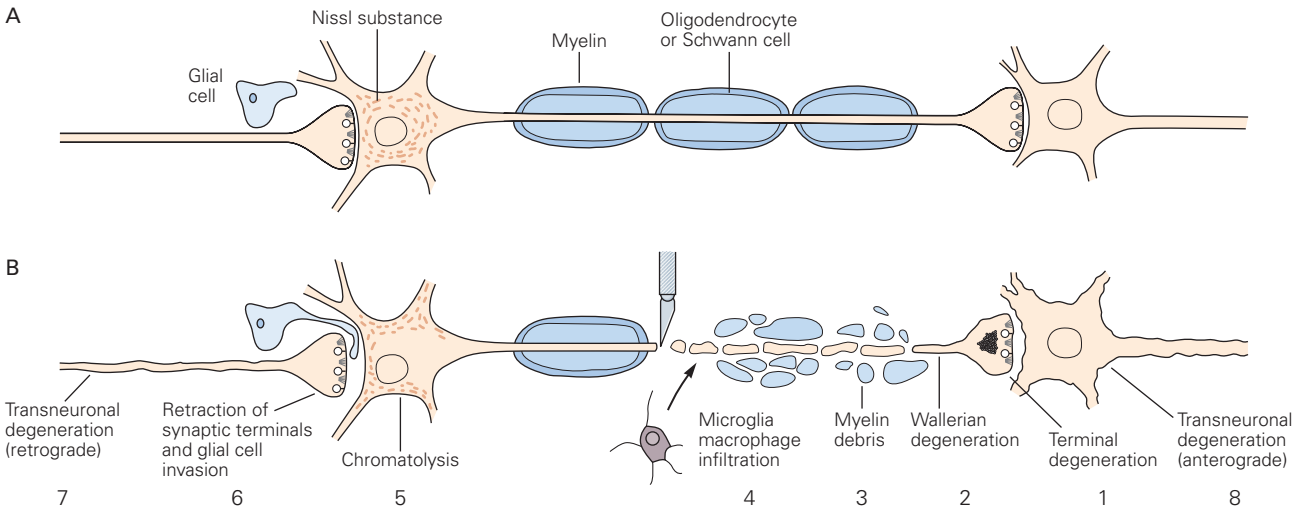

Figure 50–1 Axotomy affects the injured neuron and its synaptic partners.

A. A normal neuron with an intact functional axon wrapped by myelinating cells contacts a postsynaptic neuron. The neuron's cell body is itself a postsynaptic target.

B. After axotomy, the nerve terminals of the injured neuron begin to degenerate (**1**). The distal axonal stump separates from the parental cell body, becomes irregular, and undergoes Wallerian degeneration (**2**). Myelin begins to fragment (**3**) and the lesion site is invaded by phagocytic cells (**4**). The cell body of the damaged neuron undergoes chromatolysis: The cell body swells and the nucleus moves to an eccentric position (**5**). Synaptic terminals that contact the damaged neuron withdraw and the synaptic site is invaded by glial cell processes (**6**). The injured neuron's inputs (**7**) and targets (**8**) can atrophy and degenerate.

of changes, called *Wallerian degeneration*, that were initially described in 1850 by Augustus Waller.

The degeneration of transected axons was long thought to be a passive process, the consequence of separation from the cell body, where most of the cell's proteins are synthesized. Lacking a source of new protein, the distal stump was thought to simply wither away. But the discovery and analysis in mice of a spontaneously occurring mutation called *Wlds* (Wallerian degeneration slow) challenged this view (Figure 50–2). In *Wlds* mutant mice, the distal stumps of peripheral nerves persist for several weeks after transection, about 10-fold longer than in normal mice. This remarkable finding suggested that degeneration is not a passive consequence of separation from the cell body, but is rather an actively regulated response.

Analysis of the *Wlds* mutant mice led to insights into the nature of this regulation. The mutation led to formation of a mutant form of nicotinamide mononucleotide adenyltransferase 1 (NMNAT1), an enzyme involved in biosynthesis of a metabolic cofactor, nicotinamide adenine dinucleotide (NAD). A related enzyme, NMNAT2, which is normally present in the axon, becomes quite unstable and breaks down rapidly following axotomy, leading to loss of NAD, which is critical for maintenance of energy homeostasis in the axon. Although normal NMNAT1 is confined to the nucleus, the mutant *Wlds* form mislocalizes to the axon, where it substitutes for NMNAT2 to prolong axonal survival. Surprisingly, a main way that both the wild type and *Wlds* forms of NMNAT maintain NAD levels is not by synthesizing it but by inhibiting another protein, SARM1, that breaks down NAD. Thus, loss of SARM protects damaged axons, whereas activation of SARM1 leads to degeneration (Figure 50–3A). Several other proteins modulate this core pathway (Figure 50–3B).

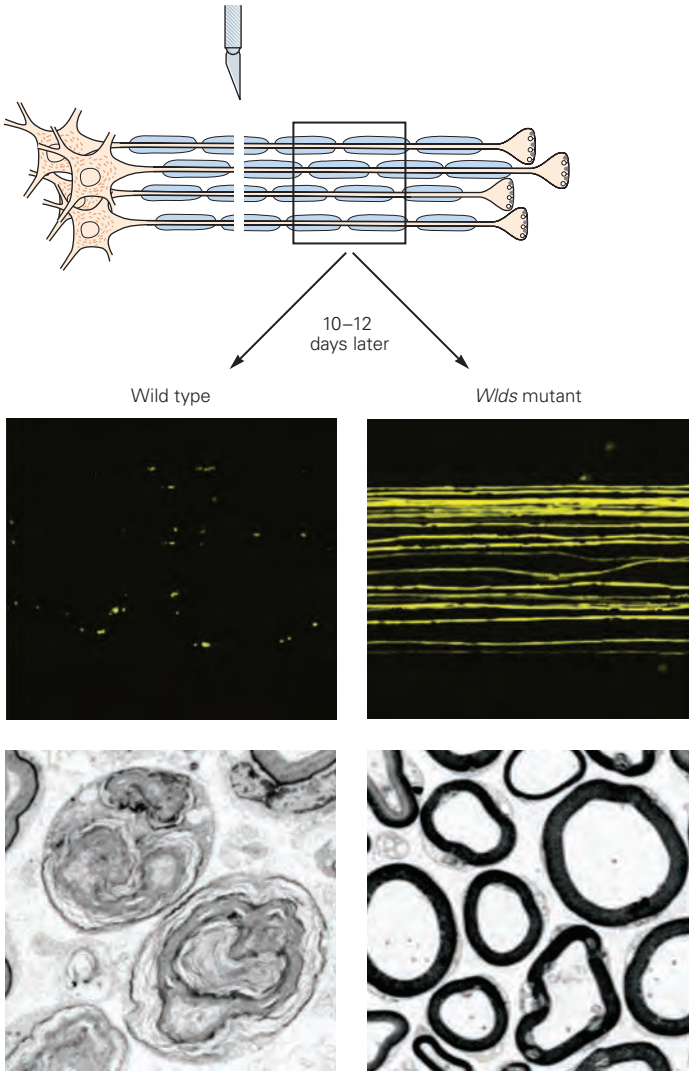

Figure 50–2 Axonal degeneration is delayed in *Wlds* mutant mice. In wild type animals, axons in the distal stump degenerate rapidly after sectioning of a peripheral nerve, as shown by disrupted axonal fragments (**yellow**) and the lack of myelinated axonal profiles at the electron micrographic level. In *Wlds* mutant mice the distal portion of severed axons persists for a long time. (Confocal micrographs reproduced, with permission, from Beirowski et al. 2004. Copyright © 2004 Elsevier B.V.; electron micrographs reproduced, with permission, from Mack TGA, Reiner M, Beirowski B, et al. 2001. Copyright © 2001 Springer Nature.)

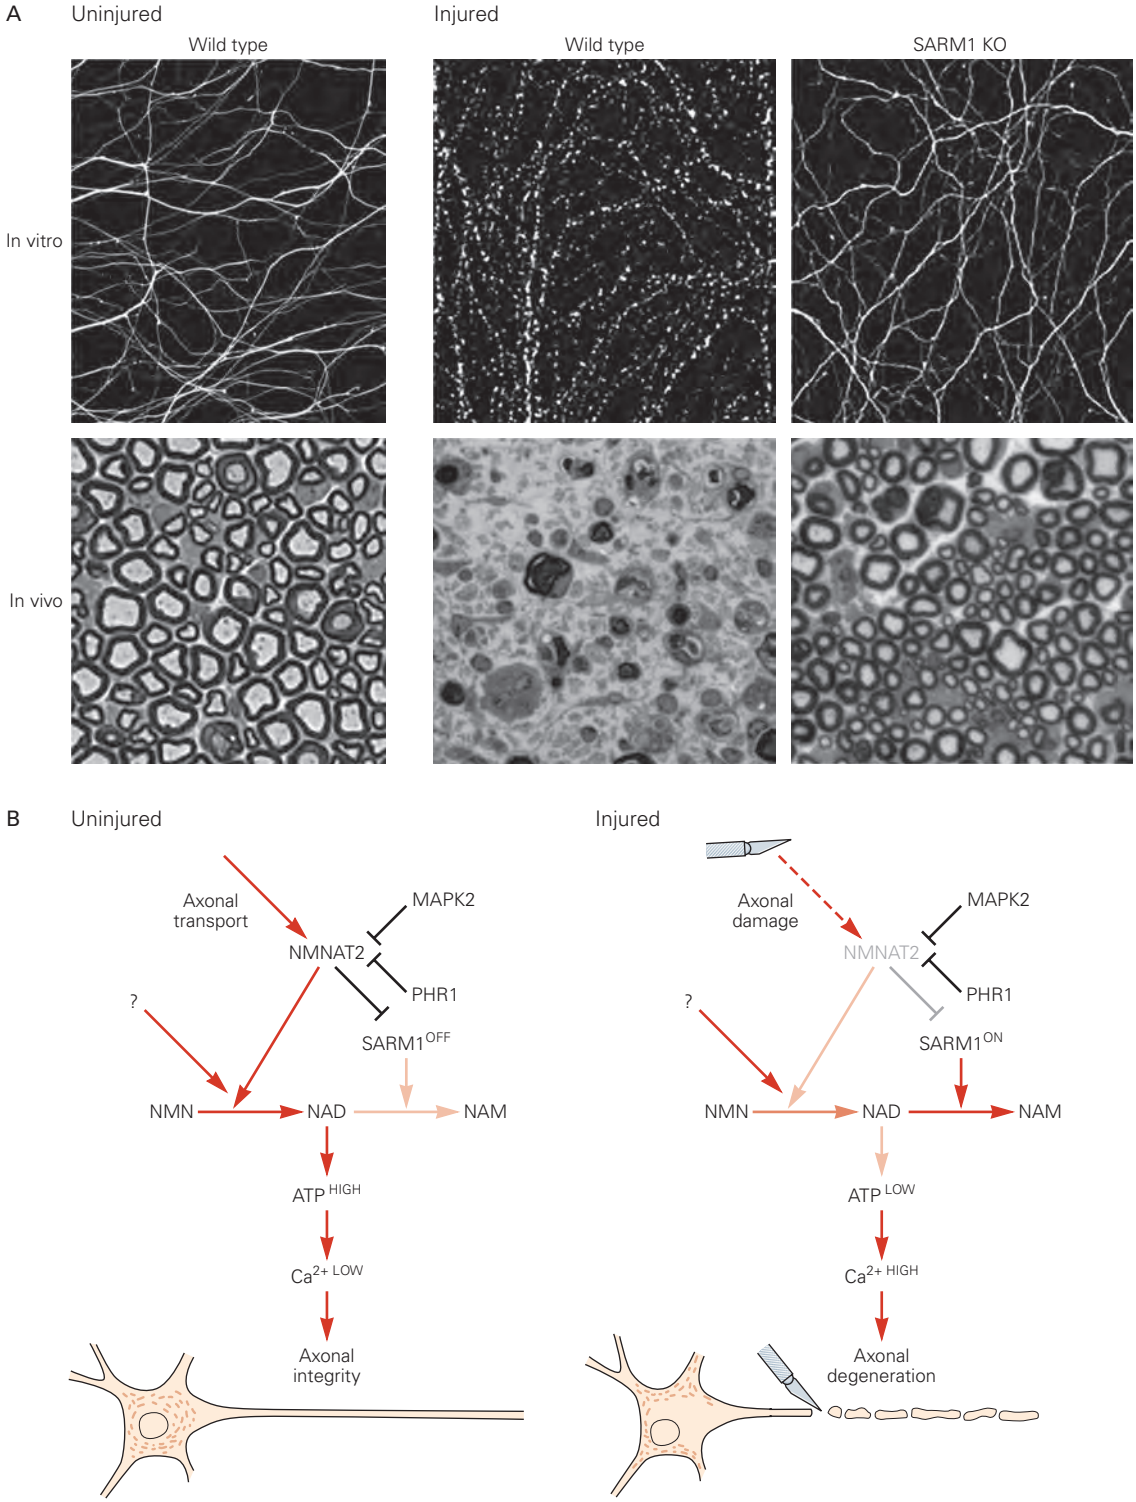

Figure 50–3 A core pathway regulates axon degeneration following axotomy in mice.

A. Damage to neurites in vitro leads to degeneration of the portions separated from the cell body. Likewise, axotomy in vivo leads to Wallerian degeneration, as shown by loss of myelin profiles in the cross section. Both in vitro and in vivo axons are spared if the *SARM1* gene is deleted. (From Gerdts et al. 2013.)

B. NMNAT2, closely related to the mutant *Wlds* protein, is normally present in axons. It can generate nicotinamide adenine dinucleotide (**NAD**) and inhibit SARM1, which degrades NAD. High NAD levels are required for energy metabolism, keeping adenosine triphosphate (**ATP**) levels high and calcium levels low in the axon. Following axotomy, NMNAT2 levels decrease rapidly, disinhibiting SARM1. NAD levels fall, ATP is depleted, calcium levels rise, calcium-dependent proteases are activated, and the axon is degraded. Kinases (MAPK) and a ubiquitin ligase (Phr1) regulate the pathway.

Together, these exciting new discoveries provide an answer to the question of why, following axotomy, the distal stump degenerates while the proximal stump is preserved. The conventional explanation that the distal stump is deprived of nutrients normally delivered from the cell body is incomplete. Instead, a signaling pathway in the axon senses damage and rapidly triggers degeneration. In this scenario, the key element supplied by the axon is NMNAT2. Its breakdown following axotomy disinhibits SARM1 and, perhaps in parallel with activation of factors that stimulate SARM1, triggers the loss of NAD, leading to the energy crisis that results in Wallerian degeneration.

These recent discoveries may be useful in devising treatments for neurological disorders in which axonal degeneration is prominent and generally precedes neuronal death. A fatal disease of motor neurons, amyotrophic lateral sclerosis, falls into this category. Other possibilities include some forms of spinal muscular atrophy, Parkinson disease, and even Alzheimer disease. Axon degeneration that occurs in these diseases, as well as after metabolic, toxic, or inflammatory insults, resembles the degeneration that follows acute trauma and may be regulated in similar ways. Thus, while methods for saving transected distal axons are unlikely to be useful clinically for treating patients who have suffered traumatic injury, the same techniques could be useful in treating neurodegenerative diseases.

Even though the proximal portion of the axon remains attached to the cell body, it too suffers. And in some cases, the neuron itself dies by apoptosis, probably because axotomy isolates the cell body from its supply of target-derived trophic factors. Even when this does not occur, the cell body often undergoes a series of cellular and biochemical changes called the *chromatolytic reaction:* The cell body swells, the nucleus moves to an eccentric position, and the rough endoplasmic reticulum becomes fragmented (Figure 50–1B). Chromatolysis is accompanied by other metabolic changes, including an increase in protein and RNA synthesis as well as a change in the pattern of genes that the neuron expresses. These changes are reversed if regeneration is successful.

Axotomy Leads to Reactive Responses in Nearby Cells

Axotomy sets in motion a cascade of responses in numerous types of neighboring cells. Among the most important responses are those of the glial cells that ensheath the distal nerve segment. One is fragmentation of the myelin sheath, which is then removed by phagocytes. This process is rapid in the peripheral nervous system, where the myelin-producing Schwann cells break the myelin into small fragments and engulf it. Schwann cells, which then divide, secrete factors that recruit macrophages from the blood stream. The macrophages in turn assist the Schwann cells in disposing of debris. Schwann cells also produce growth factors that promote axon regeneration, a point to which we will return later.

In contrast, in the central nervous system, the myelin-forming oligodendrocytes have little or no ability to dispose of myelin, and removal of debris depends on resident phagocytic cells called *microglia*. This difference in cellular properties may help explain the observation that Wallerian degeneration proceeds to completion much more slowly in the central nervous system.

Axotomy also affects both the synaptic inputs to and the synaptic targets of the injured neuron. When axotomy disrupts the major inputs to a cell—as happens in denervated muscle, or to neurons in the lateral geniculate nucleus when the optic nerve is cut—the consequences are severe. Usually the target atrophies and sometimes dies. When targets are only partially denervated, their responses are more limited. In addition, axotomy affects presynaptic neurons. In many instances, synaptic terminals withdraw from the cell body or dendrites of chromatolytic neurons and are replaced by the processes of glial cells—Schwann cells in the periphery and microglia or astrocytes in the central nervous system. This process, called *synaptic stripping*, depresses synaptic activity and can impair functional recovery.

Although the mechanism of synaptic stripping remains unclear, two possibilities have been suggested. One is that postsynaptic injury causes axon terminals to lose their adhesiveness to synaptic sites so that they are subsequently wrapped by glia. The other is that glia initiate the process of synaptic stripping in response to factors released from the injured neuron or to changes in its cell surface. Whatever the trigger, the activation of microglia and astrocytes by axotomy clearly contributes to the stripping process. In addition, biochemically altered astrocytes, called reactive astrocytes, contribute to formation of a *glial scar* near sites of injury.

As a result of these transsynaptic effects, neuronal degeneration can propagate through a circuit in both anterograde and retrograde directions. For example, a denervated neuron that becomes severely atrophic can fail to activate its target, which in turn becomes atrophic. Likewise, when synaptic stripping

prevents an afferent neuron from obtaining sufficient sustenance from its target cell, the afferent neuron's inputs are placed at risk. Such chain reactions help to explain how injury in one area in the central nervous system eventually affects regions far from the site of the injury.

Central Axons Regenerate Poorly After Injury

Central and peripheral nerves differ substantially in their ability to regenerate after injury. Peripheral nerves can often be repaired following injury. Although the distal segments of peripheral axons degenerate, connective tissue elements surrounding the distal stump generally survive.

Axonal sprouts grow from the proximal stump, enter the distal stump, and grow along the nerve toward its targets (Figure 50–4). The mechanisms that drive this process are related to those that guide embryonic axons. Chemotropic factors secreted by Schwann cells attract axons to the distal stump, adhesive molecules within the distal stump promote axon growth along cell membranes and extracellular matrices, and inhibitory molecules in the perineural sheath prevent regenerating axons from going astray.

Once regenerated peripheral axons reach their targets, they are able to form new functional nerve endings. Motor axons form new neuromuscular junctions; autonomic axons successfully reinnervate glands, blood vessels, and viscera; and sensory axons reinnervate muscle spindles. Finally, those axons that lost their myelin sheaths are remyelinated, and chromatolytic cell bodies regain their original appearance. Thus, in all three divisions of the peripheral nervous system—motor, sensory, and autonomic—the effects of axotomy are reversible. Peripheral regeneration is not perfect, however. In the motor system, recovery of strength may be substantial, but recovery of fine movements is usually impaired. Some motor axons never find their targets, some form synapses on inappropriate muscles, and some motor neurons die. Nevertheless, the regenerative capacities in the peripheral nervous system are impressive.

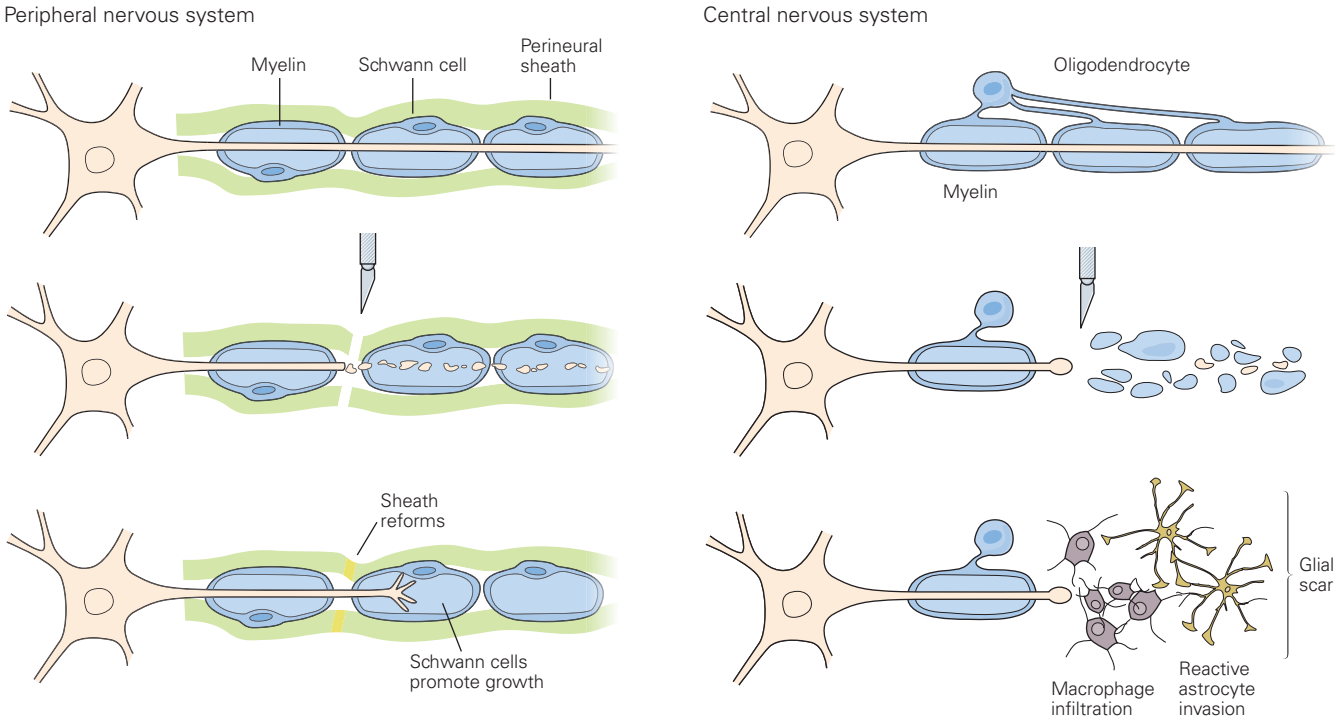

Figure 50–4 Axons in the periphery regenerate better than those in the central nervous system. After sectioning of a peripheral nerve, the perineural sheath reforms rapidly and Schwann cells in the distal stump promote axonal growth by producing trophic and attractant factors and expressing high levels of adhesive proteins. After sectioning of an axona in the central nervous system, the distal segment disintegrates and myelin fragments. In addition, reactive astrocytes and macrophages are attracted to the lesion site. This complex cellular milieu, termed a *glial scar*, inhibits axonal regeneration.

In contrast, regeneration after injury is poor in the central nervous system (Figure 50–4). The proximal stumps of damaged axons can form short sprouts, but these soon stall and form swollen endings called "retraction bulbs", which fail to progress. Long-distance regeneration is rare. The failure of central regeneration is what led to the long-standing belief that injuries to the brain and spinal cord are largely irreversible and that therapy must be restricted to rehabilitative measures.

For some time, neurobiologists have been seeking the reasons why regenerative capacity in the central and peripheral nervous systems differs so dramatically. The goal of this work has been to identify the crucial barriers to regeneration so that they can be overcome. These studies have begun to bear fruit, and there is now cautious optimism that the injured human brain and spinal cord have a regenerative capacity that can eventually be exploited.

Before discussing these new developments, it is helpful to consider the problem of neural regeneration in a broader biological context. Is it the ability of peripheral axons to regenerate that is unusual, or the inability of central axons to do so? It is in fact the latter. Obviously, central axons grow well during development. More surprisingly, axons in immature mammals can also regenerate following transection in the brain or spinal cord. Moreover, regeneration is robust in the adult central nervous systems of lower vertebrates such as fish and frogs, as exemplified by the studies of Roger Sperry on restoration of vision following damage to the optic nerve (Chapter 47).

So why have mature mammals lost this seemingly important capacity for repair? The answer may lie in what the mammalian brain *can* do peerlessly, which is to remodel its basic wiring diagram in accordance with experience during critical periods in early postnatal life, so that each individual's brain is optimized to deal with the changes and challenges of internal and external worlds (Chapter 49). Once remodeling has occurred, it must be stabilized. Although it is obviously useful to reassign cortical space to one eye if the other is blinded in childhood, we would not want our cortical connections similarly rearranged in response to a brief period of unusual illumination or darkness. Maintaining constancy in the face of small perturbations in connectivity may therefore have the unavoidable consequence of limiting the ability of central connections to regenerate in response to injury. In this view, our limited regenerative capacity is a Faustian bargain in which we have sacrificed recuperative power to ensure the maintenance of precisely wired circuits that underlie our superior intellectual capacity.

Therapeutic Interventions May Promote Regeneration of Injured Central Neurons

In seeking reasons for the poor regeneration of central axons, one critical question is whether it reflects an inability of neurons themselves to grow or an inability of the environment to support axonal growth. This issue was addressed by Albert Aguayo and his colleagues in the early 1980s. They inserted segments of a central nerve trunk into a peripheral nerve, and segments of a peripheral nerve into the brain or spinal cord, to find out how axons would respond when confronted with a novel environment.

As expected, axons in the grafts, which were separated from their somata, promptly degenerated, leaving "distal stumps" containing glia, support cells, and extracellular matrix. What was striking was the behavior of axons near the translocated segments. Spinal axons that regenerated poorly following spinal cord injury grew several centimeters into the peripheral graft (Figure 50–5). Similarly, retinal axons, which regenerated poorly following damage to the optic nerve, grew long distances into a peripheral graft placed in their path.

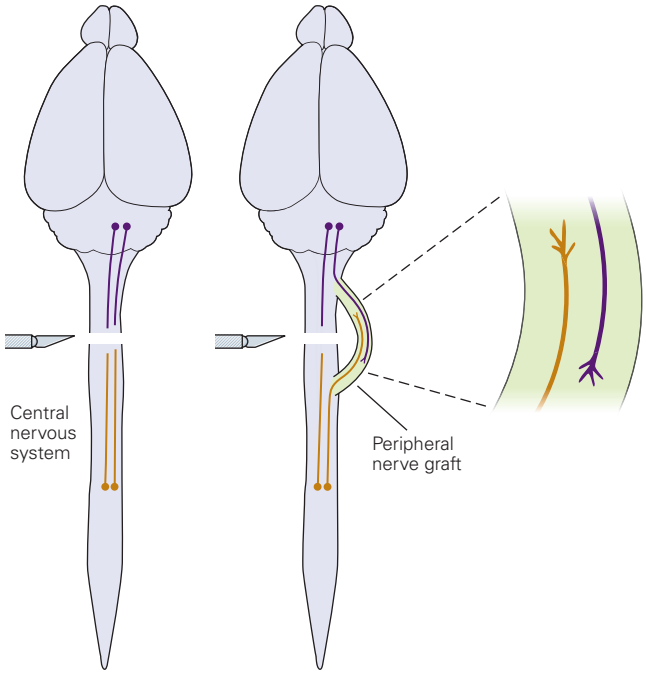

Figure 50–5 A transplanted peripheral nerve provides a favorable environment for the regeneration of central axons. *Left*: After sectioning of the spinal cord, ascending and descending axons fail to cross the lesion site. *Right*: Insertion of a peripheral nerve graft that bypasses the lesion site promotes regeneration of both ascending and descending axons. (Adapted from David and Aguayo 1981.)

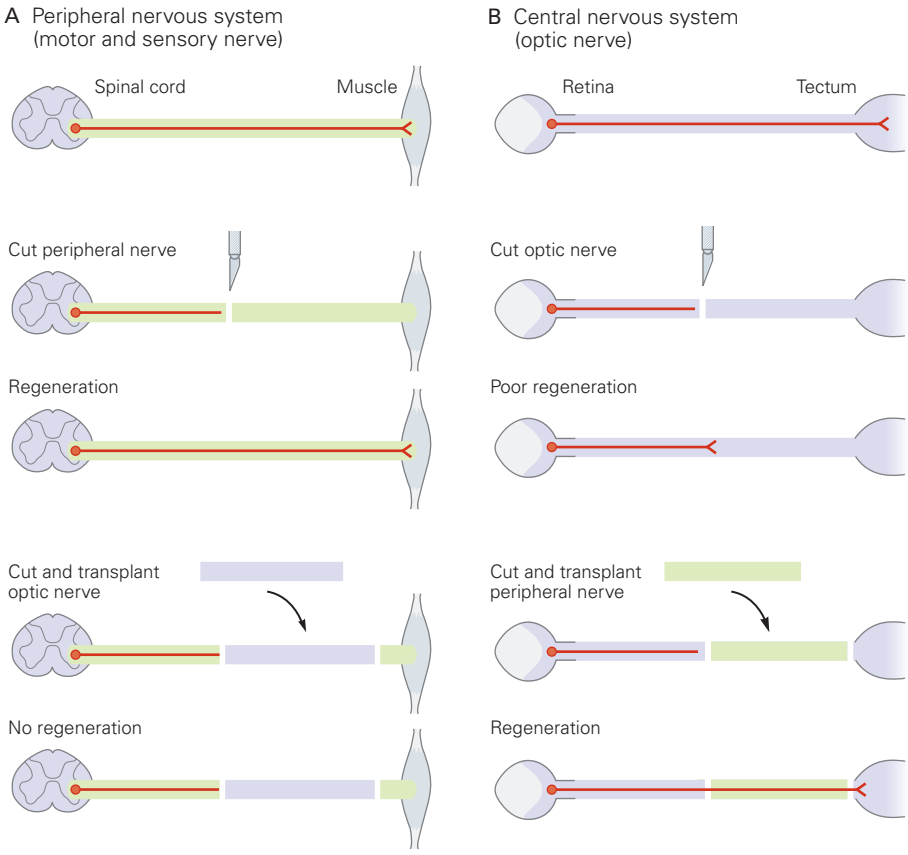

Figure 50–6 Peripheral and central nerves differ in their ability to support axonal regeneration.

A. In the peripheral nervous system, severed axons regrow past the site of injury. Insertion of a segment of optic nerve into a peripheral nerve suppresses the ability of the peripheral nerve to regenerate.

B. In the central nervous system, severed axons typically fail to regrow past the site of injury. Insertion of a section of peripheral nerve into a central nerve tract promotes regeneration.

Conversely, peripheral axons regenerated well through their own distal nerve trunk, but fared poorly when paired with a severed optic nerve (Figure 50–6).

Aguayo extended these studies to show that axons from multiple regions, including the olfactory bulb, brain stem, and mesencephalon, could all regenerate long distances if provided with a suitable environment. Even an optimal environment cannot fully restore the growth potential of central axons for reasons we will discuss in a later section. Nevertheless, these pioneering experiments focused attention on components of the central environment that inhibit regenerative ability and motivated an intensive search for the molecular culprits.

Environmental Factors Support the Regeneration of Injured Axons

In probing the differences between peripheral and central growth environments, initial searches were influenced by the results of experiments performed by Ramón y Cajal's student Francisco Tello nearly a century before Aguayo's studies. Tello transplanted segments of peripheral nerves into the brains of experimental animals and found that injured central axons grew toward the implants, whereas they barely grew when implants were not available.

This result implied that peripheral cells provide growth-promoting factors to the injured areas, factors normally absent from the brain. Ramón y Cajal reasoned that central nerve pathways lacked "substances able to sustain and invigorate the indolent and scanty growth" similar to those provided by peripheral pathways. Numerous studies over the succeeding century identified constituents of peripheral nerves that are potent promoters of neurite outgrowth. These include components of Schwann cell basal laminae, such as laminin, and cell adhesion molecules of the immunoglobulin superfamily. In addition, cells in denervated

distal nerve stumps begin to produce neurotrophins and other trophic molecules of the sort described in Chapter 46. Together, these molecules nourish neurons and guide growing axons in the embryonic nervous system, so it makes sense that they also promote the regrowth of axons. By contrast, central neuronal tissue is a poor source of these molecules, containing little laminin and low levels of trophic molecules. Thus, in the embryo, both central and peripheral nervous systems provide environments that promote axon outgrowth. But only the peripheral environment retains this capacity in adulthood or is able to regain it effectively following injury.

The practical implications of this view are that supplementing the central environment with growth-promoting molecules might improve regeneration. To this end, investigators have infused neurotrophins into areas of injury or inserted fibers rich in extracellular matrix molecules such as laminin to serve as scaffold for axonal growth. In some attempts, Schwann cells themselves, or cells engineered to secrete trophic factors, have been grafted into sites of injury. In many of these cases, injured axons grow more extensively than they do under control conditions. Yet regeneration remains limited, with axons generally failing to extend long distances. More important, functional recovery is minimal.

Components of Myelin Inhibit Neurite Outgrowth

What accounts for such disappointingly limited regeneration? One part of the explanation is that the environment encountered by severed central axons is not only poor in growth-promoting factors but also rich in growth-inhibiting factors, some of which are derived from myelin. In culture, fragments of central but not peripheral myelin potently inhibit neurite outgrowth from co-cultured central or peripheral neurons. Conversely, sprouting of spinal axon collaterals following injury is enhanced in rats treated to prevent myelin formation in the spinal cord (Figure 50–7).

These findings implied that although both central and peripheral environments might contain a supply of growth-promoting elements, central nerves also contain inhibitory components. The fact that myelin inhibits neurite growth may seem peculiar, but not if we consider that myelination normally occurs postnatally, after axon extension is largely complete.

Searches for the inhibitory components of central myelin turned up an embarrassment of riches. Several classes of molecules that occur at higher levels in central myelin compared to peripheral myelin are able to inhibit neurite outgrowth when presented to cultured neurons. The first to be discovered was identified when an antibody generated against myelin proteins proved

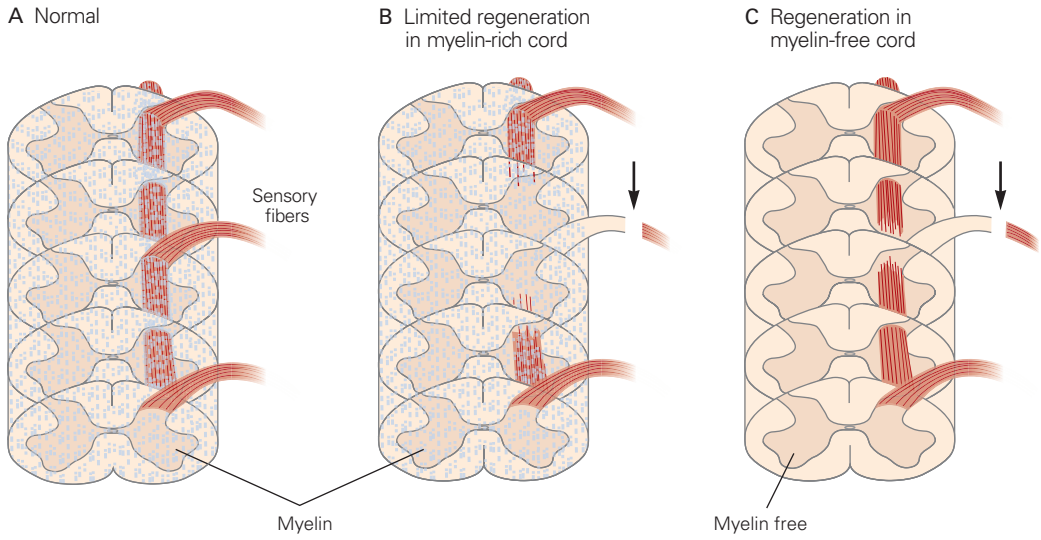

Figure 50–7 Myelin inhibits regeneration of central axons. (Adapted, with permission, from Schwegler, Schwab, and Kapfhammer 1995.)

A. Sensory fibers normally extend rostrally in a myelin-rich spinal cord.

B. Right dorsal root fibers were sectioned in 2-week-old normal rats. Regeneration of the fibers was assessed histochemically 20 days later. The central branches of the sectioned axons degenerated, leaving a portion of the spinal cord denervated. Little regeneration occurred in the myelin-rich cord.

C. Some littermates received local x-irradiation to block myelination. In these animals, sensory fibers that entered the cord through neighboring uninjured roots sprouted new collaterals following denervation.

to be capable of partially neutralizing myelin's ability to inhibit neurite outgrowth. Use of this antibody to isolate the corresponding antigen yielded the protein now called Nogo. Two other proteins, myelin-associated glycoprotein (MAG) and oligodendrocyte-myelin glycoprotein (OMgp), initially isolated as major components of myelin, have also been found to inhibit the growth of some neuronal types.

Intriguingly, Nogo, MAG, and OMgp bind to common membrane receptors, NogoR and PirB (Figure 50–8). NogoR, as well as related receptors such as LINGO that have been implicated in growth inhibition, all interact with the neurotrophin receptor p75 (Chapter 46). This interaction converts p75 from a growth-promoting to a growth-inhibiting receptor. Perhaps because there are so many growth inhibitory factors and receptors, regeneration of central axons is not greatly enhanced in mutant mice lacking any one of them. However, many of the inhibitory components trigger the same intracellular signaling pathway in which RhoA is activated, thereby stimulating Rho kinase (ROCK); ROCK in turn leads to the collapse of growth cones and blocks actin and tubulin polymerization required for neurite growth. Current studies are

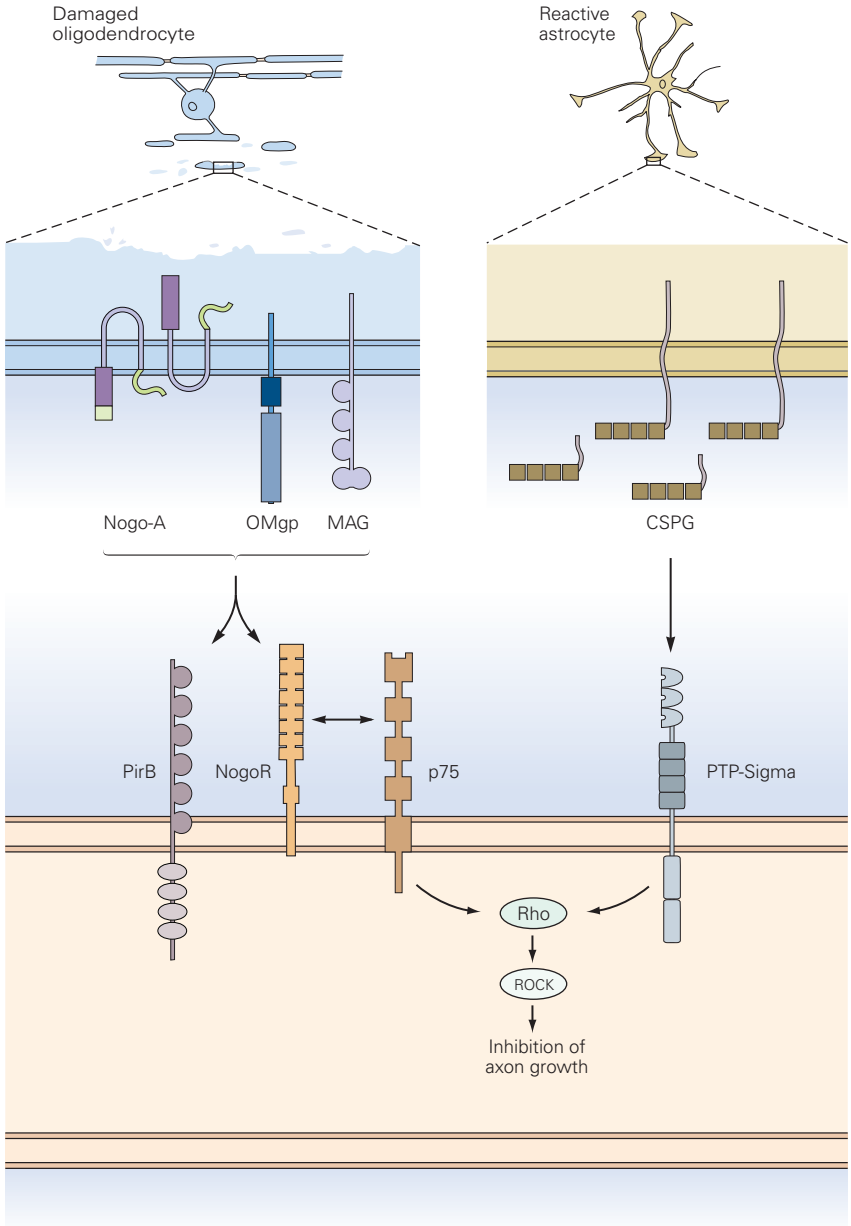

Figure 50–8 Myelin and glial scar components that inhibit regeneration of central axons. (Adapted from Yiu and He 2006.)

Left: Myelin contains the proteins Nogo-A, oligodendrocyte-myelin glycoprotein (**OMgp**), and myelin-associated glycoprotein (**MAG**). All three proteins are exposed when myelin breaks down. They can bind to the receptor protein NogoR, which can associate with the neurotrophin receptor p75, as well as an immunoglobulin-like receptor protein PirB. Inactivation of PirB results in a modest enhancement of corticospinal axon regeneration. *Right:* Chondroitin sulphate proteoglycans (**CSPG**) are major components of the glial scar and are thought to suppress axon regeneration through interaction with the receptor tyrosine phosphatase PTP-sigma, which activates intracellular mediators such as Rho and ROCK.

exploring whether interference with that shared pathway might neutralize the impact of many inhibitors in one fell swoop.

Injury-Induced Scarring Hinders Axonal Regeneration

Myelin debris is not the only source of growth-inhibiting material in the injured brain or spinal cord. As noted earlier, astrocytes become activated and proliferate following injury, acquiring features of reactive astrocytes that generate scar tissue at sites of injury. Scarring is an adaptive response that helps to limit the size of the injury, reestablish the blood-brain barrier, and reduce inflammation.

But the scar itself hinders regeneration in two ways: through mechanical interference with axon growth and through growth-inhibiting effects of proteins produced by cells within the scar. Chief among these inhibitors are a class of chondroitin sulfate proteoglycans (CSPG) that are produced in abundance by reactive astrocytes and directly inhibit axon extension by interaction with tyrosine phosphatase receptors on axons (Figure 50–8). Attention has therefore focused on ways of dissolving the glial scar by infusion of an enzyme called *chondroitinase*, which breaks down the sugar chains on CSPG. This treatment promotes axon regeneration and functional recovery in animals. Drugs that reduce inflammation and decrease scarring, notably prednisolone, are also beneficial if administered shortly after injury, before the scar forms.

An Intrinsic Growth Program Promotes Regeneration

So far, we have emphasized differences between the local environments of peripheral and central axons. However, environmental differences cannot completely account for the poor regeneration of central axons. Even though they can regenerate in peripheral nerves, central axons grow much less well than peripheral axons when navigating the same path. Thus, adult central axons may be less capable than peripheral axons of regeneration.

In support of this idea, experiments in tissue culture have shown that the growth potential of central neurons decreases with age, whereas mature peripheral neurons extend axons robustly in a favorable environment. One potential explanation for this difference is variation in the expression of proteins thought to be critical for optimal axon elongation. One example is the 43 kDa growth-associated protein, or GAP-43. This protein is expressed at high levels in embryonic central and peripheral neurons. In peripheral neurons, the level remains high in maturity and increases even more following axotomy, whereas in central neurons, its expression decreases as development proceeds. Transcription factors required to coordinate axonal growth programs are also expressed at high levels during development, and then are downregulated in maturity.

Is this reduced ability of central axons to regenerate reversible? Hope is provided by two sets of studies. One involves what has been called a "conditioning lesion." Recall that primary sensory neurons in dorsal root ganglia have a bifurcated axon, with a peripheral branch that extends to skin, muscle, or other targets, and a central branch that enters the spinal cord. The peripheral branch regenerates well following injury, whereas the central branch regenerates poorly. However, the central branch will regenerate successfully if the peripheral branch is damaged several days before the central branch is damaged (Figure 50–9). Somehow, prior injury or conditioning lesion activates an axonal growth program.

One component of the growth program responsible for regeneration of the central branch appears to be cyclic adenosine monophosphate (cAMP). This second-messenger molecule activates enzymes that in turn promote neurite outgrowth. Levels of cAMP are high when neurons initially form circuits; they decline postnatally in central but not peripheral neurons. In some instances, increased supplies of cAMP or proteins normally activated by cAMP can promote regeneration of central axons following injury. Accordingly, drugs that increase cAMP levels or activate targets of cAMP are being actively considered as therapeutic agents to be administered following spinal cord injury.

A second group of investigations has manipulated developmentally regulated intrinsic factors to restore regenerative ability in adults. For example, injury sometimes leads to formation of cytokines such as ciliary neurotrophic factors (CNTFs) that promote growth by activating a signaling pathway involving molecules called JAK and STAT that travel to the nucleus and regulate a growth program. In adults, however, the pathway is inhibited by a protein called suppressor of cytokine signaling 3 (SOCS3). Deletion of the *SOCS3* gene in mice relieves the inhibition and augments the ability of cytokines to promote regeneration of injured axons (Figure 50–10A).

Similarly, a signaling pathway involving the kinase mammalian target or rapamycin (mTOR) regulates energy metabolism, promoting an anabolic growth-promoting state required for axon regeneration. However, mTOR is downregulated as central neurons

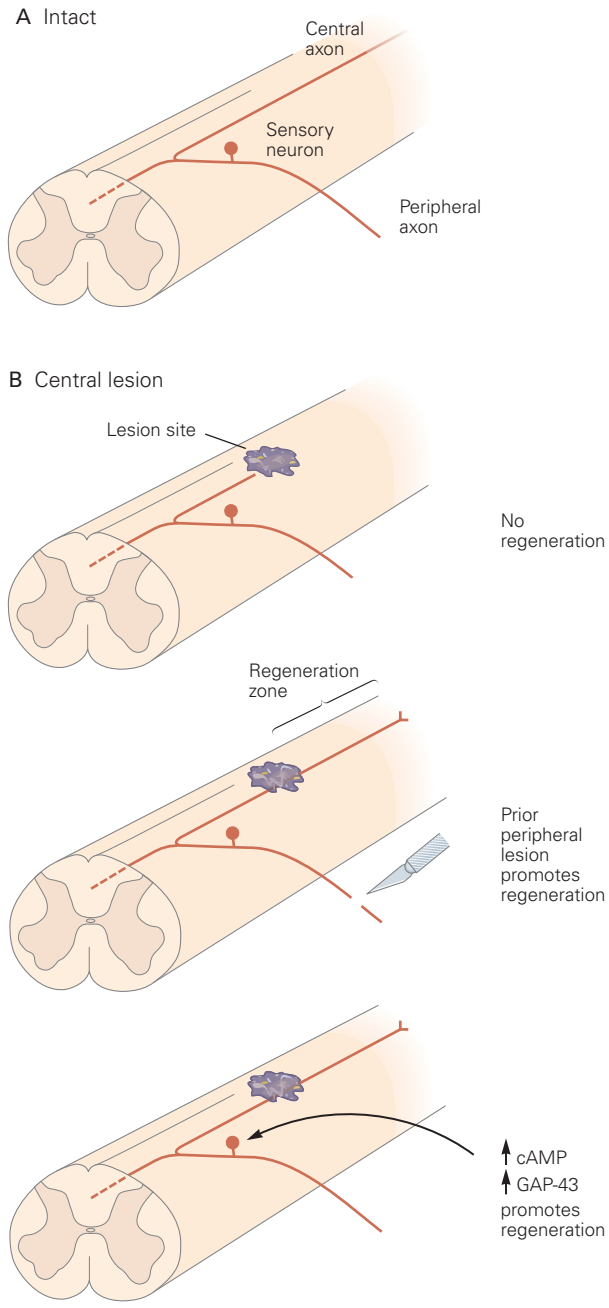

Figure 50–9 A conditioning lesion promotes regeneration of the central branch of a primary sensory neuron axon. After lesions of the spinal cord, there is little regeneration of the central branch beyond the injury site. However, if the peripheral branch of the axon is sectioned before the central branch is damaged, the latter will grow beyond the lesion site. The impact of such a "conditioning lesion" can be mimicked by elevating levels of cyclic adenosine monophosphate (**cAMP**) or of the growth-associated protein GAP-43 in the peripheral branch.

mature and is further inhibited by a phosphatase called PTEN. Analogous to SOCS3 and JAK/STAT signaling, deletion of the *PTEN* gene in mice promotes axonal regrowth following injury to the optic nerve or spinal cord (Figure 50–10B). Moreover, loss of SOCS3 and PTEN stimulates regeneration significantly more than loss of either one. Although their multiple roles make it unlikely that either SOCS3 or PTEN is a useful target for therapy, the signaling pathways they regulate provide multiple starting points for designing drugs that could augment regeneration.

Formation of New Connections by Intact Axons Can Lead to Recovery of Function Following Injury

So far, we have discussed interventions designed to enhance the limited regenerative capacity of injured central axons. An alternative strategy focuses on the significant, although incomplete, functional recovery that can occur following injury even without appreciable regeneration of cut axons. If the basis for this limited recovery of function can be understood, it may be possible to enhance it.

A rearrangement of existing connections in response to injury may contribute to recovery of function. We have learned that axotomy leads to changes in both the inputs to and the targets of the injured neuron. Although many of these changes are detrimental to function, some are beneficial. In particular, the central nervous system can, following injury, spontaneously undergo adaptive reorganization that helps it regain function. For example, after transection of the descending corticospinal pathway, which occurs with many traumatic injuries of the spinal cord, the cortex can no longer transmit commands to motor neurons below the site of the lesion. Over several weeks, however, intact corticospinal axons rostral to the lesion begin to sprout new terminal branches and form synapses on spinal interneurons whose axons extend around the lesion, thereby forming an intraspinal detour that contributes to limited recovery of function (Figure 50–11).

Similar instances of functional reorganization have been demonstrated in the motor cortex and brain stem. These compensatory responses attest to the latent plasticity of the nervous system. The ability of the nervous system to rewire itself is most vigorous during the critical periods of early postnatal life but can be revived by traumatic events in adulthood (Chapter 49).

How can the rewiring ability of the central nervous system be improved? It is possible that some of the beneficial effects of grafts in experimental animals reflect reorganization of intact axons rather than regeneration of transected axons. As the nervous system's

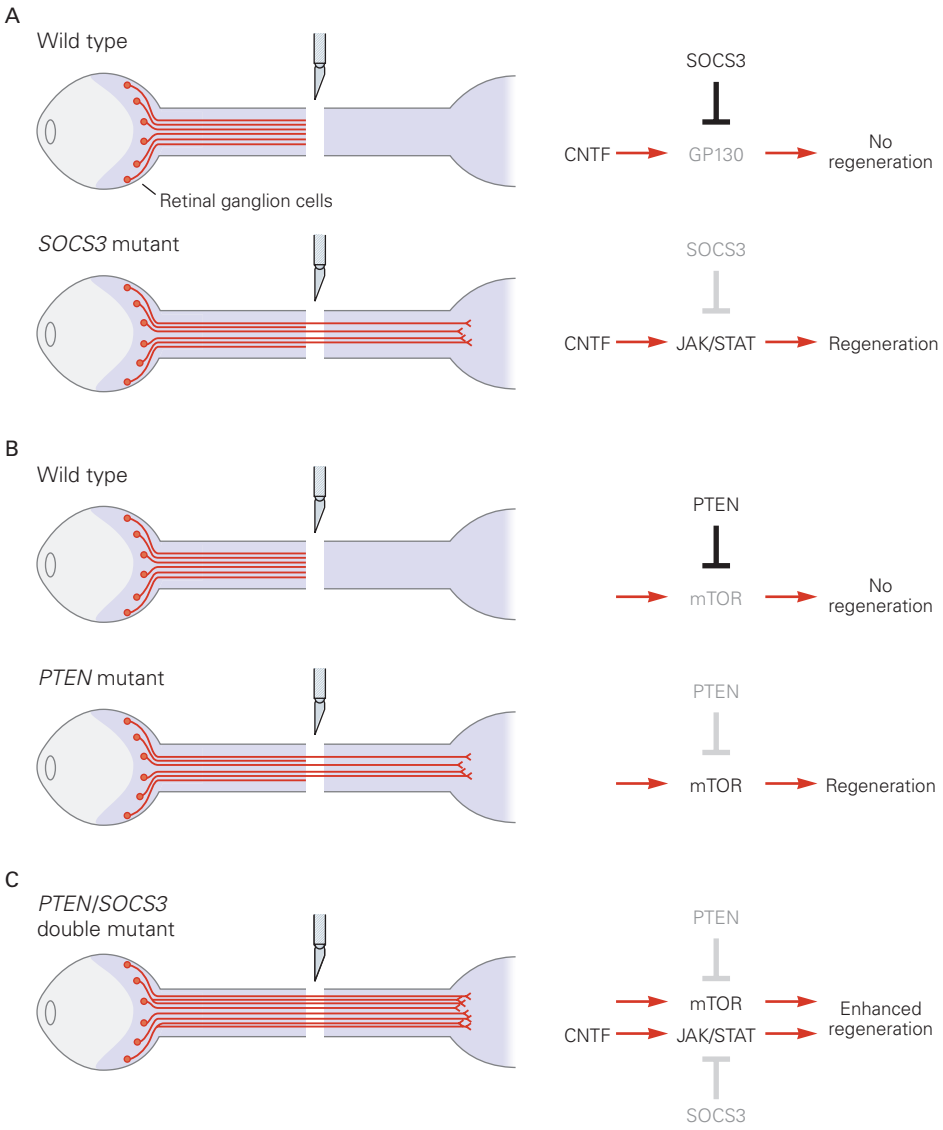

Figure 50–10 Signaling pathways that regulate axon regeneration in the optic nerve.

A. The regeneration of retinal ganglion cell axons in the optic nerve is normally constrained by neuronal expression of several genes. One encodes SOCS3, which blocks the ability of ciliary neurotrophic factor (**CNTF**) to bind its receptor GP130 and thus blocks CNTF from promoting regeneration. In *SOCS3* mutant mice, ambient levels of CNTF are sufficient to improve optic nerve regeneration. Elimination of GP130 as well as SOCS3 blocks the capacity for regeneration. Addition of extra CNTF enhances the capacity for regeneration in *SOCS3* mutant mice.

B. Another gene encodes PTEN, which blocks signaling through the mammalian target of rapamycin (**mTOR**) pathway, which regulates energy metabolism. Accordingly, regeneration is enhanced in *PTEN* mutant mice.

C. Because *SOCS3* and *PTEN* regulate different growth-promoting signals, mutant mice lacking both genes exhibit greater regenerative ability than either single mutant. (Adapted from Smith et al. 2009.)

plasticity becomes better understood, therapeutic strategies that promote specific changes in circuitry may become possible. Perhaps most promising is an approach in which cellular or molecular interventions that promote growth are combined with behavioral therapies that result in circuit rewiring.

Neurons in the Injured Brain Die but New Ones Can Be Born

The failure to grow a new axon is by no means the worst fate that can befall an injured neuron. For many neurons, axotomy leads to the death of the cell. Efforts

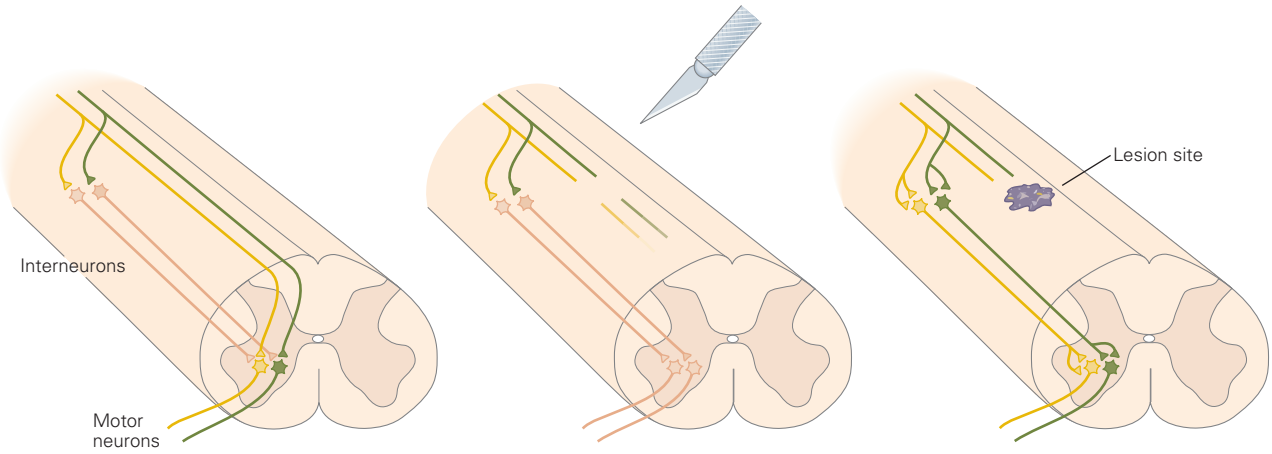

Figure 50–11 Function can be recovered after spinal cord injury through reorganization of spinal circuits. Severed corticospinal axons can reestablish connections with motor neurons by sprouting axon collaterals that innervate propriospinal interneurons whose axons bypass the lesion and contact motor neurons located caudal to the lesion site. (Adapted from Bareyre et al. 2004.)

to improve recovery following injury therefore need to consider survival of neurons and not simply the regrowth of axons. Since neuronal death is a frequent consequence of other neural insults, such as stroke and neurodegenerative disease, improved ways of retaining or replacing neurons would have broad utility.

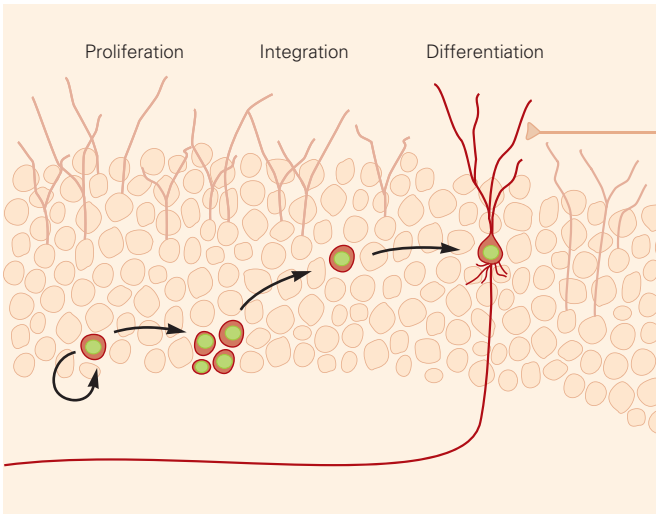
The loss of cells following injury is not unique to the nervous system, although in other tissues, new cells are often effective at repairing damage. This regenerative capacity is most dramatic in the hematopoietic system, where a few stem cells can repopulate the entire adaptive immune system. In contrast, it has long been believed that the generation of neurons is complete by birth. Because of this, approaches to regeneration have often focused on finding ways to spare neurons that would otherwise die.

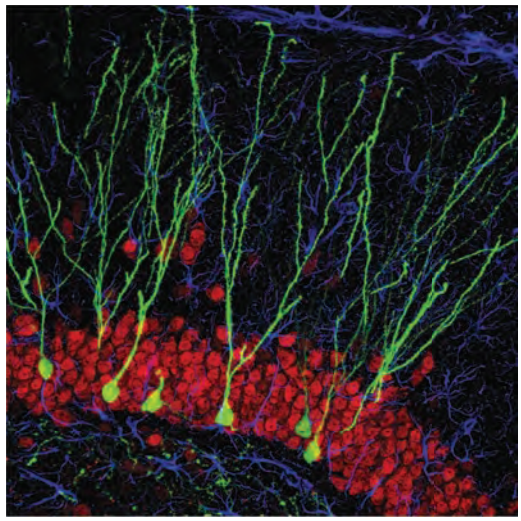
This traditional view has changed, prompted initially by Joseph Altman's discovery in the 1960s that neurogenesis continues into adulthood in some parts of the mammalian brain. Since this finding challenged fundamental tenets of prevailing dogma, the idea that new neurons could form in postnatal rodents was met with skepticism for three decades.

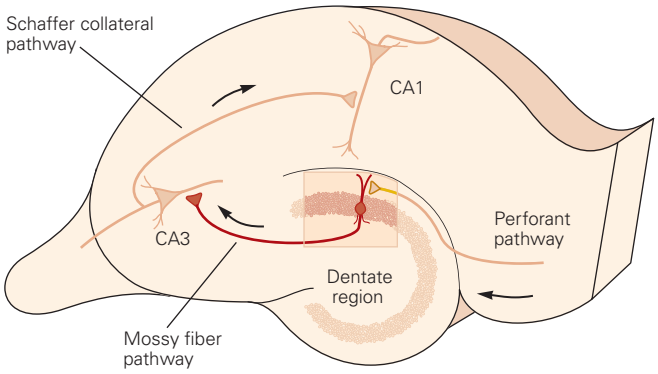
Eventually, however, the application of better cell labeling technologies amply supported Altman's conclusion and showed that it also applies to nonhuman primates and even, in a limited way, to humans. We are now confident that new neurons are added to the dentate gyrus of the hippocampus and to the olfactory bulb throughout life, although the rate of addition declines with age. Some of the newborn cells in the dentate gyrus of the adult hippocampus die soon after they are born and others become glial cells, but a substantial minority differentiate into granule cells that are indistinguishable from those born at embryonic stages (Figure 50–12). New neurons are also added to the adult olfactory bulb. They are generated near the surface of the lateral ventricles, far from the bulb itself, and then migrate to their destination (Figure 50–13). In both cases, the new neurons extend processes, form synapses, and become integrated into functional circuits. Thus, neurons born at embryonic stages are gradually replaced by later-born neurons, so that the total number of neurons in these regions of the brain is maintained.

The properties of neurons born in mature animals are not completely understood, but they appear able to recapitulate many of the properties of neurons that arise in the embryo. When the generation of new neurons in the adult is prevented, certain behaviors mediated by the olfactory bulb and hippocampus are degraded. Conversely, some behavioral alterations are accompanied by alterations in the tempo of adult neurogenesis. Adult neurogenesis can be decreased in animal models of depression and chronic stress, whereas enrichment of the habitat of an animal or an increase in the physical activity of otherwise sedentary rodents can increase the generation of new neurons.

What cells give rise to adult-born neurons? The principle that embryonic neurons and glia arise from multipotential progenitors also applies to neurons born in adults. Stem cells are the source of neurons in the adult as well as the embryo. They are likely derived from radial glia, which also serve as a source of







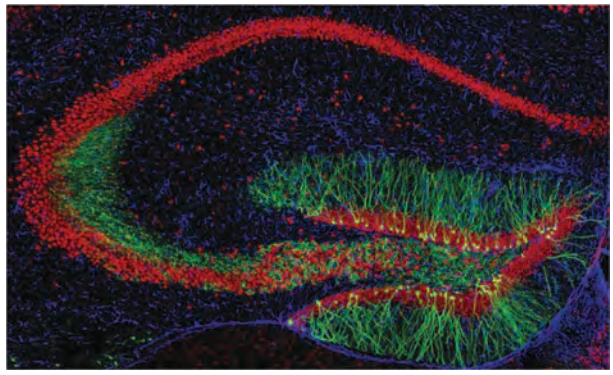


Figure 50–12 Neurons born in the germinal zone of the dentate gyrus in adult rodents are integrated into hippocampal circuits. The diagrams on the left show the pathways of neuronal differentiation and integration into dentate gyrus circuits. The images on the right show newly generated neurons and their dendritic arbors labeled with a virus expressing green fluorescence protein. (Micrographs reproduced, with permission, from F. Gage.)

neurons during embryonic development (Chapter 46). A subset of these cells exit the cell cycle during gestation, become quiescent, and take up residence near the ventricular surface. In adulthood, they are activated, reenter the cell cycle, and give rise to neurons.

Although so far adult neurogenesis has not been directly linked to repair of damaged tissue, its discovery has influenced research on recovery from injury in two important ways. First, the findings that endogenously generated neurons can differentiate and extend processes through the thicket of adult neuropil, and can be integrated into functional circuits, led researchers to test the idea that the same could be true for transplanted neurons or precursors. Second, since neural precursors can be induced to divide and differentiate, strategies designed to augment this innate ability are now being considered, with the goal of producing neurons in large enough numbers to replace those lost to injury or neurodegenerative disease. As we describe below, these ideas have progressed over the past few decades from science fiction to efforts that are tantalizingly close to clinical tests.

Therapeutic Interventions May Retain or Replace Injured Central Neurons

Transplantation of Neurons or Their Progenitors Can Replace Lost Neurons

For many years, neurologists have transplanted developing neurons into experimental animals to see if the new neurons could reverse the effects of injury or disease. These attempts have had promising results in a few cases.

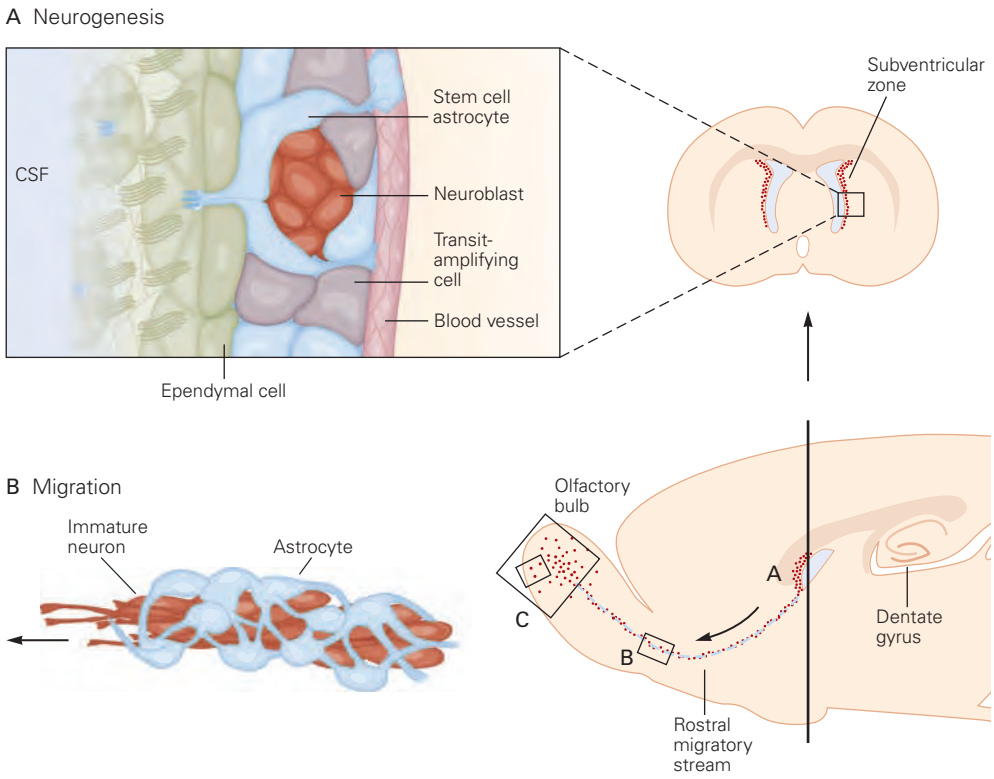

Figure 50–13 The origin and fate of neurons born in the adult ventricular zone. (Adapted from Tavazoie et al. 2008.)

A. Neuroblasts develop in an orderly progression from astrocytic stem cells via a population of cells within a local niche close to blood vessels in the subventricular zone. (Abbreviation: **CSF**, cerebrospinal fluid.)

B. Neuroblasts differentiate into immature neurons that migrate to the olfactory bulb using astrocytes as guides. They crawl along each other in a process called chain migration.

C. On arrival in the olfactory bulb, immature neurons differentiate into granule cells and periglomerular cells, two classes of olfactory bulb interneurons. (Image reproduced, with permission, from A. Mizrahi.)

One is to replace dopaminergic cells that die in Parkinson disease. When transplanted into the striatum, these neurons release dopamine onto their targets without the need to grow long axons or form elaborate synapses (Figure 50–14). Another is to transplant immature inhibitory interneurons from the ganglionic eminences in which they are produced (Chapter 46) to the cortex, where they mature and form synapses. By enhancing inhibition, these neurons attenuate the manifestations of disorders in which insufficient inhibitory drive plays a role, such as epilepsy and anxiety.

Unfortunately, application of these methods to human patients has been fraught with difficulties. One is the difficulty of obtaining and growing developing neurons in sufficient numbers and with sufficient purity. Second, it has been challenging to modify neurons by introducing new genes so as to improve their chances of functioning in a new environment. Third, in many cases, the grafted neurons are already too mature

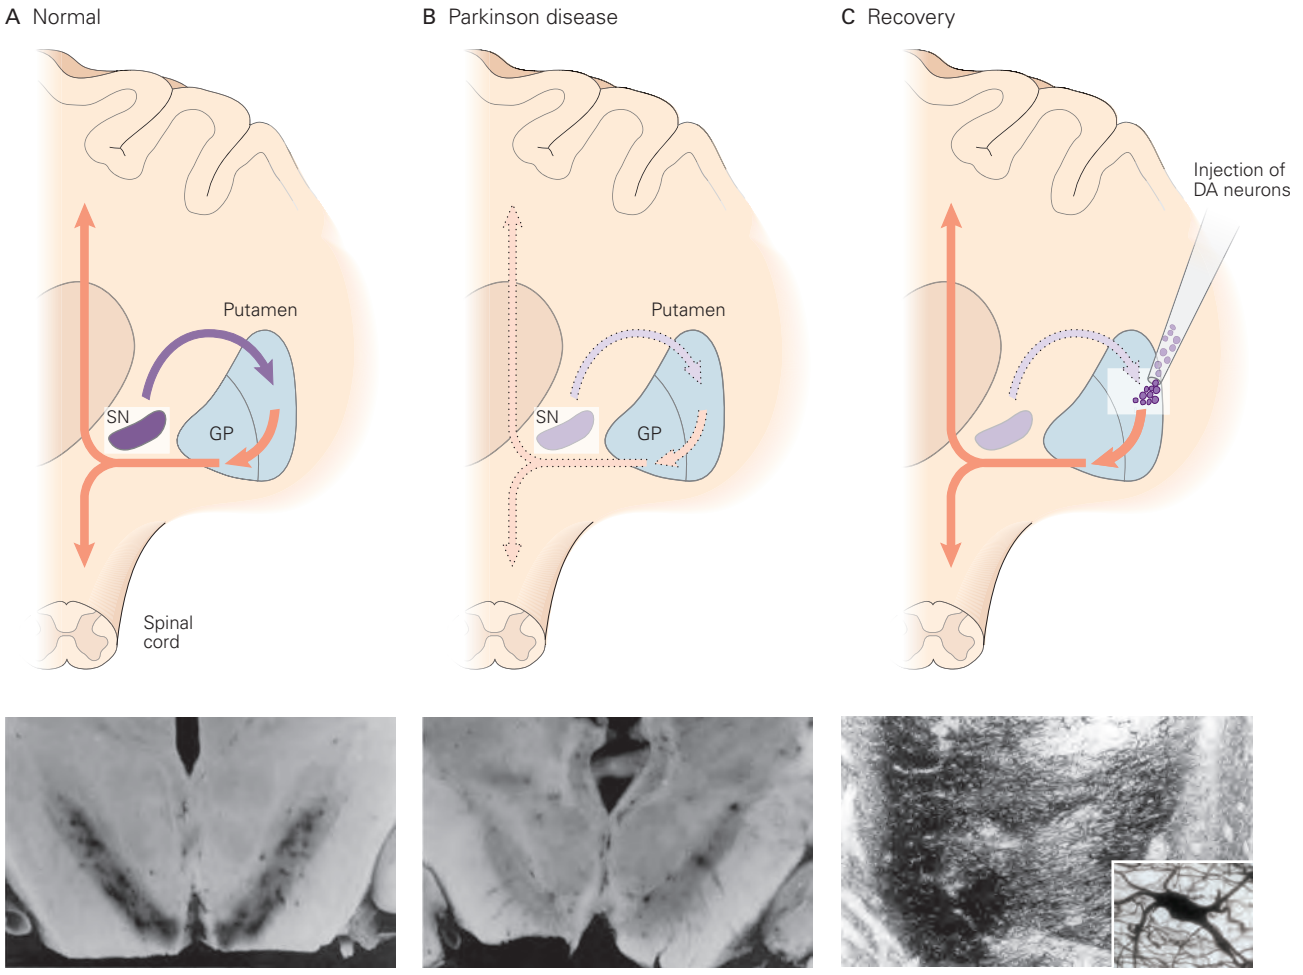

Figure 50–14 Loss of dopaminergic (DA) neurons in Parkinson disease can be treated by grafting embryonic cells into the putamen.

A. In the healthy brain, dopaminergic projections from the substantia nigra (**SN**) innervate the putamen, which in turn activates neurons in the globus pallidus (**GP**). Pallidal outputs to the brain and spinal cord facilitate movement. The image below shows melanin-rich dopaminergic neurons in human substantia nigra.

B. In Parkinson disease, the loss of dopaminergic neurons in the substantia nigra deprives the putamen–globus pallidus pathways of their drive. The image beneath the diagram shows the virtual absence of melanin-rich dopaminergic neurons in the substantia nigra of an individual with Parkinson disease.

C. Direct injection of embryonic dopaminergic neurons into the putamen reactivates the globus pallidus output pathways. The image below shows tyrosine hydroxylase expression in the cell bodies and axons of embryonic mesencephalic dopaminergic neurons grafted into the putamen of a human patient. (Image reproduced, with permission, from Kordower and Sortwell 2000. Copyright © 2000. Published by Elsevier B.V.)

to differentiate properly or to integrate effectively into functional circuits.

These obstacles can be overcome by transplanting neural precursors into the adult brain where they can go on to differentiate into neurons in a hospitable environment. Several classes of precursors have been transplanted successfully, including neural stem cells and committed precursors. Some initial success has been obtained with embryonic stem (ES) cells. These cells are derived from early blastocyst stage embryos and can give rise to all cells of the body. Because they can divide indefinitely in culture, large numbers of cells can be generated, induced to differentiate, and then engrafted.

More recently, this technology has been enhanced by the molecular reprogramming of skin fibroblast cells to create induced pluripotent stem (iPS) cells (Figure 50–15). These cells have a distinct advantage over ES cells; embryos are not required for their production, effectively bypassing a minefield of practical, political, and ethical concerns that have hindered research using human ES cells. Another advantage of iPS cells is that they can be generated from an individual patient's own skin cells, neatly avoiding issues of immunological incompatibility. It is also possible to genetically modify the iPS cells in culture by repairing a defective gene before transplantation.

Because ES and iPS cells have the potential to generate any cell type, it is essential that their differentiation be guided along specific pathways in culture before they are transplanted. Methods for generating specific classes of neural precursors, neurons, and glial cells from ES and iPS cells have now been devised (Figure 50–15).

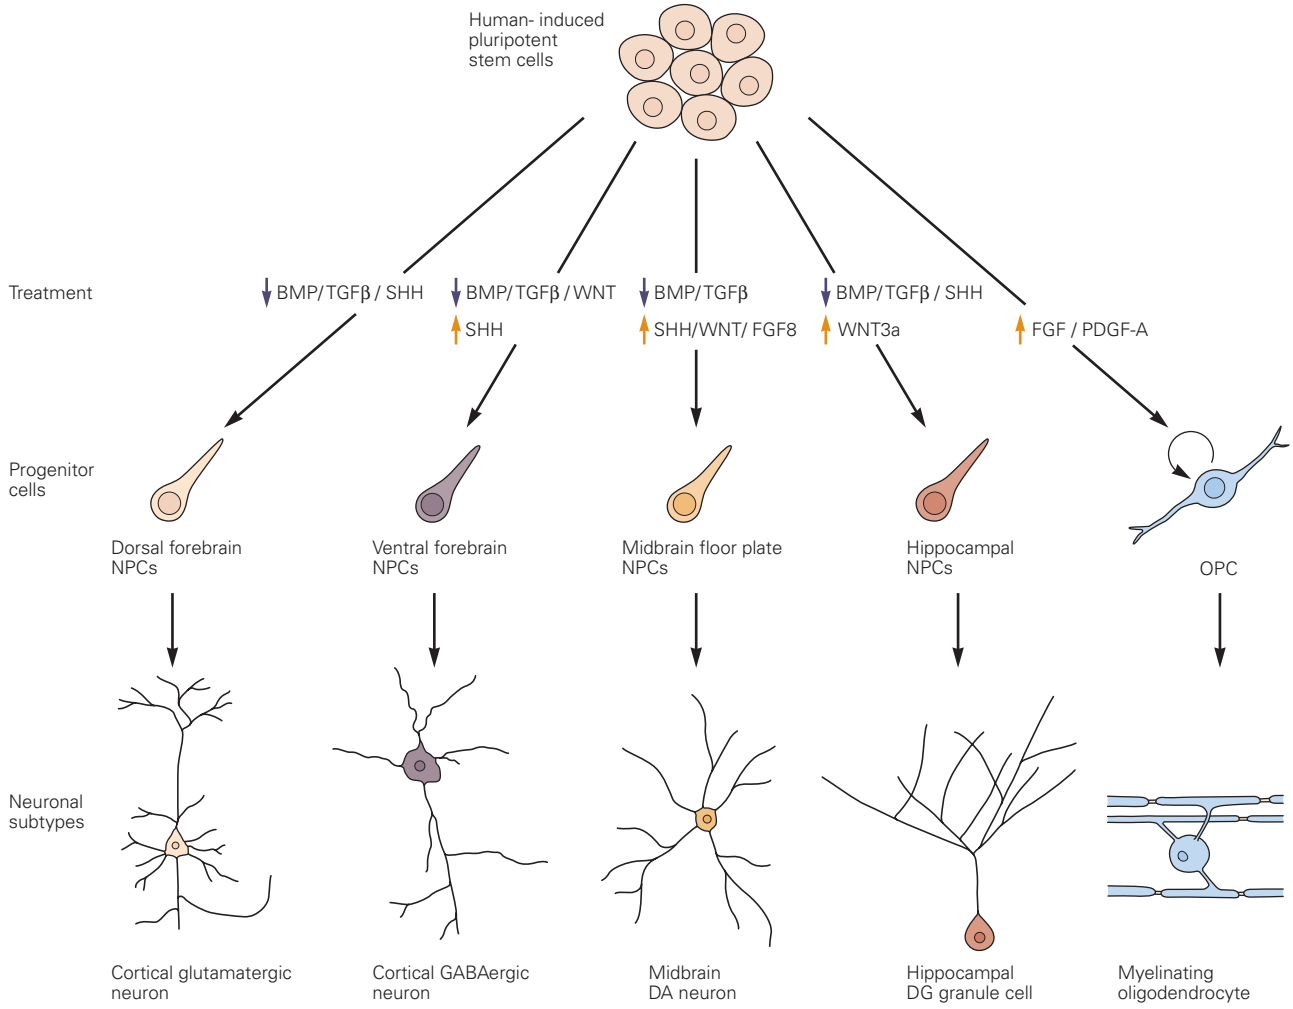

Figure 50–15 Induced pluripotent stem cells can be reprogrammed to generate precursors of many neuronal and glial types. The precursors can then be transplanted into the brain or spinal cord, where cells complete their differentiation and integrate into functional circuits. (Abbreviations: **DA**, dopamine; **DG**, dentate gyrus; **NPC**, neural progenitor cell; **OPC**, oligodendrocyte progenitor cell.) (Adapted, with permission, from Wen et al. 2016. Copyright © 2016 Elsevier Ltd.)

For example, it is possible to generate neurons that possess many or all of the properties of the spinal motor neurons that are lost in amyotrophic lateral sclerosis (Figure 50–16) or to generate the dopaminergic neurons lost from the striatum in Parkinson disease and then to engraft such neurons into the spinal cord or brain.

Although many hurdles need to be overcome, clinical trials using ES and iPS cell-derived neurons are underway. In addition, these cells are being used in chemical screens to identify compounds that counteract the cellular defects that underlie human neurodegenerative disease.

Stimulation of Neurogenesis in Regions of Injury May Contribute to Restoring Function

What if, following injury in adults, endogenous neuronal precursors could be stimulated to produce neurons capable of replacing those that have been lost? Two sets of recent findings suggest that this idea is not so far-fetched.

First, precursors capable of forming neurons in culture have been isolated from many parts of the adult nervous system, including the cerebral cortex and spinal cord, even though neurogenesis in adults is ordinarily confined to the olfactory bulb and hippocampus. This diversion of cell fate led to the idea that neurogenesis in the adult occurs in only a few sites, because only they contain appropriate permissive or stimulatory factors. This hypothesis has spurred a search for such factors, in the hope that they could be used to render a larger range of sites capable of supporting neurogenesis.

Second, in a few cases, the generation of new neurons can be stimulated by traumatic or ischemic injury (akin to stroke), even in areas such as the cerebral cortex

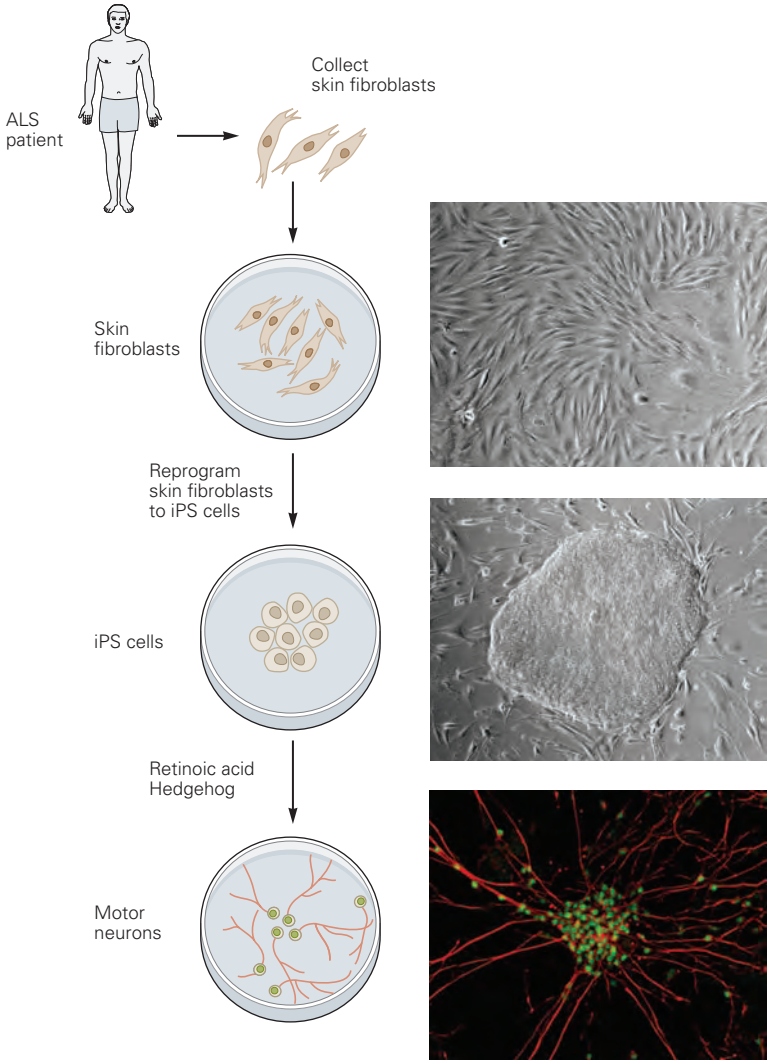

Figure 50–16 **Induced pluripotent stem cells derived from an individual with amyotrophic lateral sclerosis (ALS) can differentiate into spinal motor neurons.** Fibroblasts from the skin of a patient with ALS were used to generate induced pluripotent stem (**iPS**) cells, which were then directed to a motor neuron fate (see Figure 50–15). These cells can be used to analyze mechanisms that underlie motor neuron loss in ALS. The images at right show (from top to bottom) cultured fibroblasts, an iPS cell clump, and differentiated motor neurons expressing characteristic nuclear transcription factors (**green**) and axonal proteins (**red**). (Micrographs reproduced, with permission, from C. Henderson, H. Wichterle, G. Croft, and M. Weygandt.)

or spinal cord in which neurogenesis normally fails to occur. The fact that recovery after stroke and injury is poor demonstrates that spontaneous compensatory neurogenesis, if it occurs in humans, is insufficient for tissue repair. However, injury-induced neurogenesis has been enhanced in experimental animals in several ways. In one, administration of growth factors promotes neuronal production from progenitors grown in culture. In another, glial cells that retain the capacity to divide, such as Müller glia in the retina or astrocytes in the cortex, are reprogrammed to differentiate into neurons. If such interventions could be adapted to humans, the range of neurons subject to replacement would be greatly increased.

Transplantation of Nonneuronal Cells or Their Progenitors Can Improve Neuronal Function

Cells other than neurons are lost after brain injury. Among the most profound losses are those of oligodendrocytes, the cells that form the myelin sheath around central axons. The stripping of myelin continues long after traumatic injury and contributes to progressive loss of function of axons that may not have been injured directly.

Although the adult brain and spinal cord are capable of generating new oligodendrocytes and replacing lost myelin, this production is insufficient to restore function in many cases. Since several common neurological diseases, most notably multiple sclerosis, are accompanied by a profound state of demyelination, there is strong interest in providing the nervous system with additional oligodendrocyte precursors in order to augment remyelination.

Neural stem cells, multipotential progenitors, ES cells, and iPS cells can give rise not only to neurons but also to nonneural cells, including oligodendrocytes and their direct precursors. Indeed, at present, human ES cells are being channeled into oligodendrocyte progenitor cells and implanted into injured spinal cords of experimental animals. Transplanted cells that differentiate into oligodendrocytes enhance remyelination and substantially improve the locomotor ability of experimental animals (Figure 50–17).

Restoration of Function Is the Aim of Regenerative Therapies

We need to bear in mind that efforts to replace central neurons or to enhance the regeneration of their axons

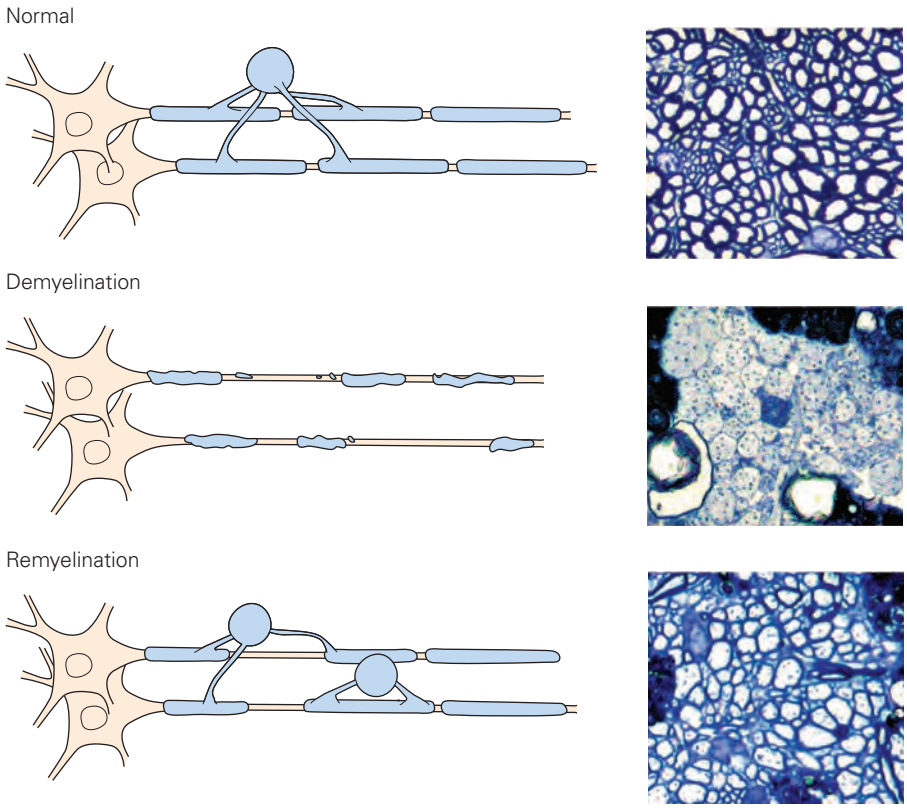

Figure 50–17 Restoration of myelination in the central nervous system by transplanted oligodendrocyte stem cells. In rodents with demyelinated axons, grafts of oligodendrocyte precursor cells can restore myelination to near normal. Sections through central nerve tracts are shown in the images at right. Figure 50–18 Regenerated retinal ganglion axons in the optic nerve can form functional synapses. (Adapted, with permission, from Keirstead et al. 1989. Copyright © 1989 AAAS.)

A. A segment of optic nerve in an adult rat was removed, and a segment of sciatic nerve was grafted in its place. The other end of the sciatic nerve was attached to the superior colliculus. Some retinal ganglion cell axons regenerated through the sciatic nerve and entered the superior colliculus.

B. Once the axons of the retinal ganglion neurons had regenerated, recordings were made from the superior colliculus. Flashes of light delivered to the eye elicited action potentials in collicular neurons, demonstrating that at least some regenerated axons had formed functional synapses.

would be of little use if these axons were unable to form functional synapses with their target cells. The same fundamental questions asked about axon regeneration in adults therefore apply to synaptogenesis: Can it happen, and if not, why not?

It has been difficult to address these questions because axonal regeneration following experimentally induced injury is usually so poor that the axons never reach appropriate target fields. However, several of the studies discussed earlier in this chapter offer hope that synapse formation is possible within the dense adult neuropil. In fact, axon branches that regenerate following injury can form synapses on nearby targets. For example, Aguayo and his colleagues found that retinal axons were able to regrow into the superior colliculus when they were channeled through a peripheral nerve that had been grafted into the optic nerve (Figure 50–18A). Remarkably, some collicular neurons fired action potentials when the eye was illuminated, showing that functional synaptic connections had been reestablished (Figure 50–18B). More recent studies have promoted regeneration of severed axons by enhancing their intrinsic growth programs, as described above, and observed some restoration of function.

Likewise, neurons that arise endogenously or are implanted by investigators can form and receive synapses. Thus, there is reason to believe that if injured axons can be induced to regenerate, or new neurons supplied to replace lost ones, they will wire up in ways that help restore lost functions and behaviors.

Highlights

1. When axons are transected, the distal segment degenerates, a process called Wallerian degeneration. The proximal segment and cell body also undergo changes, as do the injured neuron's synaptic inputs and targets.
2. It was long thought that Wallerian degeneration was a passive and inevitable consequence of the distal segment being deprived of sustenance from the cell body, but it is not known to be an active, regulated process. Genes called *NMNAT* and *SARM1* are key components of a core signaling pathway that controls the process. Intervention in the pathway can slow or even halt degeneration.
3. Axons can regenerate and form new synapses following injury, but in mammals, regeneration is far more widespread and effective in peripheral axons than in central axons.

4. A key factor in the differential response of peripheral and central axons is that the environment confronting injured central axons is poor at supporting growth. It both lacks nutritive factors present in the pathway of peripheral nerves and contains growth-inhibitory factors absent from peripheral nerves.
5. Structures that inhibit regeneration include myelin fragments that persist following Wallerian degeneration and astrocytes that form glial scars at injury sites. Inhibitory factors in myelin include Nogo and myelin-associated glycoprotein. Inhibitory factors secreted by astrocytes include chondroitin sulfate proteoglycans.
6. Central regeneration is also hindered by intrinsic decreased ability of adult central neurons to grow, due to downregulation of growth programs active during development. Interventions that restore or disinhibit growth pathways, such as JAK/STAT and mTOR signaling, enable regeneration.
7. However, it is important to note that the failure of regeneration following injury may be related to the stabilization of connections that occurs at the end of critical periods. For example, myelination, which occurs largely at the end of a critical period, may have the secondary effect of preventing further, large-scale rearrangement of synaptic connections. Thus, caution will be needed to ensure that treatments aimed at fostering recovery following injury do not end up promoting formation of maladaptive circuits.
8. Another approach for restoring function following damage is to harness the ability of intact axons to form new connections, generating adaptive circuits that can compensate to some extent for those lost to injury.
9. The traditional view that all neurogenesis occurs during or shortly after gestation has now been modified by the discovery that new neurons are born throughout life in a few brain areas. These neurons arise from resident stem cells and can integrate into functional circuits.
10. Cells capable of forming new neurons are also present in many other areas of the brain and spinal cord but remain quiescent. Attempts to activate them by providing growth factors or introducing growth-promoting genes (transcriptional reprogramming) could harness their potential following injury or in neurodegenerative disease.
11. Another approach to neuronal replacement is to implant developing neurons. Although fetal neurons are sometimes used for this purpose in experimental animals, a more useful source may be neurons derived from ES or iPS cells. They can be grown in large quantities, genetically modified if necessary, and treated to differentiate into specific neuronal types. Clinical studies using this approach are now beginning.

Sexual Differentiation of the Nervous System

Few words are more loaded with meaning than the word "sex." Sexual activity is a biological imperative and a major human preoccupation. The physical differences between men and women that underlie partner recognition and reproduction are obvious to all of us, and their developmental origins are well understood. In contrast, our understanding of behavioral differences between the sexes is primitive. In many cases, their very existence remains controversial, and the origins of those that have been clearly demonstrated remain unclear.

In this chapter, we first briefly summarize the embryological basis of sexual differentiation. We then discuss at greater length the behavioral differences between the two sexes, focusing on those differences or dimorphisms for which some neurobiological basis has been found. These dimorphisms include physiological responses (erection, lactation), drives (maternal behavior), and even more complex behaviors (gender identity). In analyzing these dimorphisms, we will discuss three issues.

First, what are the genetic origins of sexual differences? Human males and females have a complement of 23 chromosomal pairs, and only one differs between the sexes. Females have a pair of X chromosomes (and are therefore XX), whereas males have one copy of the X chromosome paired with a Y chromosome (XY). The other 22 chromosome pairs, called *autosomes*, are shared between males and females. We will see that the initial genetic determinants arise from a single gene on the Y chromosome, while later ones arise indirectly from sex-specific patterns of expression imposed upon other genes as development proceeds.

Second, how are sexual differences initiated by the Y chromosome translated into differences between the brains of men and women? We will see that key intermediates are the sex hormones, a set of steroids that

includes testosterone and estrogens. These hormones act during embryogenesis as well as postnatally, first organizing the physical development of both genitalia and brain regions, and later activating particular physiological and behavioral responses. Hormonal regulation is especially complex because the nervous system, which is profoundly influenced by sex steroids, also controls their synthesis. This feedback loop may help to explain how the external environment, including social and cultural factors, can ultimately shape sexual dimorphism at a neural level.

Third, what are the crucial neural differences that underlie sexually dimorphic behaviors? Clear physical and molecular differences between the brains of men and women have been found. These differences reflect differences in neural circuitry between the sexes, and in a few cases, these distinctions in connectivity are directly related to behavioral differences. In other cases, however, sexually dimorphic behaviors appear to result from differential usage of the same basic circuits.

Before proceeding, we must define two words that are commonly used in many ways and sometimes confused with each other: *sex* and *gender.* As a descriptor of biological differences between men and women, the word *sex* is used in three ways. First, *anatomical sex* refers to overt differences including the differences in the external genitalia as well as other sexual characteristics such as the distribution of body hair. *Gonadal sex* refers to the presence of male or female gonads, the testes or ovaries. Finally, *chromosomal sex* refers to the distribution of the sex chromosomes between females (XX) and males (XY).

Whereas *sex* is a biological term, *gender* encompasses the collection of social behaviors and mental states that typically differ between males and females. *Gender role* is the set of behaviors and social mannerisms that is typically distributed in a sexually dimorphic fashion within the population. Toy preferences in children as well as distinctive attire are some examples of gender roles that can distinguish males from females. *Gender identity* is the feeling of belonging to the category of the male or female sex. Importantly, gender identity is distinct from *sexual orientation*, the erotic responsiveness displayed toward members of one or the other sex.

Are gender and sexual orientation genetically determined? Or are they social constructs molded by cultural expectations and personal experience? As the examples in this chapter will illustrate, we are still far from untangling the contributions of genes and environment to these complex phenomena. However, our recognition that genes and experience interact to shape neural circuits gives us a more realistic framework with which to answer this question compared to our predecessors, who were constrained by the simplistic view that genes and experience acted in mutually exclusive ways.

Genes and Hormones Determine Physical Differences Between Males and Females

Chromosomal Sex Directs the Gonadal Differentiation of the Embryo

Sex determination is the embryonic process whereby chromosomal sex directs the differentiation of the gonadal sex of the animal. Surprisingly, this process differs in fundamental ways within the animal kingdom and even among vertebrates. In most mammals, including humans, however, an XY genotype drives differentiation of the embryonic gonad into testes, whereas an XX genotype leads to ovarian differentiation. Hormones produced by the testes and ovaries subsequently direct sexual differentiation of the nervous system and the rest of the body.

It is the presence of the Y chromosome rather than the lack of a second X chromosome that is the crucial determinant of male differentiation. This was first evident in rare individuals born with two or even three X chromosomes in addition to a Y chromosome (XXY or XXXY). These individuals are men who exhibit male-typical traits. In fact, female cells do not have two active X chromosomes. Early in embryogenesis, one of the two X chromosomes in each female cell is chosen at random for inactivation, and the genes on it are rendered transcriptionally silent. Thus, both male and female cells have a single active X chromosome, and male cells also have a Y chromosome.

The sex-determining activity of the Y chromosome is encoded by the gene *SRY* (sex-determining region on Y) whose activity is required for masculinization of the embryonic gonads (Figure 51–1). Inactivation or deletion of *SRY* leads to complete sex reversal: Individuals are chromosomally male (XY) but externally indistinguishable from females. Conversely, in rare instances, *SRY* translocates to another chromosome (to the X chromosome or an autosome) during spermatogenesis. Such sperm can fertilize eggs to produce individuals who are chromosomally female (XX) but externally male. However, such XX sex-reversed men are infertile, as many of the genes required for sperm function are located on the Y chromosome.

How does *SRY* instruct the undifferentiated gonads to develop into testes? The female differentiation

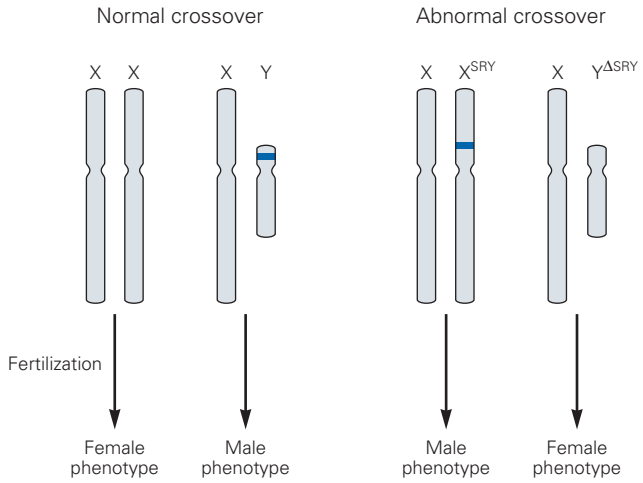

Figure 51–1 The role of the *SRY* gene in sex determination in humans. *SRY*, the sex-determining locus (**blue domain**), resides on the nonhomologous region of the short arm of the Y chromosome. The presence of *SRY* is determinative for male differentiation in many mammals, including primates and most rodents. Normally X- or Y-bearing sperm fertilize an oocyte to generate XX females or XY males, and the resulting phenotypic sex is concordant for the chromosomal sex. Rarely, *SRY* translocates to the X chromosome or an autosome (not shown). In such cases, XX^{SRY} offspring are phenotypically male, whereas $XY^{\Delta SRY}$ offspring (the Δ indicating a gene deletion) are phenotypically female. (Adapted from Wilhelm, Palmer, and Koopman 2007.)

program appears to be the default mode; patterning genes prime the body and gonads to develop along female-specific pathways. The *SRY* gene encodes a transcription factor that regulates expression of genes, some of which prevent execution of the default program and initiate the process of male gonadal differentiation. One of the best-studied targets of the SRY transcription factor is another transcription factor, SOX9, which is required for differentiation of the testes. Thus, SRY initiates a cascade of inductive interactions that ultimately lead to male-specific gonad development.

Gonads Synthesize Hormones That Promote Sexual Differentiation

The chromosomal complement of the embryo directs sexual differentiation of the gonads, and in turn, the gonads determine the sex-specific features of all organs of the body, including the nervous system. They do this by secreting hormones. Gonadal hormones have two major roles. Their developmental role is traditionally referred to as *organizational* because the early effects of hormones on the brain and the rest of the body lead to major, generally irreversible, aspects of cell and tissue differentiation. Later, some of the same hormones trigger physiological or behavioral responses. These influences, generally termed *activational*, are reversible.

One example of an organizational role of gonadal hormones is seen in the differentiation of structures that connect the gonads to the external genitalia. In males, the Wolffian duct gives rise to the vas deferens, the seminal vesicles, and the epididymis. In females, the Müllerian duct differentiates into the oviduct, the uterus, and the vagina (Figure 51–2). Initially, both female (XX) and male (XY) embryos possess Wolffian and Müllerian ducts. In males, the developing testes secrete a protein hormone, the Müllerian inhibiting substance (MIS), and a steroid hormone, testosterone. MIS leads to a regression of the Müllerian duct, and testosterone induces the Wolffian duct to differentiate into its mature derivatives. In females, the absence of MIS permits the Müllerian duct to differentiate into its adult derivatives, and the absence of circulating testosterone causes the Wolffian duct to resorb. Thus, the Y chromosome overrides a female default program to generate male gonads, which in turn secrete hormones that override a female default program of genital differentiation.

The action of MIS is largely confined to embryos, but steroid hormones exert effects throughout life—that is, they also have activational roles at later stages. All of the steroid hormones derive from cholesterol (Figure 51–3). The sex steroids can be divided into androgens, which generally promote male characteristics, and the estrogens plus progesterone that promote female characteristics. The testes produce mostly the androgen testosterone, while the ovaries produce mostly progesterone and an estrogen, 17-β-estradiol. The menstrual cycle is a good example of the activational function of estrogen and progesterone.

A glance at the metabolic relationships among steroid hormones (Figure 51–3) reveals a surprise. The female hormone progesterone is the precursor of the male hormone testosterone, and testosterone is the direct precursor of the female hormone 17-β-estradiol. Thus, the enzymes that convert one hormone to the other control not only the level of the hormone but also the "sign" (male or female) of the hormonal effect. Aromatase, the enzyme that converts testosterone to estradiol, is present at high levels in the ovaries but not in the testes. Differential expression of aromatase is the reason for sexual dimorphism in circulating testosterone and estrogen. Aromatase is also expressed in various regions of the brain (Figure 51–4A), and many of the effects of testosterone on neurons are thought to occur after its conversion to estrogen. Testosterone

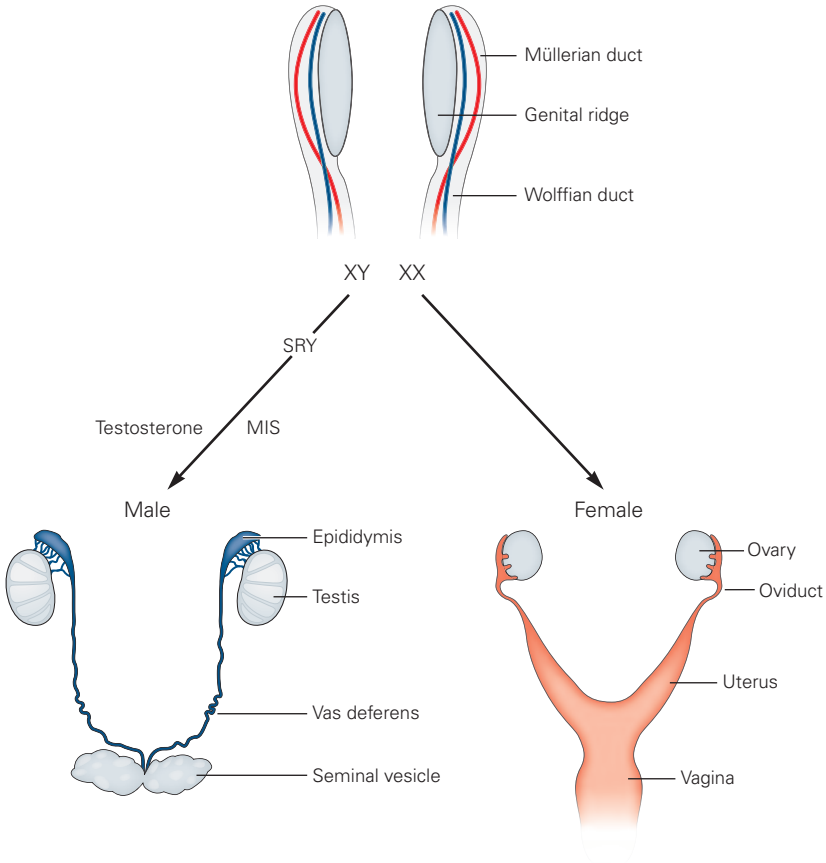

Figure 51–2 Sexual differentiation of the internal genitalia. Embryos of both sexes develop bilateral genital ridges (the gonadal anlagen) that can differentiate into either testes or ovaries; Müllerian ducts, which can differentiate into oviducts, the uterus, and the upper vagina; and Wolffian ducts, which can differentiate into the epididymis, the vas deferens, and the seminal vesicles. In XY embryos, the expression of the *SRY* gene in the genital ridge induces differentiation of this tissue into testes and of the Wolffian ducts into the rest of the male internal genitalia, while the Müllerian ducts are resorbed. In XX embryos, the *absence* of *SRY* permits the genital ridges to develop into ovaries and the Müllerian ducts to differentiate into the rest of the female internal genitalia; in the absence of circulating testosterone, the Wolffian ducts degenerate. (Abbreviation: **MIS**, Müllerian inhibiting substance.) (Adapted, with permission, from Wilhelm, Palmer, and Koopman 2007.)

is also converted by the enzyme 5α-reductase into another androgenic steroid, 5α-dihydrotestosterone (DHT), in various target tissues, including the external genitalia. In these tissues, DHT is responsible for induction of secondary male characteristics such as facial and body hair and growth of the prostate. Later in life, DHT is the culprit in male pattern baldness.

Disorders of Steroid Hormone Biosynthesis Affect Sexual Differentiation

As one can imagine, mutations in genes encoding enzymes involved in steroid hormone biosynthesis have far-reaching consequences. The resulting phenotypes dramatically illustrate both the organizational and activational effects of steroid hormones, as well as the difficulty of neatly distinguishing the two. Here, we describe three disorders (Table 51–1).

The first, congenital adrenal hyperplasia (CAH), is a genetic deficiency in the synthesis of corticosteroids by the adrenal glands that results in overproduction of testosterone and related androgens. This condition is autosomal recessive and occurs once in 10,000 to 15,000 live births. In girls born with CAH, excess androgens lead to some masculinization of the external genitalia, a process called *virilization*. Virilization clearly reflects the organizational roles of steroids. This condition can be diagnosed at birth and resolved by surgical intervention. Treatment with corticosteroids reduces testosterone levels, permitting these females to undergo puberty and become fertile.

A second genetic disorder, 5α-reductase II deficiency, can also affect sexual differentiation. In male fetuses, 5α-reductase II is expressed at high levels in the precursor of the external genitalia, where it converts circulating testosterone into DHT. The high local concentrations of DHT virilize the external genitalia. Clinical 5α-reductase II deficiency is inherited in an autosomal recessive manner, and males present at birth with ambiguous (under-virilized) or overtly feminized external genitalia. In many instances, therefore, chromosomally male patients (XY) with this condition are mistakenly raised as females until puberty, at which time the large increase in circulating testosterone virilizes the body hair, musculature, and, most dramatically, the external genitalia.

The critical role of steroid receptors in controlling sexual differentiation is well illustrated by patients

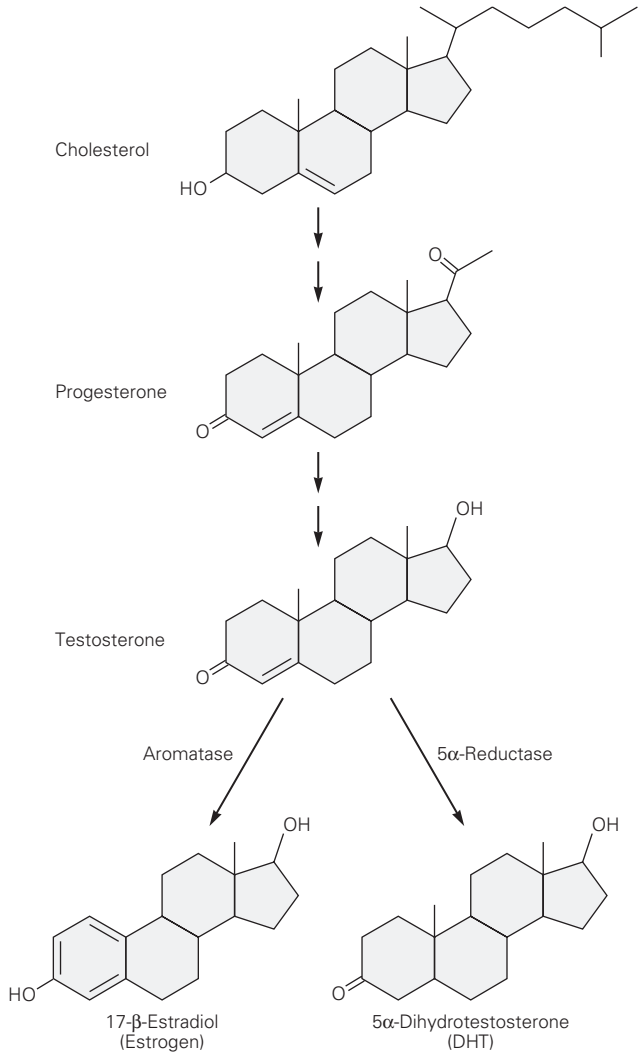

Figure 51–3 Steroid hormone biosynthesis. Cholesterol is the precursor of all steroid hormones and is converted via a series of enzymatic reactions into progesterone and testosterone. Testosterone or related androgens are obligate precursors of all estrogens in the body, a conversion that is catalyzed by aromatase. The expression of 5α-reductase in target tissues converts testosterone into dihydrotestosterone, an androgen.

with a third disorder, complete androgen insensitivity syndrome (CAIS). Testosterone, estrogen, and progesterone are hydrophobic molecules that are able to diffuse across cell membranes, enter the bloodstream, enter cells in many organs, and bind to intracellular ligand-specific receptors. The receptors for these hormones are encoded by distinct but homologous genes.

A single gene encodes a receptor that binds the androgens testosterone and DHT. The androgen receptor binds DHT approximately three-fold more tightly than testosterone, accounting for the greater potency of DHT. There is also a single receptor for progesterone (progesterone receptor), whereas two genes encode receptors that bind estrogens (estrogen receptors α and β). These steroid hormone receptors are present in many tissues of the body, including the brain (Figure 51–4B).

These receptor proteins are transcription factors that bind specific sites in the genome and modulate transcription of target genes. They contain several signature motifs, including a hormone-binding domain, a DNA-binding domain, and a domain that modulates the transcriptional activity of target genes (Figure 51–5A). Hormones activate the transcriptional activity by binding to the receptor. In the absence of ligand, the receptors bind to protein complexes that sequester them in the cytoplasm. Upon binding of ligand, the receptors dissociate from the complex and enter the nucleus, where they dimerize and bind to specific sequence elements in the promoter and enhancer regions of target genes, modulating their transcription (Figure 51–5B).

Patients with CAIS are chromosomally XY but carry a loss-of-function allele of the X-linked androgen receptor that abolishes cellular responses to testosterone and DHT. Because the pathway of sex determination via *SRY* remains functional, these patients have testes. However, because of deficient androgen signaling, the Wolffian ducts do not develop, the testes fail to descend, and the external genitalia are feminized. In adulthood, most of these patients opt for surgical removal of the testes and hormonal supplementation appropriate for females.

Sexual Differentiation of the Nervous System Generates Sexually Dimorphic Behaviors

Sex-specific behaviors occur because the nervous system differs between males and females. These differences arise from a combination of genetic factors, such as signaling pathways initiated by sex determination, as well as environmental factors, such as social experience. In many cases, both genetic and environmental inputs act through the steroid hormone system to sculpt the nervous system. Many instances of sexual dimorphism have been documented, including differences in the numbers and size of neurons in particular structures, differences in gene expression in various neuronal groups, and differences in the pattern and number of connections. Here, we examine a few cases in which studies in experimental animals have provided insights. In later sections, we ask whether similar

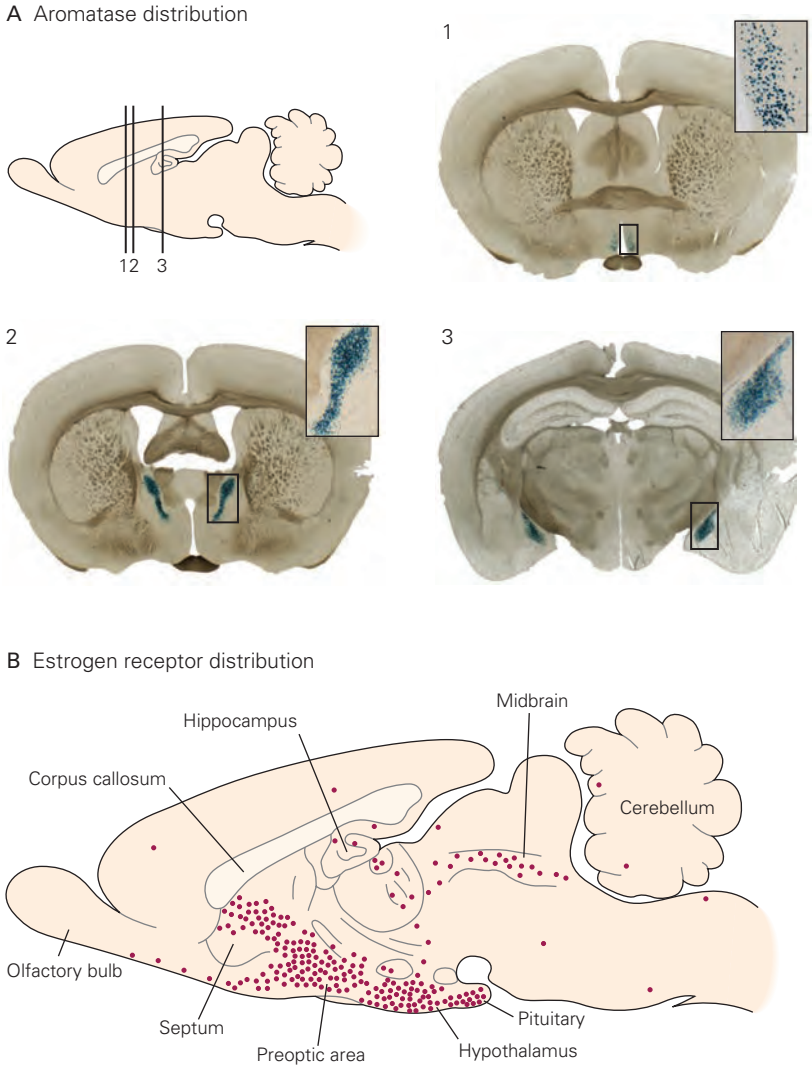

Figure 51–4 Aromatase and estrogen receptors are expressed in specific regions of the brain.

A. The enzyme aromatase catalyzes the conversion of testosterone into estrogen (Figure 51–3) and is expressed in discrete neuronal populations in the brain. The distribution of aromatase-expressing neurons labeled with a reporter protein (**blue**) in transgenic mice is shown here in three coronal planes of the brain: in neurons in the preoptic hypothalamus (**1**), in the bed nucleus of the stria terminalis (BNST) (**2**), and in the medial amygdala (**3**). These areas contain sexually dimorphic neurons that regulate sexual behavior, aggression, and maternal behaviors. (Adapted, with permission, from Wu et al. 2009.)

B. This midsagittal section of an adult rat brain shows binding of estrogen to cells in various hypothalamic regions, including the sexually dimorphic preoptic area. Additional estrogen binding is seen in the septum, hippocampus, pituitary, and midbrain. Other, more lateral areas such as the amygdala (not shown) also contain estrogen receptors.

Table 51–1 Three Clinical Syndromes That Highlight the Role of Androgens in Masculinization in Humans

	Complete androgen insensitivity syndrome (CAIS)	**5α-Reductase II deficiency**	**Congenital adrenal hyperplasia (CAH)**
Chromosomal sex	XY	XY	XX
Molecular basis	Nonfunctional androgen receptor, leading to inability to respond to circulating androgens	Nonfunctional 5α-reductase II, leading to deficit in conversion of testosterone to 5α-dihydrotestosterone (DHT) in target tissues	Defect in corticosteroid synthesis, leading to increase in circulating androgens from the adrenals
Gonad	Testis	Testis	Ovary
Wolffian derivatives	Vestigial	Present	Absent
Müllerian derivatives	Absent	Absent	Present
External genitalia			
At birth	Feminized	Variably feminized	Variably virilized
After puberty	Feminized	Masculinized	Feminized
Gender identity	Female	Female or male	Female or male
Sexual partner preference	Male	Female or male	Female or male

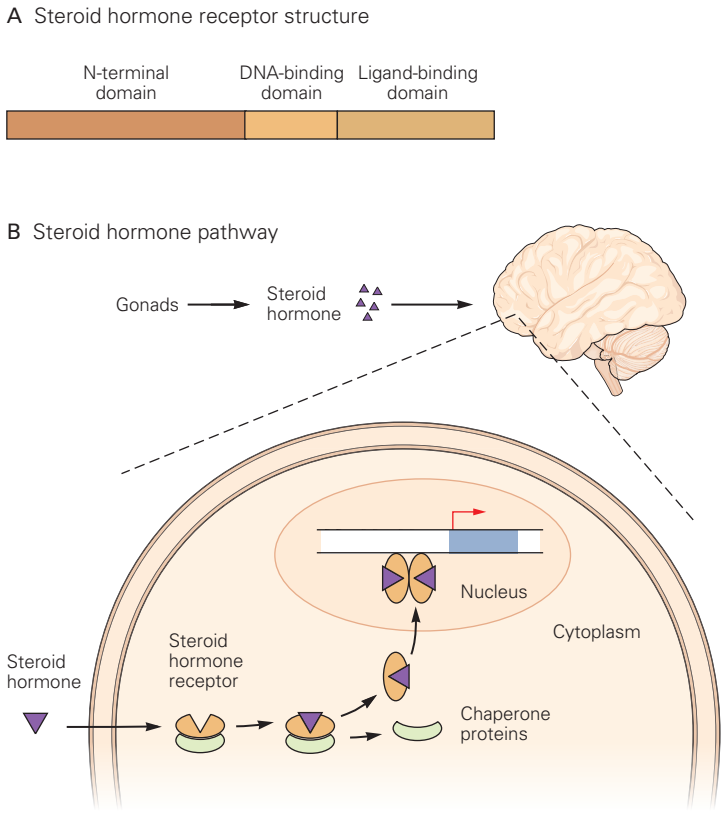

Figure 51–5 Steroid hormone receptors and their mechanism of action.

A. The canonical receptors for steroid hormones are ligand-activated transcription factors. These receptors have an N-terminal domain, which contains a transcriptional transactivator domain; a central DNA-binding domain; and a C-terminal ligand-binding domain, which may contain an additional transcriptional transactivator domain.

B. Sex steroid hormones are hydrophobic and enter the circulation by diffusing across the plasma membrane of steroidogenic cells in the gonads. They enter target cells in distant tissues such as the brain by passing through the plasma membrane and bind their cognate receptors. The steroid hormone receptor typically exists in a multiprotein complex with chaperone proteins in the cytoplasm of hormone-responsive cells. Ligand-binding promotes dissociation of the receptor from the chaperone complex and translocation into the nucleus. In the nucleus, the receptor is thought to bind to hormone response elements as a homodimer to modulate transcription of target genes. (Adapted from Wierman 2007.)

mechanisms underlie sexually dimorphic behaviors in humans.

However, before proceeding, we note that the ways in which chromosomal mechanisms of sex determination are linked to the cellular processes of sexual differentiation in the central nervous system vary widely among species. In insects, sex differences in behavior are independent of hormonal secretion from the gonads, and instead rely exclusively on a sex determination pathway within individual neurons. This mode of sexual differentiation of the brain and behavior is particularly well understood in the fruit fly, where it has been demonstrated that the sex determination cascade initiates expression of a transcription factor, fruitless (Fru), that specifies much of the repertoire of male sexual behaviors (Box 51–1).

Erectile Function Is Controlled by a Sexually Dimorphic Circuit in the Spinal Cord

The lumbar spinal cord of many mammals, including humans, contains a sexually dimorphic motor center, the spinal nucleus of the bulbocavernosus (SNB). Motor neurons in the SNB innervate the bulbocavernosus muscle, which plays an important part in penile reflexes in males and vaginal movements in females.

In adult rats, the male SNB contains many more motor neurons than the female SNB. In addition, male SNB motor neurons are larger in size and have larger dendritic arbors, with a corresponding increase in the number of synapses they receive. Like the SNB motor neurons, the bulbocavernosus muscle is larger in males than females; it is completely absent in the females of some mammalian species. SNB motor neurons also innervate the levator ani muscle, which is involved in copulatory behavior and is also larger in males than females.

How do these differences arise? Initially, the circuit is not sexually dimorphic. At birth, male and female rats have similar numbers of neurons in the SNB and similar numbers of fibers in the bulbocavernosus and levator ani muscles. In females, however, many motor neurons in the SNB and many fibers in the bulbocavernosus and levator ani muscles die in early postnatal life. Thus, this sexual dimorphism arises not by male-specific generation of cells, but rather by female-specific cell death (Figure 51–7A).

Perinatal injections of testosterone or DHT can rescue a significant number of the dying neurons and muscle fibers in the female rat. Conversely, treatment of male pups with an androgen receptor antagonist increases the number of dying neurons and muscle fibers. So at a deeper level, we see that the dimorphism results from male-specific preservation of motor neurons and muscle fibers that would die in the absence of hormone.

Where does testosterone act to establish this structural dimorphism? Is it primarily a survival factor for the motor neurons, with muscle fibers dying secondarily because they lose their innervation? Or does testosterone act on muscles, which then provide a trophic factor to support the survival of SNB motor neurons? This issue has been examined in rats carrying a mutation of the androgen receptor (*tfm* allele) that reduces binding of ligand to 10% of normal. The receptor resides on the X chromosome, so all males that carry a mutant gene on their one and only X chromosome are feminized and sterile. For female heterozygotes, the situation is more complicated. As described earlier, one of the X chromosomes is randomly inactivated in each XX female.

Female heterozygotes are therefore mosaics: Some cells express a functional androgen receptor allele, others the mutated allele. Each muscle fiber has many nuclei, so most bulbocavernosus muscle fibers in the heterozygous female express functional androgen receptors. Motor neurons have a single nucleus, however, so each neuron is either normal or receptor-deficient. If androgen receptors were required in the neuron, one would expect only receptor-expressing SNB motor neurons to survive, whereas if receptors were required only in muscles, one would expect surviving motor neurons to be a mixture of wild type and mutant.

In fact, the latter situation occurs, indicating that survival of SNB motor neurons does not depend on a neuron-autonomous function of the androgen receptor. Rather, these neurons receive a trophic cue from the androgen-dependent bulbocavernosus and the levator ani muscles (Figure 51–7A). These cues may include the ciliary neurotrophic factor (CNTF) or a related molecule, because mutant male mice lacking a CNTF receptor exhibit a decreased number of SNB motor neurons, typical of females.

Male and female SNB motor neurons also differ in size. Androgens determine the differences in number and size of these neurons in different ways. Studies of *tfm* mutants showed that androgens exert an organizational effect during early postnatal life through a direct effect on muscle. Low levels of androgens during this critical period lead to an irreversible reduction in the number of SNB motor neurons. Later, androgens act directly on SNB motor neurons to increase the extent of their dendritic arbors. A loss of circulating testosterone, such as that occurring after castration, leads to a dramatic pruning of dendritic arbors; injection of supplemental testosterone to a castrated male rat can restore this dendritic branching pattern (Figure 51–7B). This effect persists in adulthood and is reversible, so it can be viewed as an activational influence. Thus, androgens can exert diverse effects, even on a single neuronal type.

Song Production in Birds Is Controlled by Sexually Dimorphic Circuits in the Forebrain

Several species of songbirds learn species-specific vocalizations that are used for courtship rituals and territorial marking (Chapter 55). A set of interconnected brain nuclei controls the learning and production of birdsong (Figure 51–8A). In some songbird species, both sexes sing and the structure of the song circuit is similar in males and females. In other species, such as zebra finches and canaries, males alone sing. In these species, several song-related nuclei are significantly larger in the male than in the female.

The development of sexual dimorphism in song circuitry has been studied in detail in the zebra finch. The robust nucleus of the archistriatum (RA) in the adult male zebra finch contains five times as many neurons as the same nucleus in females. In addition, the afferent projections to RA exhibit a striking sexual dimorphism—only in males does the RA receive input from high vocal centers (HVCs) (Figure 51–8B). These sex differences in cell number and connectivity of RA are not evident until after hatching, when in females a large number of RA neurons die and in males the axons of HVC neurons enter the RA nucleus.

These sexually dimorphic anatomical features are regulated by steroid hormones. When females are supplied with estrogen (or an aromatizable androgen such as testosterone) after hatching, the number of neurons in the RA and the termination pattern in the nucleus are similar to that of the male. However, early hormone administration to young females is not sufficient to masculinize the song nuclei to a size comparable to that of adult males, nor is it sufficient to induce singing in females. To achieve these functions, female birds that receive testosterone or estradiol after hatching must also receive testosterone or dihydrotestosterone (but not estrogen) as adults. Thus, steroids play both organizational and activational roles in this system as well.

Box 51–1 Genetic and Neural Control of Mating Behavior in the Fruit Fly

In the presence of a female fruit fly, the adult male fly engages in a series of essentially stereotyped routines that usually culminate in copulation (Figure 51–6A). This elaborate male courtship ritual is encoded by a cascade of gene transcription within the brain and peripheral sensory organs that masculinizes the underlying neural circuitry.

Sex determination in the fly does not depend on gonadal hormones as it does in vertebrates. Instead, it occurs cell autonomously throughout the body. In other words, sexual differentiation of the brain and the rest of the body is independent of gonadal sex. The male-specific Y chromosome of fruit flies does not bear a sex-determining locus. Instead, sex is determined by the ratio of X chromosome number to autosome number (X:A). A ratio of 1 is determinative for female differentiation, whereas a ratio of 0.5 drives male differentiation.

The X:A ratio sets into motion a cascade of gene transcription and alternative splicing programs that leads to the expression of sex-specific splice forms of two genes, *doublesex* (*dsx*) and *fruitless* (*fru*). The *dsx* gene encodes a transcription factor that is essential for sexual differentiation of the nervous system and the rest of the body, with the sex-specific splice variants responsible for male- and female-typical development.

The *fru* gene encodes a set of putative transcription factors that are generated by multiple promoters and alternative splicing. In males, one particular mRNA (fru^M) is translated into functional proteins. In female flies, alternative splicing results in the absence of such proteins.

Males carrying a genetically modified *fru* allele that can only be spliced in the female-specific manner (fru^F) have essentially normal, *dsx*-dependent sexual differentiation. These fru^F males therefore resemble wild type males externally. However, the loss of Fru^M in these animals abolishes male courtship behavior directed toward females. These data indicate that Fru^M is required for male courtship and copulation.

Conversely, transgenic female flies carrying a fru^M allele exhibit male mating behavior toward wild type females, indicating that fru^M is sufficient to inhibit female sexual responses and promote male mating.

Intriguingly, fru^F males do not court females and, like wild type females, do not reject mating attempts by wild type males or fru^M females. Similarly, fru^M females attempt to mate with both fru^M and wild type females. These data suggest that fru^M may also specify sexual partner preference, which in the case of wild type males would be directed to females.

In wild type females without fru^M, the neural pathways are wired such that these flies exhibit sexually receptive behaviors toward males. When groups of fru^F males (or fru^M females) are housed together, they court each other vigorously, often forming long chains of flies attempting copulation.

To build the circuitry underlying male courtship rituals, fru^M appears to initiate cell-autonomous male-typical differentiation of the neurons in which it is expressed. This leads to overt neuroanatomic dimorphism in cell number or projections of many classes of neurons (Figure 51–6B). Some neurons that express fru^M are not distributed in dimorphic patterns. In these neurons, fru^M may regulate the expression of particular classes of genes whose products drive a male-specific program of physiology and function.

Are neurons that express fru^M required for male courtship behavior? When synaptic transmission is genetically blocked in these neurons in adult males, all components of courtship behavior are abolished. Importantly, these males continue to exhibit normal movement, flight, and other behaviors in response to visual and olfactory stimuli. These findings demonstrate that fru^M appears to be expressed in a neural circuit that is essential for and dedicated to male fly courtship.

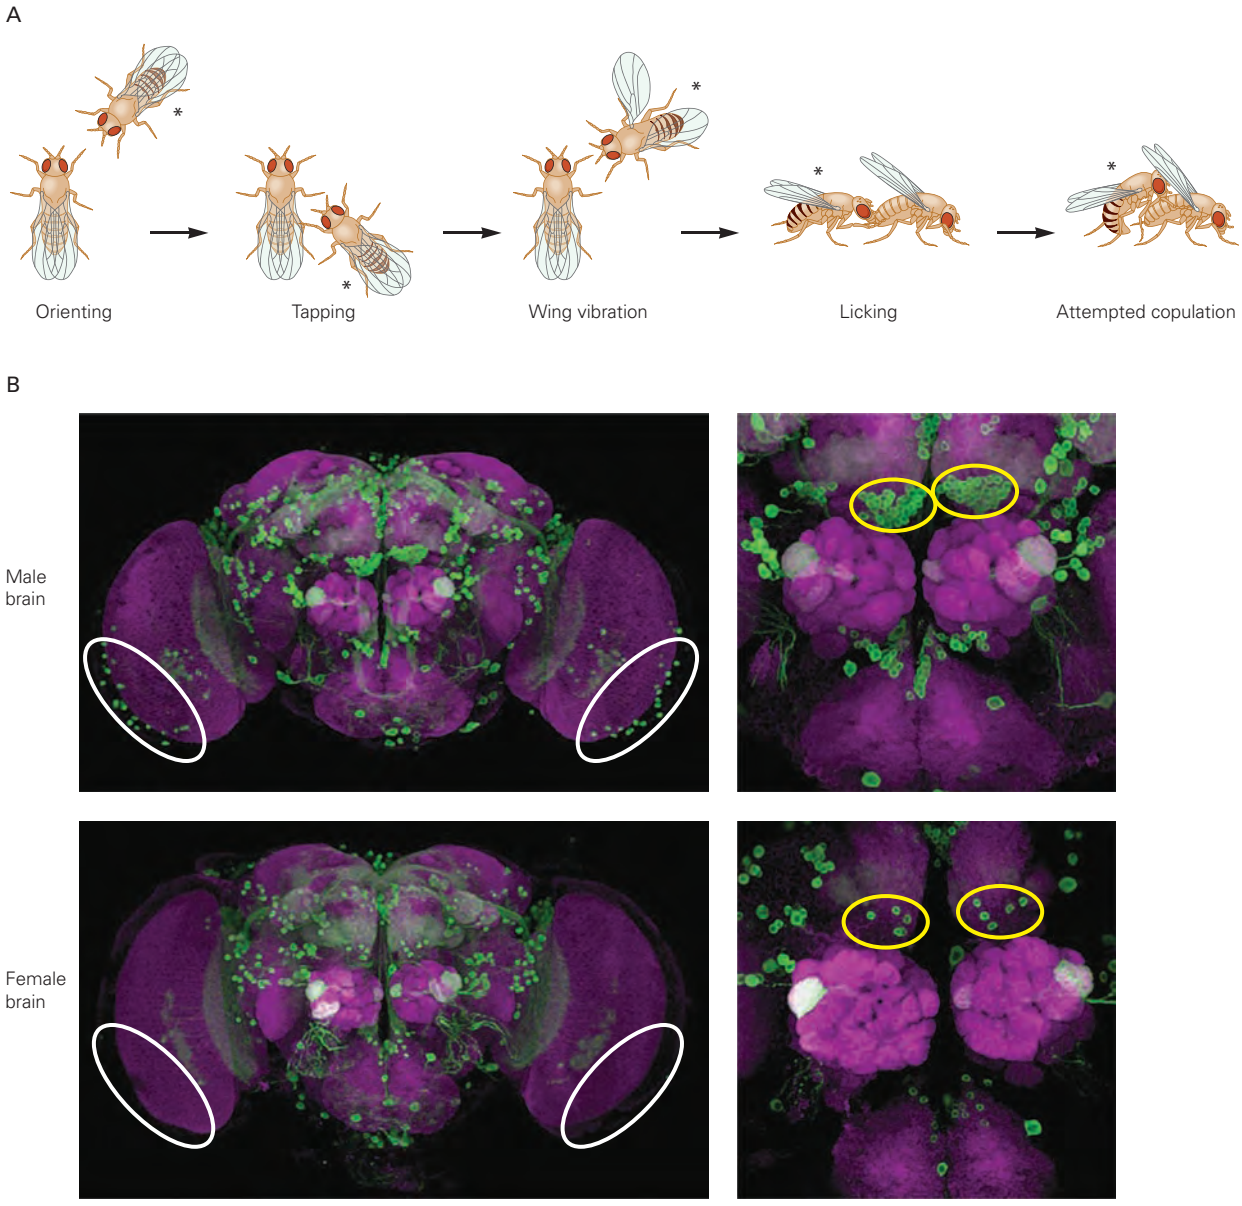

Figure 51–6 Control of male courtship in the fruit fly *Drosophila melanogaster.*

A. Male flies (labeled with **asterisk**) engage in a stereotyped sequence of behavioral routines that culminate in attempted copulation. The male fly orients toward the female and then taps her with his forelegs. This is followed by wing extension in the male and a species-specific pattern of wing vibrations that is commonly referred to as the fly courtship song. If the female fly is sexually receptive, she slows down and permits the male to lick her genitalia. The female then opens her vaginal plates in order to allow the male to initiate copulation. All steps in the male mating ritual require the expression of a sex-specific splice variant of the *fruitless* (*fru*) gene. (Adapted, with permission, from Greenspan and Ferveur 2000.)

B. The *fru* gene encodes a male-specific splice variant that is necessary and sufficient to drive most steps in the male fly courtship ritual. *Fru* expression is visualized using a fluorescent reporter protein (**green**) in transgenic flies. Neuronal clusters that express *Fru* are present in comparable numbers in the central nervous system of both male and female flies. However, there are regional sex differences in *Fru* expression. A cluster of *Fru*-expressing neurons is present in the male optic lobes (in the area within the **white ellipses**) but absent in the corresponding regions in the female brain. The two male antennal lobe regions (areas within **yellow ellipses**) contain about 30 neurons each, whereas each female region has only four to five neurons. (Adapted, with permission, from Kimura et al. 2005.)

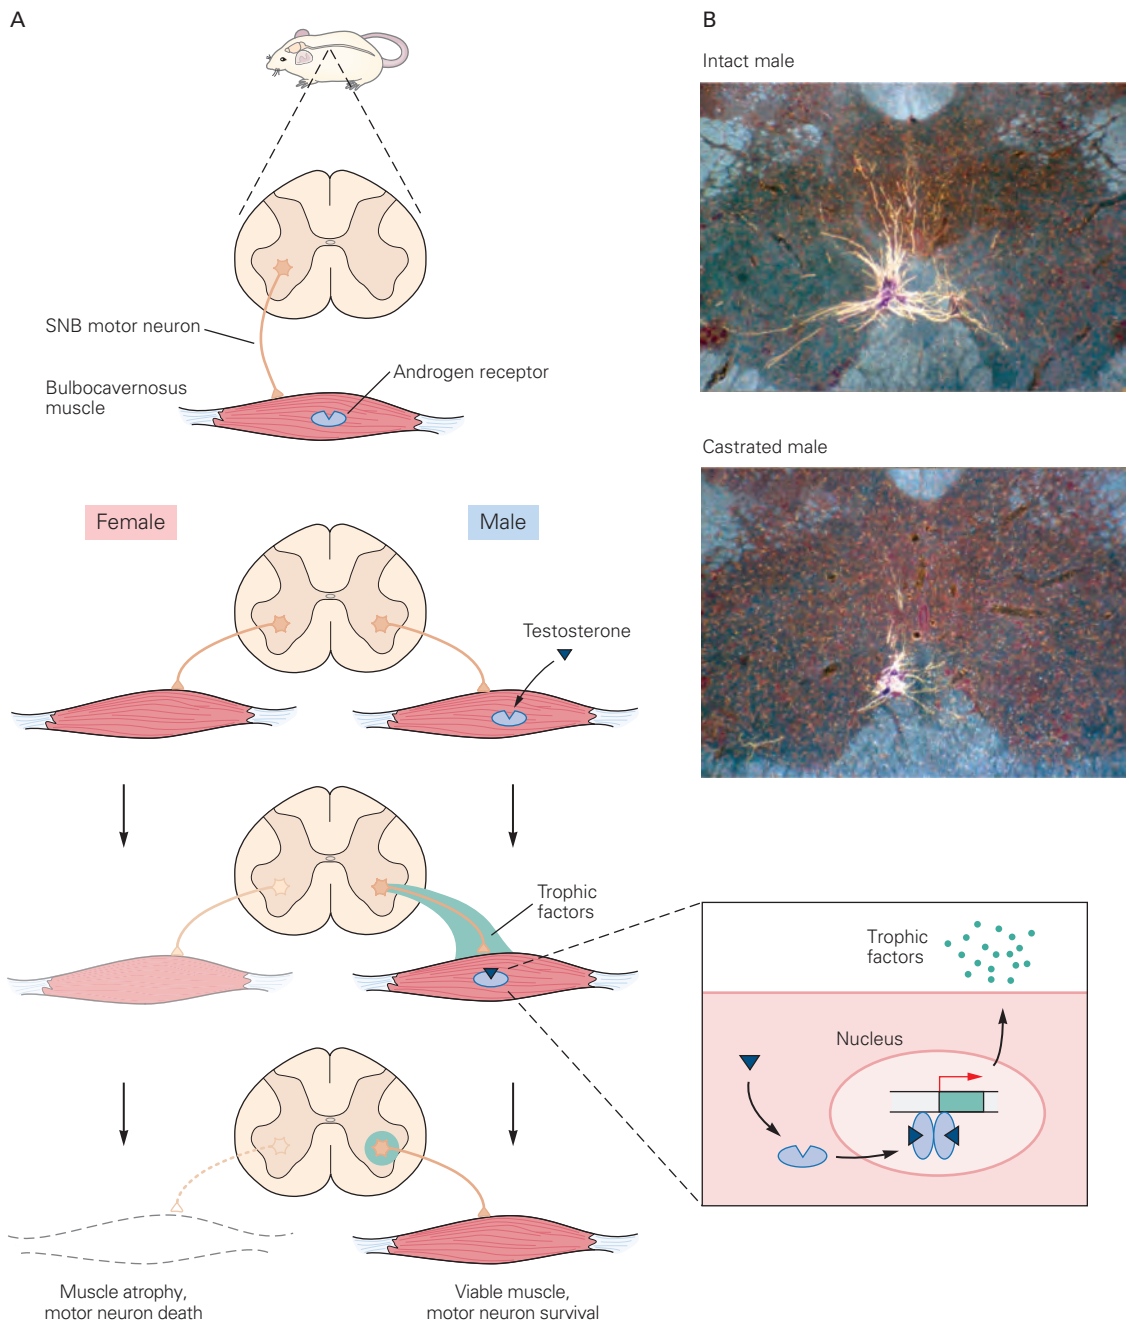

Figure 51–7 Sexual dimorphism in the spinal nucleus of the bulbocavernosus muscle in the rat.

A. The spinal nucleus of the bulbocavernosus (**SNB**) is found in the male lumbar spinal cord but is greatly reduced in the female. The motor neurons of the nucleus are present in both sexes at birth, but the lack of circulating testosterone in females leads to death of the SNB neurons and their target muscles. It is thought that testosterone in the male circulation promotes the survival of the target muscles, which express the androgen receptor. In response to testosterone, the muscles provide trophic support to the innervating SNB neurons. This muscle-derived survival factor is likely to be ciliary neurotrophic factor or a related member of the cytokine family. Thus, testosterone acts on muscle cells to control the sexual differentiation of SNB neurons. (Reproduced, with permission, from Morris, Jordan, and Breedlove 2004. Copyright © 2004 Springer Nature.)

B. Dendritic branching of SNB neurons is regulated by circulating testosterone in adult male rats. In males, the dendrites arborize extensively within the spinal cord (**upper photo**). The fact that the arbors are pruned in adult castrated male rats (**lower photo**) is evidence that this dendritic branching depends on androgens. The spinal cord is shown in transverse section, and the SNB neurons and their dendrites are labeled by a retrograde tracer injected into target muscles. (From Cooke and Woolley 2005. Reproduced, with permission from D. Sengelaub.)

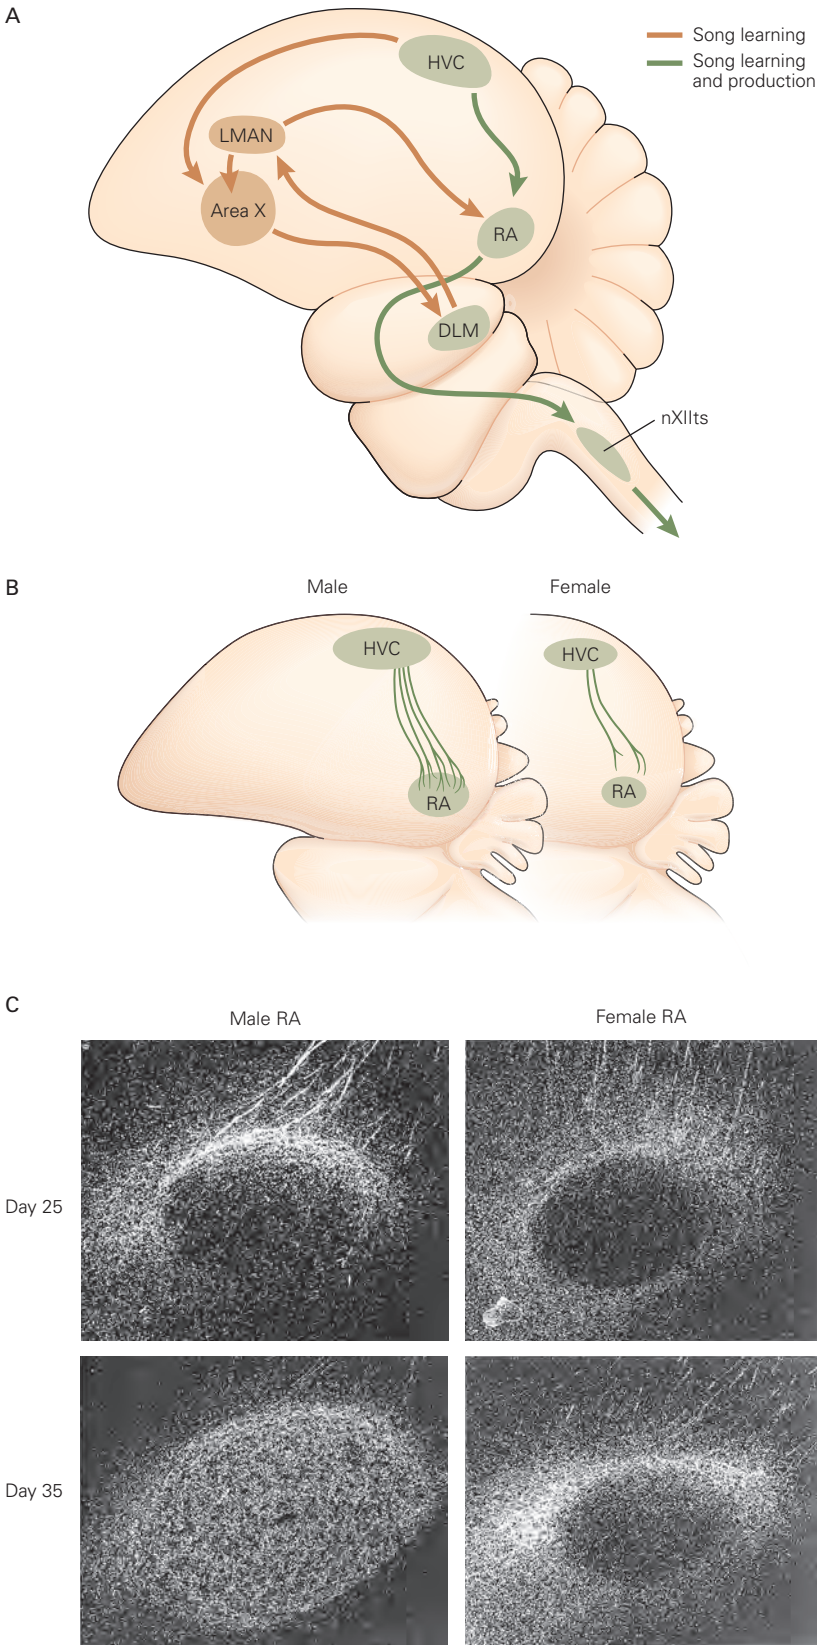

Figure 51–8 Sexual dimorphism in the avian song circuit.

A. Songbirds have a dedicated neural circuit for song production and learning, with distinct components contributing to learning or production. Many of these components are sexually dimorphic in songbirds in which only one sex sings. For example, in zebra finches, only the male sings, and the male high vocal center (**HVC**), robust nucleus of the archistriatum (**RA**), lateral magnocellular nucleus of the anterior neostriatum (**LMAN**), and area X are larger in volume and contain more neurons than the comparable regions in the female. (Abbreviations: **DLM**, medial nucleus of the dorsolateral thalamus; **nXIIts**, hypoglossal nucleus.) (Reproduced, with permission, from Brainard and Doupe 2002. Copyright © 2002 Springer Nature.)

B. In the male, the axons of HVC neurons terminate on neurons in the RA nucleus, whereas in females, the axons terminate in a zone surrounding the nucleus. The sexual dimorphism in cell number and connectivity of these regions is regulated by estrogen. (Reproduced, with permission, from Morris, Jordan, and Breedlove 2004. Copyright © 2004 Springer Nature.)

C. The pattern of termination of the axons of HVC neurons in the RA nucleus varies in males and females at different ages after hatching. (Reproduced, with permission, from Konishi and Akutagawa 1985. Copyright © 1985 Springer Nature.)

Mating Behavior in Mammals Is Controlled by a Sexually Dimorphic Neural Circuit in the Hypothalamus

In many mammalian species, the preoptic region of the hypothalamus and a reciprocally connected region, the bed nucleus of the stria terminalis (BNST), play important roles in sexually dimorphic mating behaviors (Chapter 41; Figure 51–4). In male rodents and monkeys, these areas are activated during mating behavior; surgical lesions that ablate the preoptic region or the BNST result in deficits in male sexual behavior in male rodents and, in the case of preoptic lesions, disinhibit female-type sexual receptivity in males.

Both the preoptic hypothalamus and the BNST are sexually dimorphic, containing more neurons in males compared to females. The sexually dimorphic nucleus of the preoptic area (SDN-POA) also contains significantly more neurons in the male. A male-specific perinatal surge of testosterone promotes survival of neurons in the SDN-POA and BNST, whereas in females, these same cells gradually die off in the early postnatal period. This development is similar to that in the sexually dimorphic nuclei of the rodent spinal cord and the songbird brain, suggesting that androgen control is a common mechanism for production of sex differences in the size of neuronal populations.

Curiously, the ability of brain testosterone to promote the survival of neurons is likely to be exerted via aromatization into estrogen and subsequent activation of the estrogen receptors (see Figures 51–3 and 51–4). How then is the neonatal female brain shielded from the effects of circulating estrogen? In newborn females, there is very little estrogen in the circulation, and the small amount present is easily sequestered by binding to α-fetoprotein, a serum protein. This explains why female mice lacking α-fetoprotein exhibit male-typical behaviors and reduced female-typical sexual receptivity. In this case, then, structural sexual dimorphism does not result from differential effects of androgens and estrogens, but rather from sex differences in the level of hormone available to the target tissue.

Environmental Cues Regulate Sexually Dimorphic Behaviors

Sex-specific behaviors are usually initiated in response to sensory cues in the environment. There are many such cues, and different species use distinct sensory modalities to elicit similar responses. Courtship rituals can be triggered by species-specific vocalizations, visual signals, odors, and even, in the case of weakly electric fish, by electric discharges. Recent genetic and molecular studies have led to significant insight into how sensory experience controls some of these behaviors in rodents. Here, we discuss two examples: the regulation of partner choice by pheromones and the regulation of maternal behavior by experience during infancy.

Pheromones Control Partner Choice in Mice

Many animals rely on their sense of smell to move about, obtain food, and avoid predators. They also rely on pheromones—chemicals that are produced by an animal to affect the behavior of another member of the species. In rodents, pheromones can trigger many sexually dimorphic behaviors, including mate choice and aggression.

Pheromones are detected by neurons in two distinct sensory tissues in the vertebrate nose: the main olfactory epithelium (MOE) and the vomeronasal organ (VNO) (Figure 51–9A). It is thought that sensory neurons in the MOE detect volatile odors, whereas those in the VNO detect nonvolatile chemosensory cues. Removal of the olfactory bulb, the only synaptic target of neurons in the MOE and the VNO, abolishes mating as well as aggression in mice and other rodents. These and other studies indicate an essential role for olfactory stimulation in initiating mating and fighting.

Genetically engineered disruption of pheromone responsiveness in the MOE or VNO reveals that these sensory tissues have a surprisingly complex role in the mating behavior of mice. A functional MOE is essential to trigger male sexual behavior, and an intact VNO is required for sex discrimination and directing the male to mate with females.

Key to these experiments is the fact that olfactory neurons in the MOE and the VNO use different signal transduction cascades to convert olfactory input into electrical responses. The cation channel Trpc2 appears essential for pheromone-evoked signaling in VNO neurons; it is not expressed in MOE neurons, which use a different signal transduction apparatus. Thus, mice lacking the gene *trpc2* have a nonfunctional VNO and an intact MOE. Mating behavior directed to animals of the opposite sex appears unaltered in *trpc2* mutant males as well as females.

However, both male and female *trpc2* mutants often exhibit male sexual behavior with members of either sex. For example, *trpc2* mutant females mate with females in a manner seemingly indistinguishable from wild type males, except of course the females cannot ejaculate. These and other findings suggest that the VNO is used to discriminate among sexual partners.

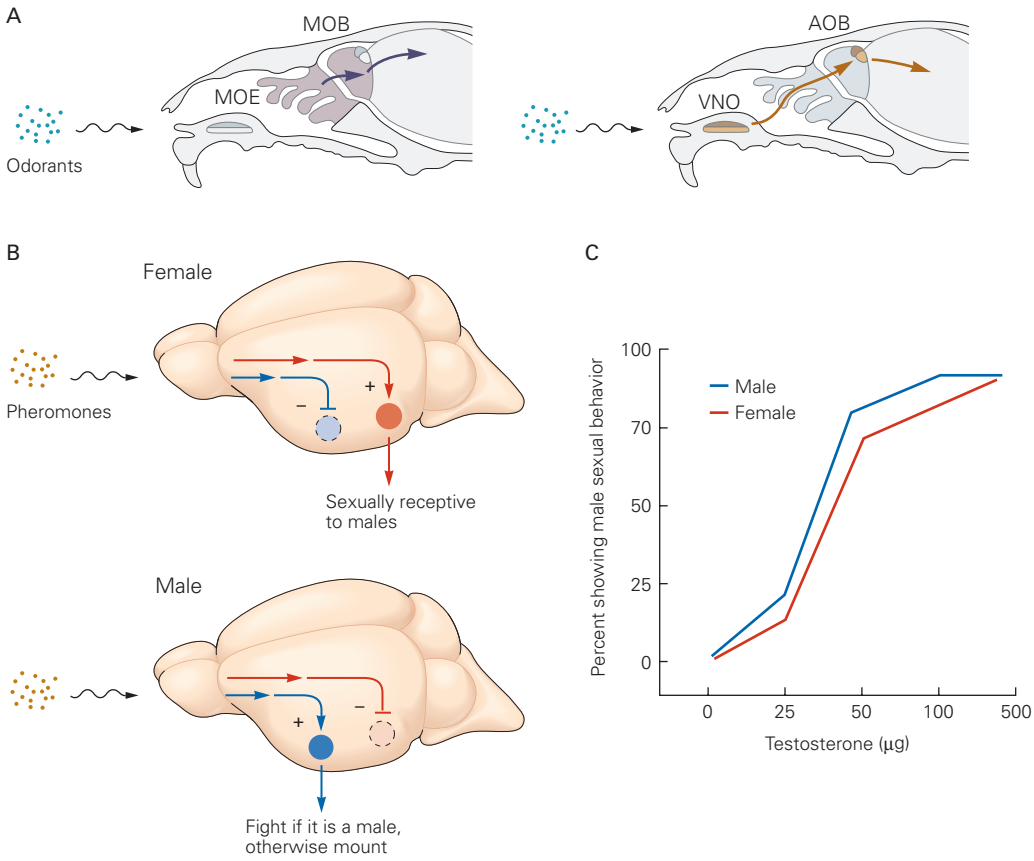

Figure 51–9 Pheromonal and hormonal control of sexually dimorphic behavior in mice.

A. Odorants are detected by sensory neurons in the main olfactory epithelium (**MOE**), which projects to the main olfactory bulb (**MOB**), and by neurons in the vomeronasal organ (**VNO**), which projects to the accessory olfactory bulb (**AOB**). Many of the central connections of the MOE and VNO pathway are anatomically segregated. (Adapted, with permission, from Dulac and Wagner 2006.)

B. Female mice possess the neural circuitry that can activate either male (**blue**) or female (**red**) mating behaviors. In wild type females, pheromones activate female mating behavior and inhibit male-type mating. By contrast, in males, pheromones activate a circuitry that will initiate fights with males and mating with females. (Adapted, with permission, from Kimchi, Xu, and Dulac 2007.)

C. Testosterone activates male sexual behavior in male and female mice. The data are from a study in which the gonads of male and female mice were surgically removed in adulthood. None of the animals exhibited male sexual behavior with wild type females following surgery. After administration of testosterone, mating behavior was restored in castrated males, and females displayed male sexual behavior. This effect was dose-dependent; at the highest dose, male and female mice exhibited comparable levels of male-type mating behavior toward wild type females. (Adapted, with permission, from Edwards and Burge 1971. Copyright © 1971 Springer Nature.)

When the VNO is inactivated, animals can no longer distinguish between males and females, and mutants therefore exhibit male sexual behavior toward members of both sexes. Similarly, adult wild type females treated with testosterone also exhibit male sexual behavior toward females (Figure 51–9C).

One implication of these studies is that female mice possess the neural circuitry for male sexual behavior (Figure 51–9B). Activation of this neural circuit is inhibited in wild type females by sensory input from the VNO and by the lack of testosterone. Removal of the VNO or administration of testosterone activates male sexual behavior in females. Male pattern mating behavior has been observed in females of many species, indicating that the findings in mice are likely to be of general relevance. Thus, neural pathways for male sexual behavior appear to be present in both sexes. Similarly, the female-typical behavior of male rats following hypothalamic lesions suggests that the neural pathway for female sexual behavior also exists in the

male brain. In such cases, it is the differential regulation of these circuits that underlies the sexually dimorphic expression of male and female sexual behaviors.

Early Experience Modifies Later Maternal Behavior

The preoptic area of the hypothalamus and the BNST are also important for another set of sexually dimorphic behaviors in females. Nursing rodents are good mothers, building a nest for their litter, crouching over the pups to keep them warm, and returning the pups to the nest when they happen to crawl away. Surgical lesioning or experimental stimulation of the preoptic region abolishes or activates these maternal behaviors, respectively.

Studies of these behaviors have shed light on variations among individual females and how these differences exert lifelong effects on behavior of the offspring. Female lab rats exhibit distinct, stable forms of maternal care: Some lick and groom (LG) their pups frequently (high-LG mothers), whereas others lick and groom less frequently (low-LG mothers). Female offspring of high-LG mothers display high-LG activity when they themselves become mothers compared to female offspring of low-LG mothers (Figure 51–10). Moreover, pups of high-LG mothers show less anxiety-like behaviors in stressful conditions than do the pups of low-LG mothers.

These results suggested that levels of licking and grooming behavior and stress responses are genetically determined. However, studies by Michael Meaney and his colleagues provide an alternative explanation. When female rat pups are transferred from

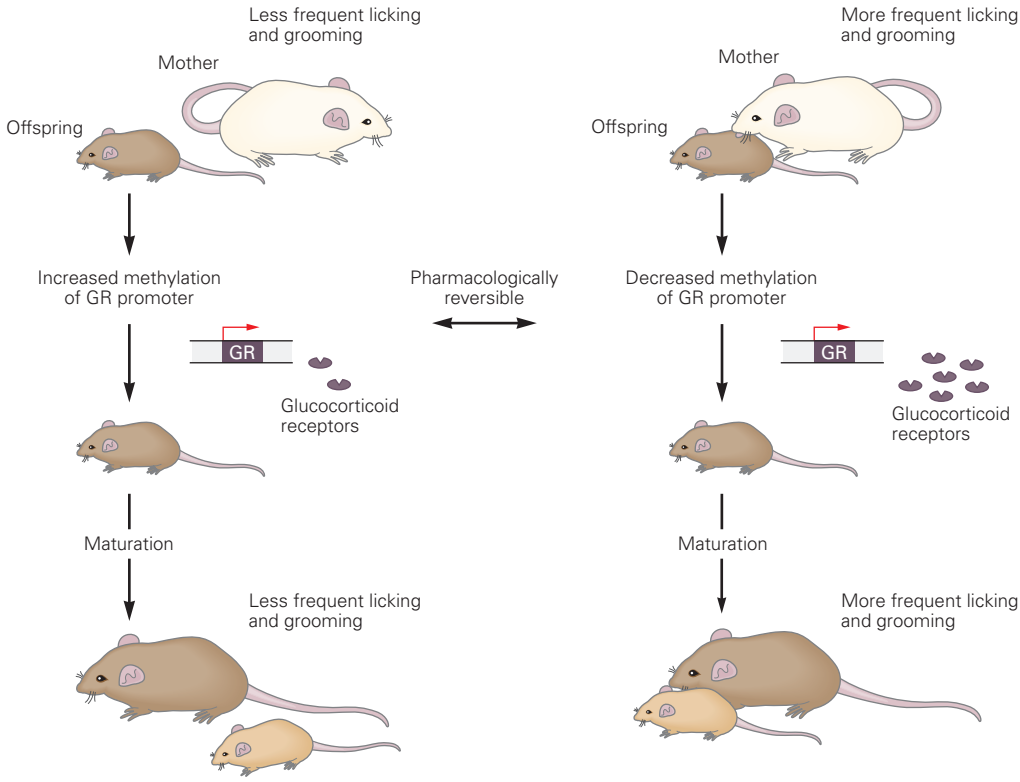

Figure 51–10 Epigenetic regulation of maternal behavior in rats. In a common lab rat strain, different mothers lick and groom their pups at low or high frequencies, resulting in distinct epigenetic modifications at the glucocorticoid receptor (**GR**) promoter. Mothers that lick and groom at high frequency raise progeny with low levels of DNA methylation at the GR promoter, resulting in higher levels of GR expression in the hippocampus. Females raised by these mothers exhibit higher frequencies of licking and grooming behavior with their own pups. Mothers that lick and groom at low frequency raise progeny with high DNA methylation levels at the GR promoter and lower levels of hippocampal GR expression. Females nursed by these mothers subsequently exhibit similar low levels of licking and grooming of their pups. Pharmacological reversal of the epigenetic modifications at the GR promoter results in a corresponding change in both GR expression and maternal behavior. (Adapted from Sapolsky 2004.)

their mother to a foster mother at birth, their maternal behavior and stress responses as adults resemble those of their foster mother rather than those of their biological mother. Thus, experience in infancy can lead to lifelong behavioral patterns. Because these patterns impact maternal behavior, their influence can endure over many generations.

How does brief and early experience lead to such long-lasting changes? One mechanism involves a covalent modification of the genome. Stress responses are coordinated by glucocorticoids acting on glucocorticoid receptors in the hippocampus. Throughout life, tactile stimulation, including grooming, leads to transcriptional activation of the glucocorticoid receptor gene, which ultimately leads to reduced release of hypothalamic hormones that trigger stress responses. Tactile stimulation during early life also regulates the glucocorticoid receptor gene in a second way. A key site in the glucocorticoid receptor gene is methylated by the enzyme DNA methyltransferase, leading to gene inactivation. Initially, gene methylation occurs in all pups, but pups reared by high-LG mothers are selectively demethylated. Thus, in animals reared by high-LG mothers, the effects of adult experience are potentiated. This is an example of epigenetic modification by which genes can be turned on or off more or less permanently. These animals exhibit blunted behavioral responses to stressful stimuli later in life.

What are the biological links between early experience and behavioral variation? A peptide hormone, oxytocin, plays a major role. Classic work showed that oxytocin regulates provision of milk by the mother, which occurs via reflex ejection in response to suckling (milk let-down). Oxytocin is synthesized by neurons in the hypothalamus and released into the general circulation through their projections in the posterior pituitary. It elicits smooth muscle contraction in the mammary gland, resulting in milk ejection. Oxytocin release from the pituitary is controlled by suckling, which provides a sensory stimulus that is conveyed to the hypothalamus by spinal afferent nerves.

Oxytocin and a related polypeptide hormone vasopressin also play important roles in regulating maternal bonding and other social behaviors (Chapter 2). In these cases, experience appears to modulate behaviors by affecting both release of oxytocin and levels of the oxytocin receptor in specific brain areas. In both rats and voles, individual differences in the care females provide their offspring correlate with variations in oxytocin receptor level in specific brain areas. Especially noteworthy is that oxytocin receptor levels in several regions are higher in female offspring reared by high-LG mothers than in female progeny of low LG-mothers. Thus, sensory stimulation may affect activity of these polypeptide hormone systems, which in turn regulate maternal and other social behaviors.

A Set of Core Mechanisms Underlies Many Sexual Dimorphisms in the Brain and Spinal Cord

In the previous few sections, we described neural circuits that regulate several sexually dimorphic behaviors. Can we discern any common themes?

A variety of sexually dimorphic neural circuits, or wiring diagrams, can in principle generate sex differences in behavior (Figure 51–11). Although it is challenging to trace the chain of causality from genetic factors to dimorphic circuits to sex-specific behaviors, there are a few general possibilities. In one, a neural circuit, from sensory input to motor output, might be unique to one sex. In fact, this alternative is seldom encountered. Most behaviors are shared between the sexes, and even behaviors such as feeding, maternal retrieval of a pup by the scruff of its neck, or biting (during territorial scuffles between males) all call upon similar jaw movements. Consistent with this commonality, it appears that most sexual dimorphisms in behavior arise from sex differences in key neuronal populations within common circuits. The activity and connectivity of these populations alter behavioral output in a male- or female-typical manner.

Estrogen can act not only during development but also in adults to periodically reconfigure presynaptic connectivity within a hypothalamic neural circuit, ensuring that female mice only mate when they are ovulating and fertile. These studies paint a picture of dynamic neural circuits in the female brain: Wiring diagrams are plastic and responsive to hormonal changes across the estrous cycle, which is analogous to the menstrual cycle in humans. Similarly, estrogen also exerts cycle-related effects on dendritic spine plasticity in other brain regions, although the behavioral consequences in these instances are less well understood.

Another recurring theme in the developing brain is that masculinization is controlled by estrogen during the organizational phase. This control has profound enduring effects on social behaviors in adult life. Testosterone (which is aromatized into estrogen) or estrogen treatment of neonatal rodent females masculinizes the brain. As adults, these females are no longer sexually receptive to males, and in fact display male-typical social interactions, albeit at reduced intensity. Providing testosterone to these females, to mimic adult levels of testosterone in males, boosts the intensity of social behaviors, including territorial aggression (the propensity of animals to fight over territory or mates),

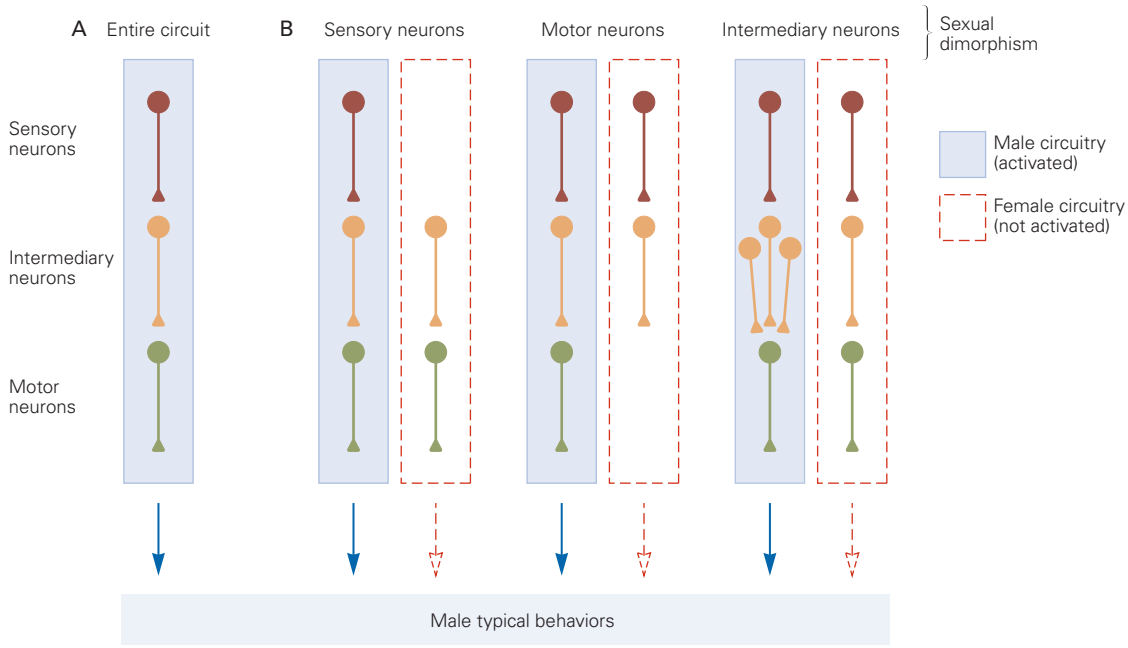

Figure 51–11 Possible circuit configurations that underlie sex differences in behavior. Neural circuit diagrams can be configured to generate sex differences in behaviors. Although it is possible to envision a neural circuit entirely exclusive to one or the other sex, most behaviors are shared between the sexes, and the current consensus is that sex differences in behavior or physiology reflect sexual dimorphisms in key neuronal populations embedded within an otherwise shared neural circuit. Such sexual dimorphisms have been found at the level of sensory neurons, motor neurons (as discussed for spinal nucleus of the bulbocavernosus neurons), or neurons interposed between sensory and motor pathways (such as the BNST and the sexually dimorphic nucleus of the preoptic area).

to male-typical levels. Thus, the perinatal surge of testosterone acts largely via aromatization into estrogens to masculinize the brain, whereas in adult life, both testosterone and estrogen facilitate the display of male-typical social interactions (Figure 51–12A).

These findings imply that male mice lacking androgen receptor exclusively in the nervous system should not only have male genitalia but also exhibit male patterns of social behavior, albeit at reduced intensity. This has in fact been borne out nicely by genetic engineering studies in mice; such mutant male mice indeed appear indistinguishable externally from control males, but they exhibit male-type sexual and aggressive behaviors with diminished intensity. However, there is growing evidence that the developmental control of masculinization of the brain by estrogen has shifted during evolution such that testosterone may be the predominant masculinizing agent in primates, including humans.

How do the actions of the limited number of sex hormones modulate the display of a large array of complex social interactions such as courtship vocalizations (similar to songbirds, many animals, including mice, vocalize as part of their mating ritual), sexual behavior, marking (the propensity of animals of many species to claim territory with pheromones secreted in bodily fluids), and aggression? As described earlier in this chapter, sex hormones bind to cognate receptors to modulate gene expression in target cells. These steroids are available at different times, amounts, and places in the brain of the two sexes. Accordingly, sex hormone–regulated genes are expressed in sexually dimorphic patterns that are also different for different brain regions. These genes regulate differentiation and adult function of neural circuits along male- or female-typical lines (Figure 51–12B).

Experimental inactivation of such sex hormone–regulated genes reveals that individual genes influence only a subset of the sexually dimorphic social interactions without altering the entire behavioral program of males and females. Thus, an additional emerging theme is that sex hormones control differentiation and function of neural circuits in a modular manner, with different sex hormone–regulated genes acting in distinct neuronal populations to regulate separate aspects of male- or female-typical behaviors. In short, there is no single neuronal population that governs

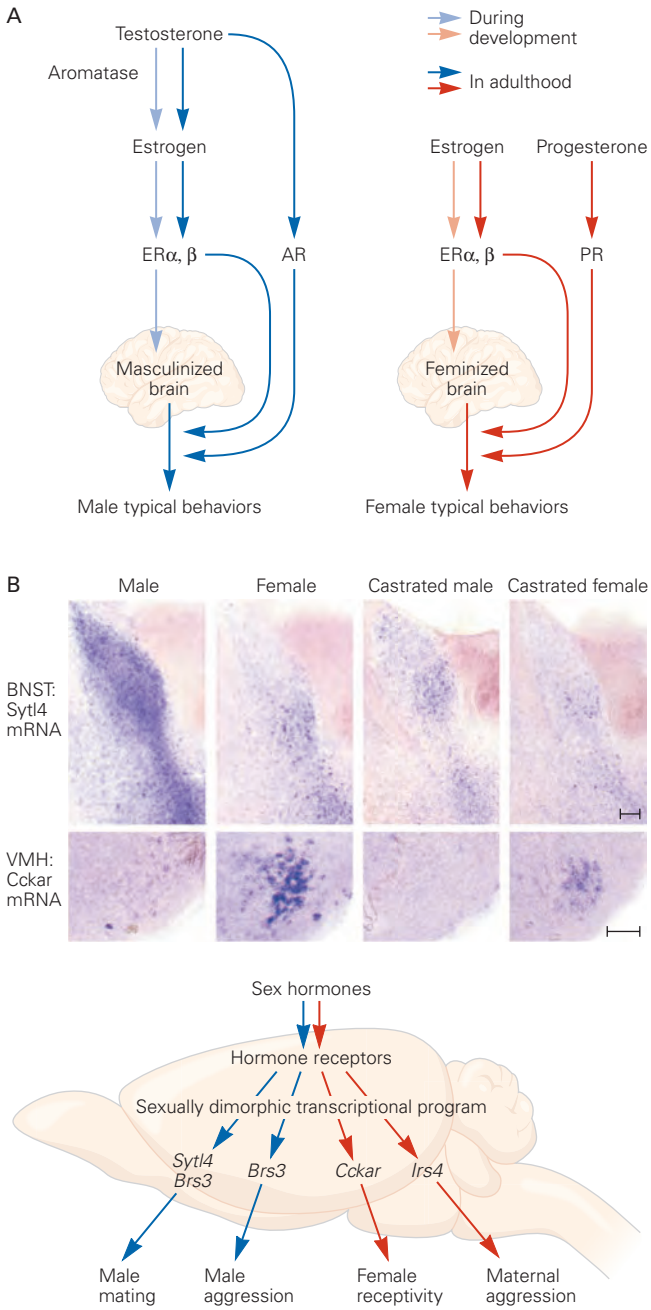

Figure 51–12 Mechanisms whereby sex hormones influence development and function of the nervous system.

A. Masculinization of the nervous systems occurs in at least two distinct steps: a developmental organizational phase largely controlled by estrogen signaling and a postpubertal activational phase controlled by estrogen and testosterone signaling via their cognate hormone receptors to regulate gene expression. (Abbreviations: **AR**, androgen receptor; **ER**, estrogen receptor; **PR**, progesterone receptor.)

B. Histological images show sexually dimorphic expression patterns of *Sytl4* mRNA in the bed nucleus of the stria terminalis (**BNST**) and *Cckar* in the ventromedial hypothalamus (**VMH**) of adult mice. Expression of these genes is clearly different in unmanipulated males and females and dramatically altered upon experimental removal of sex hormones from the circulation following castration in adult life. Both the BNST and VMH regulate mating and aggression in the two sexes.

Current thinking about how sex hormones regulate sex differences in behavior is illustrated in the diagram below. Molecular studies have identified many genes, such as *Sytl4* and *Cckar*, whose expression is sexually dimorphic in the adult brain and controlled by sex hormones. Many such genes, when experimentally mutated in mice via genetic engineering, regulate distinct components of sexually dimorphic behaviors but not the entire repertory of social interactions. In other words, sex hormones control sexually dimorphic behaviors in a modular genetic manner. (Reproduced, with permission, from Xu et al. 2012.)

gender-typical behaviors; rather, the neural control of distinct behaviors is distributed across multiple different neuronal populations.

This modular control of sexually dimorphic behaviors fits well with our thinking that most circuits are shared between the males and females and that sex differences in behavior arise from key neural populations that alter circuit function in a male- or female-typical fashion. It seems likely that neurons exhibiting sexually dimorphic molecular or anatomical features represent such key neuronal populations.

The Human Brain Is Sexually Dimorphic

Are sex differences between the brains of male and female mammals also present in humans, and if so, might they be functionally important? Early studies

revealed that a few structures are markedly larger in men. These include Onuf's nucleus in the spinal cord, the homolog of the SNB in rodents (Figure 51–7); the BNST, implicated in rodent mating behavior (Figure 51–4); and the interstitial nucleus of the anterior hypothalamus 3 (INAH3), related to the rodent SDN-POA discussed earlier (Figure 51–13).

Advances in high-resolution magnetic resonance imaging (MRI) and histology have uncovered more subtle structural and molecular dimorphisms in the

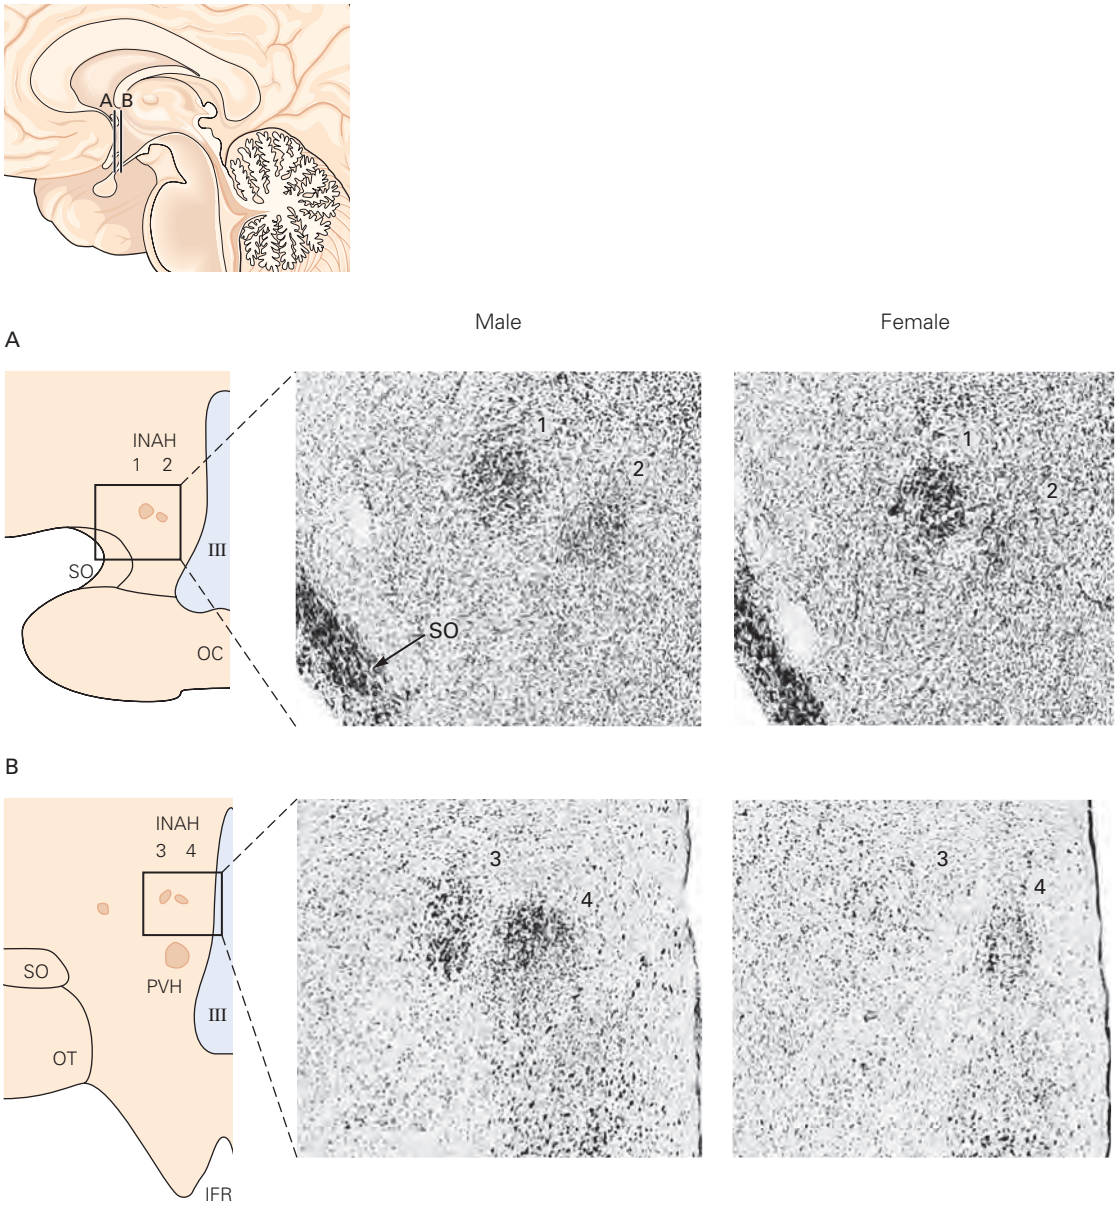

Figure 51–13 Sexual dimorphism in the interstitial nucleus of the anterior hypothalamus (INAH) 3 in the human brain. The human hypothalamus contains four small, discrete neuronal clusters, INAH1 to INAH4. The photomicrographs show these nuclei in adult male and female brains. While INAH1, INAH2, and INAH4 appear similar in men and women, INAH3 is significantly larger in men. The section in part **A** is 0.8 mm anterior to the section in part **B**. (Abbreviations: **IFR**, infundibular recess; **III**, third ventricle; **OC**, optic chiasm; **OT**, optic tract; **PVH**, paraventricular nucleus of the hypothalamus; **SO**, supraoptic nucleus.) (Adapted, with permission, from Gorski 1988.)

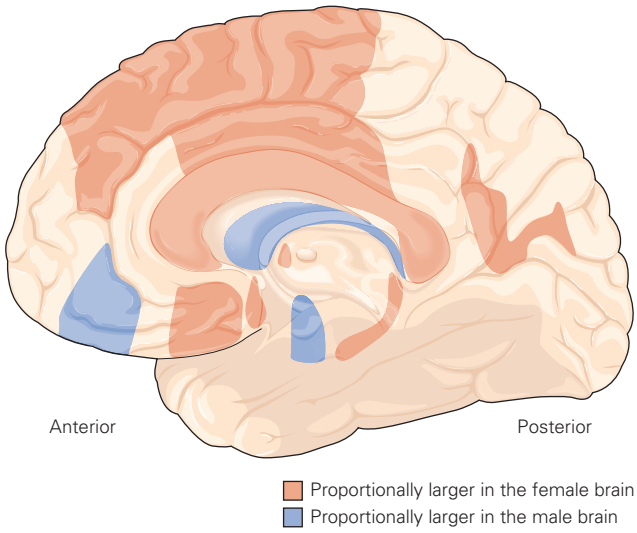

Figure 51–14 Sexual dimorphism is widespread in the adult human brain. A magnetic resonance imaging study measured the volume of many brain regions in adult men and women. The volume of each region was normalized to the size of the cerebrum for both sexes. Sex differences were significant in many regions, including several cortical areas that likely mediate cognitive functions. (Adapted, with permission, from Cahill 2006. Copyright © 2006 Springer Nature.)

central nervous system. For example, structures such as the fronto-orbital cortex and several gyri—including the precentral, superior frontal, and lingual gyri—occupy a significantly larger volume in adult women compared to a cohort of adult men (Figure 51–14). Moreover, the frontomedial cortex, amygdala, and angular gyrus volumes are larger in men compared to women. Thus, there are likely to be many sexual dimorphisms in the human brain.

Sexual Dimorphisms in Humans May Arise From Hormonal Action or Experience

What remains unclear is how these brain dimorphisms arise and how they relate to behavior. They might arise early from the organizational effects of hormones or later as a result of experience. Sex differences arising before or soon after birth could underlie behavioral differences, whereas those that arise later in life might be results of dimorphic experiences. Answers to these questions are fairly clear in a few cases. For example, studies of the development of neural circuits responsible for penile erection and lactation in rodents translate readily to humans.

Two recent observations suggest that enduring effects of experience on behavior first studied in animals (Figure 51–10) are also relevant to humans. First, as discussed in Chapter 49, children raised for lengthy periods in orphanages with little individual care have long-lasting defects in a variety of social behaviors. Even years after placement in foster homes, these children have on average lower levels of oxytocin and vasopressin in their serum than children raised with biological parents. Second, people who have suffered abuse as children often grow up to be poor parents. Postmortem studies have shown that adults who had been abused as children exhibited greater promoter methylation of their glucocorticoid receptor genes than adults in control populations. Although these studies are new and require replication, they provide tantalizing hints at the biological mechanisms that underlie the lifelong effects of early parental care.

Dimorphic Structures in the Brain Correlate with Gender Identity and Sexual Orientation

In contrast to progress in mapping the biological bases of some relatively simple sexually dimorphic behaviors in people, differences in sexual partner preference and gender identity remain poorly understood. Little progress has been made in relating sex differences in cognitive functions to structural differences in the brain, in part because the very existence of cognitive differences remains a matter of controversy; if they exist at all, they are small and represent differences in means between highly variable male and female populations. On the other hand, several lines of evidence have connected clear differences in gender identity and sexual orientation to dimorphic structures in the brain.

Early insight into this issue came from observation of people with single-gene mutations that dissociate anatomical sex from gonadal and chromosomal sex, such as CAIS, CAH, and 5α-reductase deficiency (Table 51–1). For example, girls with CAH experience an excess of testosterone during fetal life; the disorder is generally diagnosed at birth and corrected. Nevertheless, the early exposure to androgens is correlated with subsequent changes in gender-related behaviors. On average, girls with CAH tend to have toy preferences and engage in play typical of boys of equivalent age. There is also a small but significant increase in the incidence of homosexual and bisexual orientation in females treated for CAH as children, and a significant proportion of these females also express the desire to live as men, consistent with a change in gender identity. These findings suggest that early organizational effects of steroids affect gender-specific behaviors independent of chromosomal and anatomical sex.

In 5α-reductase II deficiency and CAIS, many of the affected males show completely feminized

external genitalia and are mistakenly raised as females until puberty. Thereafter, their histories diverge. In 5α-reductase II deficiency, the symptoms arise from a defect in testosterone processing largely confined to the developing external genitalia. At puberty, the large increase in circulating testosterone virilizes the body hair, musculature, and most dramatically, the external genitalia. At this stage, many but not all patients choose to adopt a male gender. In CAIS, in contrast, defects arise from a body-wide defect in the androgen receptor. These patients commonly seek medical advice after they fail to menstruate at puberty. Concordant with their feminized external phenotype, most CAIS patients express a female gender identity and a sexual preference for men. They opt for surgical removal of the testes and hormonal supplementation appropriate for females.

What accounts for the different outcomes? Among many possibilities, one is that the dramatic change in behavior in 5α-reductase II patients at puberty results from the effects of testosterone acting on the brain. In CAIS patients, these effects do not occur because androgen receptors are absent from the brain. Clearly, however, this explanation does not rule out social and cultural upbringing as important factors in determining gender identity and sexual orientation.

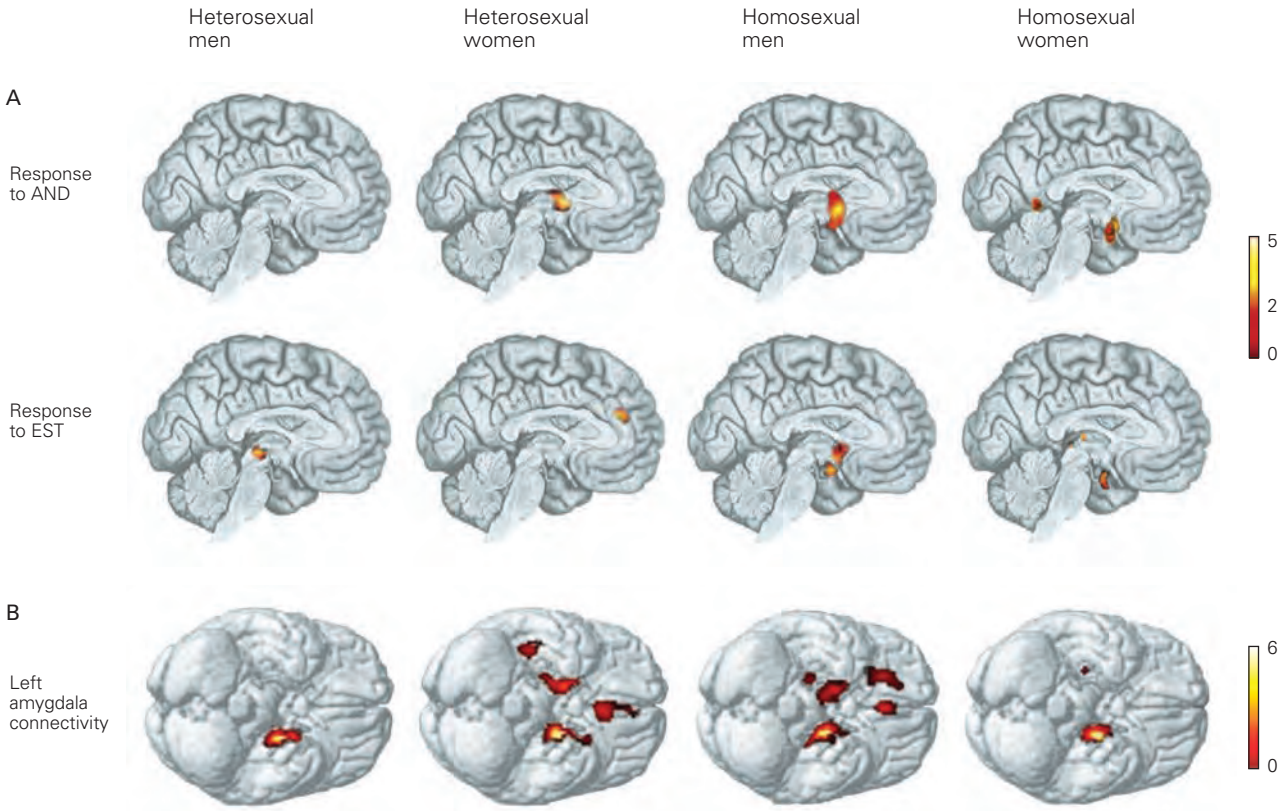

Figure 51–15 Some sexually dimorphic patterns of olfactory activation in the brain correlate with sexual orientation.

A. Positron emission tomography imaging was used to identify brain regions that were activated when subjects sniffed androstadienone (**AND**) or estratetraenol (**EST**) compared to nonodorous air. AND activated several hypothalamic centers in the brains of heterosexual women but not men, whereas EST activated several hypothalamic centers in heterosexual males but not females. Patterns of activation in the hypothalamus of homosexual men were similar to those of heterosexual women in response to AND, whereas similar patterns of activation were found in heterosexual men and homosexual women in response to EST. The color calibration on the right shows the level of putative neural activity. Because the same brain sections were selected to compare, the figure does not illustrate maximal activation for each condition. (Adapted, with permission, from Berglund, Lindstrom, and Savic 2006; Savic, Berglund, and Lindstrom 2005.)

B. Heterosexual and homosexual subjects were scanned while breathing unscented air, and a measure of covariance was used to estimate connectivity among regions. In heterosexual women and homosexual men, the left amygdala was strongly connected to the right amygdala, whereas connectivity remained local in heterosexual men and homosexual women. (Adapted, with permission, from Savic and Lindstrom 2008.)

A second set of studies probing the biology of sexual orientation assessed responses to pheromones. Pheromone perception in humans is quite different from that of mice and is likely a less important sense. Humans do not have a functional VNO, and most of the genes implicated in pheromone reception in the mouse VNO, such as *trpc2* and those encoding VNO receptors, are absent or nonfunctional in the human genome. To the extent that humans do sense pheromones, they appear to use the main olfactory epithelium and bulb. Chemicals that appear to be human pheromones include androstadienone (AND), an odorous androgenic metabolite, and estratetraenol (EST), an odorous estrogenic metabolite. AND is present at 10-fold higher concentrations in male sweat compared to female sweat, whereas EST is present in the urine of pregnant women. Both compounds can produce sexual arousal—AND in heterosexual women and EST in heterosexual men—even at concentrations so low that there is no conscious olfactory perception.

Brain areas activated by AND and EST have been identified by positron emission tomography (PET) imaging. When AND is presented, certain hypothalamic nuclei are activated in heterosexual women but not heterosexual men, whereas when EST is presented, adjacent regions containing clusters of nuclei are activated in men but not in women (Figure 51–15A). In homosexual men and women, there is a reversal of hypothalamic activation: AND but not EST activates hypothalamic centers in homosexual men, and conversely, EST but not AND activates those areas in lesbian women. Heterosexual and homosexual brains therefore appear to process olfactory sensory information in different ways.

Do sexually dimorphic structures in homosexual brains correlate with anatomical sex or sexual orientation? Imaging studies have provided support for the view that the brains of homosexual men resemble those of heterosexual woman and that the brains of homosexual women resemble those of heterosexual men (Figure 51–15B). Moreover, the volume of the sexually dimorphic BNST is small in male-to-female transsexuals compared to men, whereas female-to-male transsexuals appear to have a larger BNST compared to women (Figure 51–16). It is not clear, however, whether the structural dimorphism in these individuals is a consequence or a cause of gender identity or sexual orientation.

The male mouse counterpart of the human BNST plays a critical role in recognizing the sex of *other* mice and guides subsequent social interactions, such as aggression with males and mating with females. Thus, a region linked to gender identity in the human brain plays an important role in sex recognition in rodents.

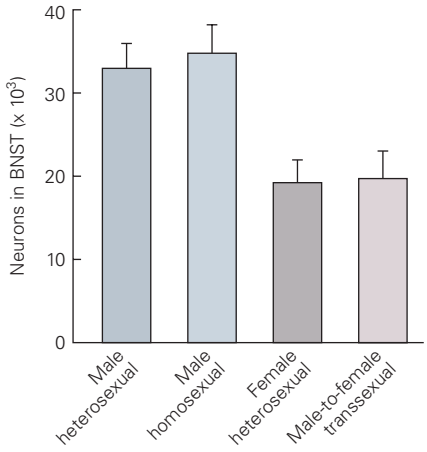

Figure 51–16 Sexual dimorphism in the bed nucleus of the stria terminalis (BNST) in humans. The nucleus has significantly more neurons in men compared to women regardless of male sexual orientation. Similar to women, male-to-female transsexuals have fewer neurons than men. In the one female-to-male transsexual brain available for postmortem analysis (not shown in the bar graph), the number of neurons is well within the normal range for men. (Adapted, with permission, from Kruijver et al. 2000.)

As is the case with the sexual dimorphism of the mouse BNST discussed earlier, hormonal influences are also thought to underlie the dimorphism of the human BNST.

If prenatal influences do lead to dissociation of sex from gender, are those influences genetic? Other than the rare syndromes described earlier, attempts to find genetic bases for sexual orientation or gender identity have not been productive. Claimed genetic contributions are small and claims of associations with specific genomic loci have not been replicated. Thus, while the current weight of evidence favors some contribution of early, even prenatal, factors in these processes, their cause and relative importance remain unknown.

Highlights

1. In humans and many other mammals, the sex determination pathway directs differentiation of the bipotential gonad into testes in males and ovaries in females. The *SRY* gene on the Y chromosome directs the gonad to form testes, whereas the absence of *SRY* enables the gonad to differentiate into ovaries.
2. Sex steroid hormones produced by the gonads—testosterone by testes and estrogens, and progesterone by ovaries—drive sexual differentiation of both the nervous system and the rest of the body.

3. Sex hormones act early during a critical window in development to irreversibly organize neural substrates for behavior in a sexually dimorphic manner, whereas in adult life, these hormones act acutely and reversibly to activate sex-typical physiological and behavioral responses.
4. During the critical window, testes produce a transient surge of testosterone that masculinizes the developing bipotential nervous system. By contrast, the ovaries are quiescent during this period, and it is thought that the absence of sex hormones enables the nervous system in this period to differentiate along a female-typical pathway.
5. Many of the actions of testosterone that masculinize the nervous system occur following its conversion to estrogen locally at the site of action. There is evidence to suggest that in humans and other primates testosterone also acts directly via its cognate hormone receptor to effect masculinization of the neural substrates of behavior.
6. Sex hormones control sexual differentiation of neural pathways by utilizing cellular processes such as apoptosis, neurite extension, and synapse formation that are employed widely during other developmental events.
7. Sex hormones bind to cognate hormone receptors that modulate gene expression. Such genes in turn regulate the cellular processes that result in sex differences in neuronal number, connectivity, and physiology.
8. Many neuronal populations that are sexually dimorphic by morphological and other criteria have been identified in the vertebrate brain over the past few decades. Functional studies show that these regions influence some, but not all, sexually dimorphic behaviors.
9. Recent molecular studies have identified many sex hormone–regulated genes whose expression patterns are sexually dimorphic. These genes as well as the neurons they are expressed in regulate sexually dimorphic social behaviors in a modular manner. In other words, individual genes and the neuronal populations that express them modulate one or a few sexually dimorphic behaviors so that the control of these behaviors is distributed among many different neuronal groups.
10. Such sexually dimorphic neuronal populations are likely embedded within neural circuits found in both sexes, and they are thought to guide behavior along male- or female-typical patterns.
11. Both sensory stimuli and past experience profoundly regulate the display of sexually dimorphic behaviors. In some cases, the influence of past experience can extend across the life span of the animal.
12. Pheromones guide choice of sexual partner in rodents. There is evidence from imaging studies that men and women may also show sexually dimorphic neural responses to male and female pheromones and that these responses can align with sexual orientation; in these cases, however, it is unclear if the neural responses are learned responses based on past experience.
13. There are many sex differences between the brains of men and women, and in some instances, these sex differences align with gender in adult life rather than gender assigned at birth. In these cases, it is not clear whether the sex differences causally reflect gender identity or are a result of it. These issues are difficult to disentangle at present.

Tingarri Men and Initiates at Marabindinya. In this painting by the Aboriginal Australian artist, Anatjari Tjampitjinpa, Tingarri instructors are depicted as concentric circles and their young initiates are shown as horseshoe shapes along the boundaries. The background of the painting depicts the sandhill country of the central Australian desert. Such symbolic representations recall the neural representations of episodic memories, consisting of events taking place in space and time, encoded in the firing of grid cells and place cells in the entorhinal cortex and hippocampus, respectively.

VIII Learning, Memory, Language and Cognition

Motor and sensory functions take up less than one-half of the cerebral cortex in humans. The rest of the cortex is occupied by the association areas, which coordinate events arising in the motor and sensory centers. Three association areas—the prefrontal, parietal-temporal-occipital, and limbic—are involved in cognitive behavior: speaking, thinking, feeling, perceiving, planning skilled movements, learning, memory, decision-making, and consciousness.

Most of the early evidence relating cognitive functions to the association areas came from clinical studies of brain-damaged patients. Thus, the study of language in patients with aphasia yielded important information about how human mental processes are distributed in the two hemispheres of the brain and how they develop. More refined analyses have come from human imaging studies using functional magnetic resonance imaging (fMRI) and other methods.

Deeper insights into the neural circuitry and cellular mechanisms giving rise to cognitive processes have come from electrophysiological recordings and genetic-based manipulations, including cell type–specific gene deletions and cell type–specific optogenetic excitation or inhibition in experimental animals, particularly in rodents. Such studies can evaluate the relative contribution of specific genes, neurons, and synaptic connections to specific types of behavior.

So far in this book, we have considered neural mechanisms associated with basic functions of the brain, including primary sensory perception, movement, and homeostatic control. In this part and the next, we begin to consider the more complex, higher-order brain functions mentioned earlier, the realm of cognitive neural science. The aim of this merger of neurophysiology, anatomy, developmental biology, cell and molecular biology, theory, and cognitive psychology is to ultimately provide an understanding of the neural mechanisms of the mind.

Until the latter part of the 20th century, the study of higher mental function was approached through behavioral observations gleaned from brain-damaged patients and animals with experimental lesions. In the first part of the 20th century, to avoid untestable

concepts and hypotheses, psychology became rigidly concerned with behaviors defined strictly in terms of observable stimuli and responses. Orthodox behaviorists thought it unproductive to deal with consciousness, feeling, attention, or even motivation. By concentrating only on observable actions, behaviorists asked: What can an organism do, and how does it do it? Indeed, careful quantitative analysis of stimuli and responses has contributed greatly to our understanding of the acquisition and use of "implicit" knowledge of perceptual and motor skills. However, humans and other higher animals also have "explicit" knowledge of facts and events. They have knowledge of space, rules, and relations—what Edward Tolman termed *cognitive maps*. Animals can choose a newly available route to a goal without ever learning the sensory-response association, and humans can reason deliberatively from what they know to imagine something unknown. Indeed, that is what makes neural science possible—in fact, all of science and the humanities.

Thus, we also need to ask: What does the animal know about the world, and how does it come to know it? How is that knowledge represented in the brain? Does explicit knowledge differ from implicit knowledge? And how can such knowledge be communicated to others and enable us to make rational decisions based on past experience? Much, perhaps most, knowledge is unconscious a great deal of the time. We need to know the nature of the unconscious processes, the systems that mediate them, and their influence on the nature of conscious mental activity. Finally, we need to know about the highest realms of conscious knowledge, the knowledge of oneself as an individual, a thinking and feeling human being.

The modern effort to understand the neural mechanisms of higher mental functions began at the end of the 19th century when Pierre Broca and Carl Wernicke discovered regions of the cerebral cortex responsible for the production and comprehension of language. Throughout the 20th century, studies of patients with brain damage resulting from accidents, war, and disease led to an expansion of knowledge of the roles of specific brain areas responsible for cognitive functions, including attention, intention (planning), reasoning, and learning and memory. However, it was only in the past 20 to 30 years, based in part on new technological approaches, that our understanding of cognitive processes advanced from anatomical localization to an understanding of how neural activity in specific brain regions underlies such processes.

In Part VIII, we explore such questions of cognitive brain science. Chapter 52 introduces basic mechanisms of human learning and memory, focusing on the use of fMRI and behavioral studies to elucidate the role of different brain regions in implicit and explicit memory. In Chapter 53, we discuss the cellular and molecular mechanisms responsible for implicit memory storage, focusing on studies in invertebrates and vertebrates that have elucidated the role of synaptic plasticity in implicit memory storage. In Chapter 54, we

expand on the theme of synaptic plasticity, this time for the storage of explicit memory by the hippocampus and related brain regions. We further consider how the synaptic connectivity between the entorhinal cortex and hippocampus enables us to perceive and remember our spatial location in a given environment. Next, in Chapter 55, we focus on the neural mechanisms underlying language, a uniquely human function that enables us to communicate our store of knowledge to others, including brain circuits necessary for speaking and perceiving the spoken word. Finally, in Chapter 56, we examine how the brain enables us to use our knowledge to make rational decisions. Viewed through the lens of decision-making, the distinction between the apparently separate processes of knowledge and know-how can be seen as a unified function, one that provides a basis for understanding how consciousness may emerge from brain activity. Achieving a full understanding of the neural mechanisms that enable us to maintain a rich set of memories of our past experiences over a lifetime, to communicate those memories to others, and to use them to make informed, conscious decisions is perhaps one of the most daunting challenges in all of science.

Learning and Memory

In his masterful novel *One Hundred Years of Solitude*, Gabriel Garcia Márquez describes a strange plague that invades a tiny village and robs people of their memories. The villagers first lose personal recollections, then the names and functions of common objects. To combat the plague, one man places written labels on every object in his home. But he soon realizes the futility of this strategy, because the plague eventually destroys even his knowledge of words and letters.

This fictional incident reminds us of how important learning and memory are in everyday life. Learning refers to a change in behavior that results from acquiring knowledge about the world, and memory refers to the processes by which that knowledge is encoded, stored, and later retrieved. Marquez's story challenges us to imagine life without the ability to learn and remember. We would forget people and places we once knew, and no longer be able to use and understand language or execute motor skills we had once learned; we would not recall the happiest or saddest moments of our lives and would even lose our sense of personal identity. Learning and memory are essential to the full functioning and independent survival of people and animals.

In 1861, Pierre Paul Broca discovered that damage to the posterior portion of the left frontal lobe (Broca's area) produces a specific deficit in language. Soon thereafter, it became clear that other mental functions, such as perception and voluntary movement, are also mediated by discrete parts of the brain (Chapter 1). This naturally led to the question: Are there discrete neural systems concerned with memory? If so, is there a "memory center," or is memory processing widely distributed throughout the brain?

Contrary to the prevalent view that cognitive functions are localized in the brain, many students of learning doubted that memory is localized. In fact, until the middle of the 20th century, many psychologists doubted that memory is a discrete function, independent of perception, language, or movement. One reason for the persistent doubt is that memory storage involves many different parts of the brain. We now appreciate, however, that these regions are not all equally important. There are several fundamentally different types of memory, and certain regions of the brain are much more important for encoding some types of memory than for others.

During the past several decades, researchers have made significant progress in the analysis and understanding of learning and memory. In this chapter, we focus on studies of normal human memory behavior, its perturbations following brain lesions due to injury or surgery, and measurements of brain activity during learning and memory recall using functional magnetic resonance imaging (fMRI) and extracellular electrophysiological recordings. These studies have yielded three major insights.

First, there are several forms of learning and memory. Each form of learning and memory has distinctive cognitive and computational properties and is supported by different brain systems. Second, memory involves encoding, storage, retrieval, and consolidation. Finally, imperfections and errors in remembering can provide clues about the nature and function of learning and memory and the fundamental role that memory plays in guiding behavior and planning for the future.

Memory can be classified along two dimensions: (1) the time course of storage and (2) the nature of the information stored. In this chapter, we consider the time course of storage. In the next two chapters, we focus on the cellular, molecular, and circuit-based mechanisms of different forms of learning and memory, based largely on studies of animal models.

Short-Term and Long-Term Memory Involve Different Neural Systems

Short-Term Memory Maintains Transient Representations of Information Relevant to Immediate Goals

When we reflect on the nature of memory, we usually think of the long-term memory that William James referred to as "memory proper" or "secondary memory." That is, we think of memory as "the knowledge of a former state of mind after it has already once dropped from consciousness." This knowledge depends on the formation of a memory trace that is durable, in which the representation persists even when its content has been out of conscious awareness for a long period.

Not all forms of memory, however, constitute "former states of mind." In fact, the ability to store information depends on a form of short-term memory, called working memory, which maintains current, albeit transient, representations of goal-relevant knowledge. In humans, working memory consists of at least two subsystems—one for verbal information and another for visuospatial information. The functioning of these two subsystems is coordinated by a third system called the *executive control processes*. Executive control processes are thought to allocate attentional resources to the verbal and visuospatial subsystems and to monitor, manipulate, and update stored representations.

We use the verbal subsystem when we attempt to keep speech-based (phonological) information in conscious awareness, as when we mentally rehearse a password before entering it. The verbal subsystem consists of two interactive components: a store that represents phonological knowledge and a rehearsal mechanism that keeps these representations active while we need them. Phonological storage depends on posterior parietal cortices, and rehearsal partially depends on articulatory processes in Broca's area.

The visuospatial subsystem of working memory retains mental images of visual objects and of the location of objects in space. The rehearsal of spatial and object information is thought to involve modulation of this information in the parietal, inferior temporal, and occipital cortices by the frontal and premotor cortices.

Single-cell recordings in nonhuman primates indicate that, over a period of seconds, some prefrontal neurons maintain spatial representations, others maintain object representations, and still others represent the integration of spatial and object knowledge. Although neurons concerned with working memory of objects tend to lie in the ventrolateral prefrontal cortex and those concerned with spatial knowledge tend to lie in the dorsolateral prefrontal cortex, all three classes of neurons are found in both prefrontal subregions (Figure 52–1).

Thus, working memory involves activation of representations of information stored in specialized cortical regions that vary based on the content of the information, as well as activation of general control mechanisms in prefrontal cortex. Prefrontal control signals in working memory are further dependent on interaction with the striatum and ascending dopaminergic inputs from the midbrain.

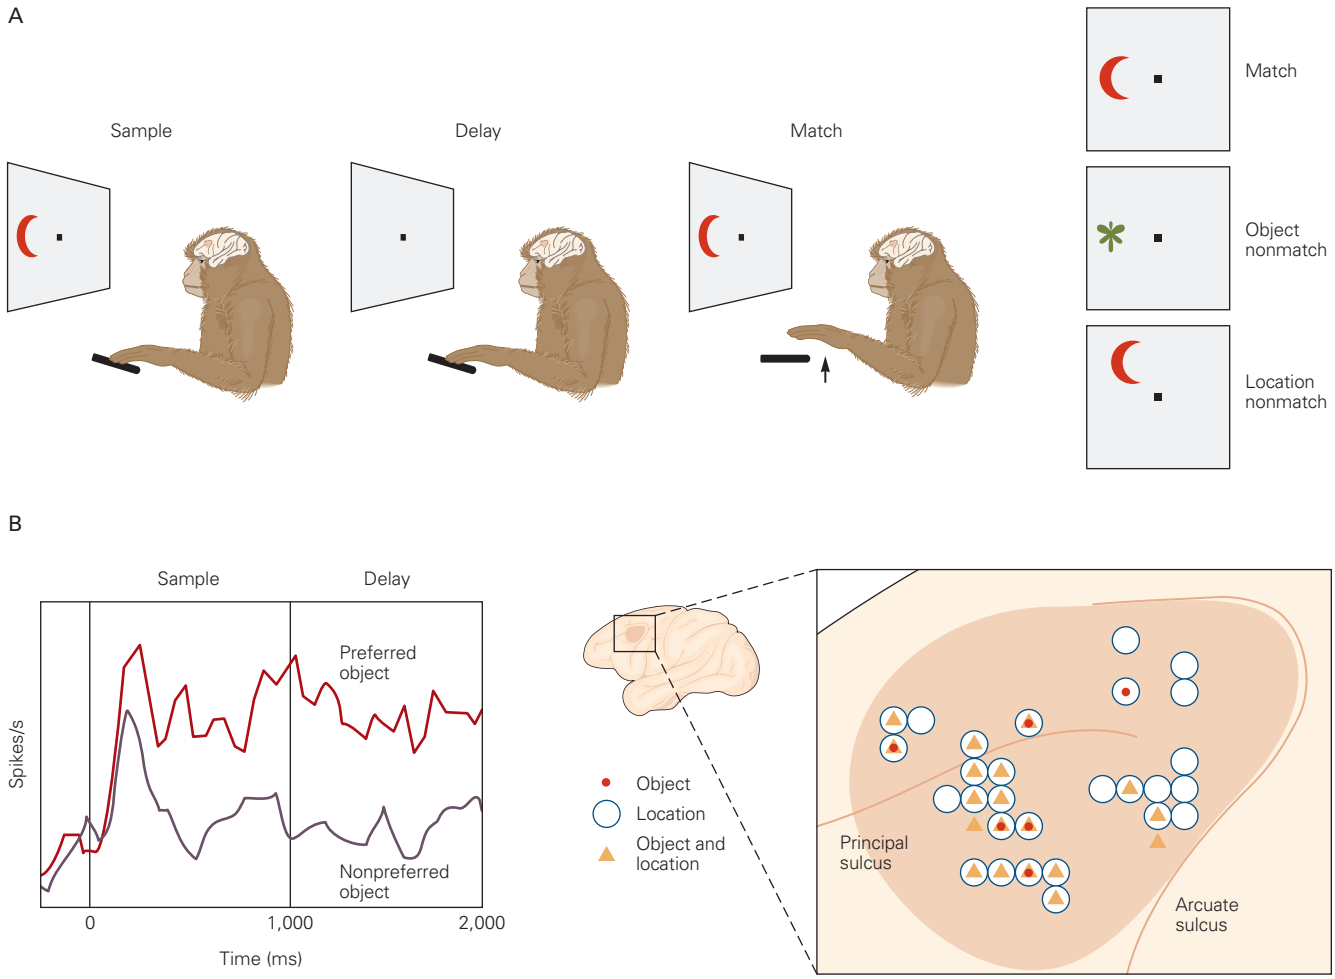

Figure 52–1 **The prefrontal cortex maintains a working memory.** (Adapted, with permission, from Rainer, Asaad, and Miller 1998.)

A. The role of prefrontal cortex in maintaining information in working memory is often assessed in monkeys using electrophysiological methods in conjunction with a delayed-match-to-sample (DMS) task. In this type of task, each trial begins when the monkey grabs a response lever and visually fixates a small target at the center of a computer screen. An initial visual stimulus (the sample) is briefly presented and must be held in working memory until the next stimulus (the match) appears. In the task illustrated here, the monkey was required to remember the sample ("what") and its location ("where") and release the lever only in response to stimuli that matched on both dimensions.

B. Neural firing rates in the lateral prefrontal cortex of a monkey during the delay period are often maintained above baseline and represent responses to the type of stimulus (what), the location (where), and the integration of the two (what and where). As shown, at left is the activity of a prefrontal neuron in response to a preferred object (to which the neuron responds robustly) and to a nonpreferred object (to which the neuron responds minimally). Activity is robust both when the monkey looks at the preferred object (sample) and during the delay. In the sketch at right, the symbols represent recording sites where neurons maintained each type of information (what, where, and what and where). Typically, several types of neurons were found at one site; hence, many symbols overlap and some symbols indicate more than one neuron.

Information Stored in Short-Term Memory Is Selectively Transferred to Long-Term Memory

In the mid-1950s, startling new evidence about the neural basis of long-term memory emerged from the study of patients who had undergone bilateral removal of the hippocampus and neighboring regions in the medial temporal lobe as treatment for epilepsy. The first and best-studied case was a patient called H.M. studied by the psychologist Brenda Milner and the surgeon William Scoville. (After H.M. died on December 2, 2008, his full name, Henry Molaison, was revealed to the world.)

H.M. had suffered for a number of years from untreatable temporal lobe epilepsy caused by brain

damage sustained at age 7 years in a bicycle accident. As an adult, his seizures rendered him unable to work or lead a normal life, and at the age of 27, he underwent surgery. Scoville removed the brain regions thought to be responsible for the seizures, including the hippocampal formation, the amygdala, and parts of the multimodal association area of the temporal cortex bilaterally (Figure 52–2). After the surgery, H.M.'s seizures were better controlled, but he was left with a devastating memory deficit (or amnesia). What was so remarkable about H.M.'s deficit was its specificity.

He still had normal working memory, for seconds or minutes, indicating that the medial temporal lobe is not necessary for transient memory. He also had long-term memory for events that had occurred before the operation. For example, he remembered his name, the job he had held, and childhood events. In addition, he retained a command of language, including his vocabulary, indicating that semantic memory—factual knowledge about people, places, and things—was preserved. His IQ remained unchanged, in the range of bright-normal.

What H.M. now lacked, and lacked dramatically, was the ability to transfer new information into long-term memory, a deficit termed anterograde amnesia. He was unable to retain for lengthy periods information about people, places, or objects that he had just encountered. Asked to remember a new telephone number, H.M. could repeat it immediately for seconds to minutes because of his intact working memory. But when distracted, even briefly, he forgot the number. H.M. could not recognize people he met after surgery, even when he met them again and again. For several years, he saw Milner every month, yet each time she entered the room, he reacted as though he had never seen her before. H.M. is not unique. All patients with extensive bilateral lesions of the limbic association areas of the medial temporal lobe show similar long-term memory deficits.

H.M. is a historic case because his deficit provided the first clear link between memory and the medial temporal lobe, including the hippocampus. Subsequent studies by Larry Squire and others of patients with brain damage more limited to the hippocampus confirmed its central role in memory. The observation that H.M. and others with medial temporal lobe damage had a profound deficit in the formation of new memories while the retrieval of old memories remained largely intact suggested that memories must be transferred over time from the hippocampus and medial temporal lobe to other brain structures. These studies gave rise to four central questions that continue to drive memory research to this day: First, what is the functional role of the medial temporal lobe memory system? Second, what are the roles of different subregions within this system? Third, how do these subregions work together with other brain circuits to support different forms of memory? Fourth, where are hippocampal-dependent memories ultimately stored?

The Medial Temporal Lobe Is Critical for Episodic Long-Term Memory

A crucial finding about H.M. was that formation of long-term memory was impaired only for certain types of information. H.M. and other patients with damage to the medial temporal lobe were able to form and retain certain types of durable memories just as well as healthy subjects.

For example, H.M. learned to draw the outlines of a star while looking at the star and his hand in a mirror (Figure 52–3). Like healthy subjects learning to remap hand–eye coordination, H.M. initially made many mistakes, but after several days of training, his performance was error-free and comparable to that of healthy subjects. Nevertheless, he did not consciously remember having performed the task.

Long-term memory formation in amnesic patients is not limited to motor skills. These patients retain simple reflexive learning, including habituation, sensitization, and some forms of conditioning (to be discussed later in this chapter). Furthermore, they are able to improve their performance on certain perceptual and conceptual tasks. For example, they do well with a form of memory called priming, in which perception of a word or object or access to the meaning of a word or object is improved by prior exposure. Thus, when shown only the first few letters of previously studied words, a subject with amnesia is able to generate the same number of studied words as normal subjects, even though the amnesic patient has no conscious memory of having recently encountered the words (Figure 52–4).

This pattern of selectively impaired performance in patients with amnesia raised questions about how to classify these different forms of memory: What are the key features that distinguish between memories that survive medial temporal lobe damage and those that do not? Early theories by Squire and colleagues suggested that a critical factor may be conscious awareness—damage to the medial temporal lobe appears to impair forms of memory that can be accessed consciously and can be reported on or expressed in words, while leaving intact forms of memory that cannot. For this reason, memories that depend on the medial temporal

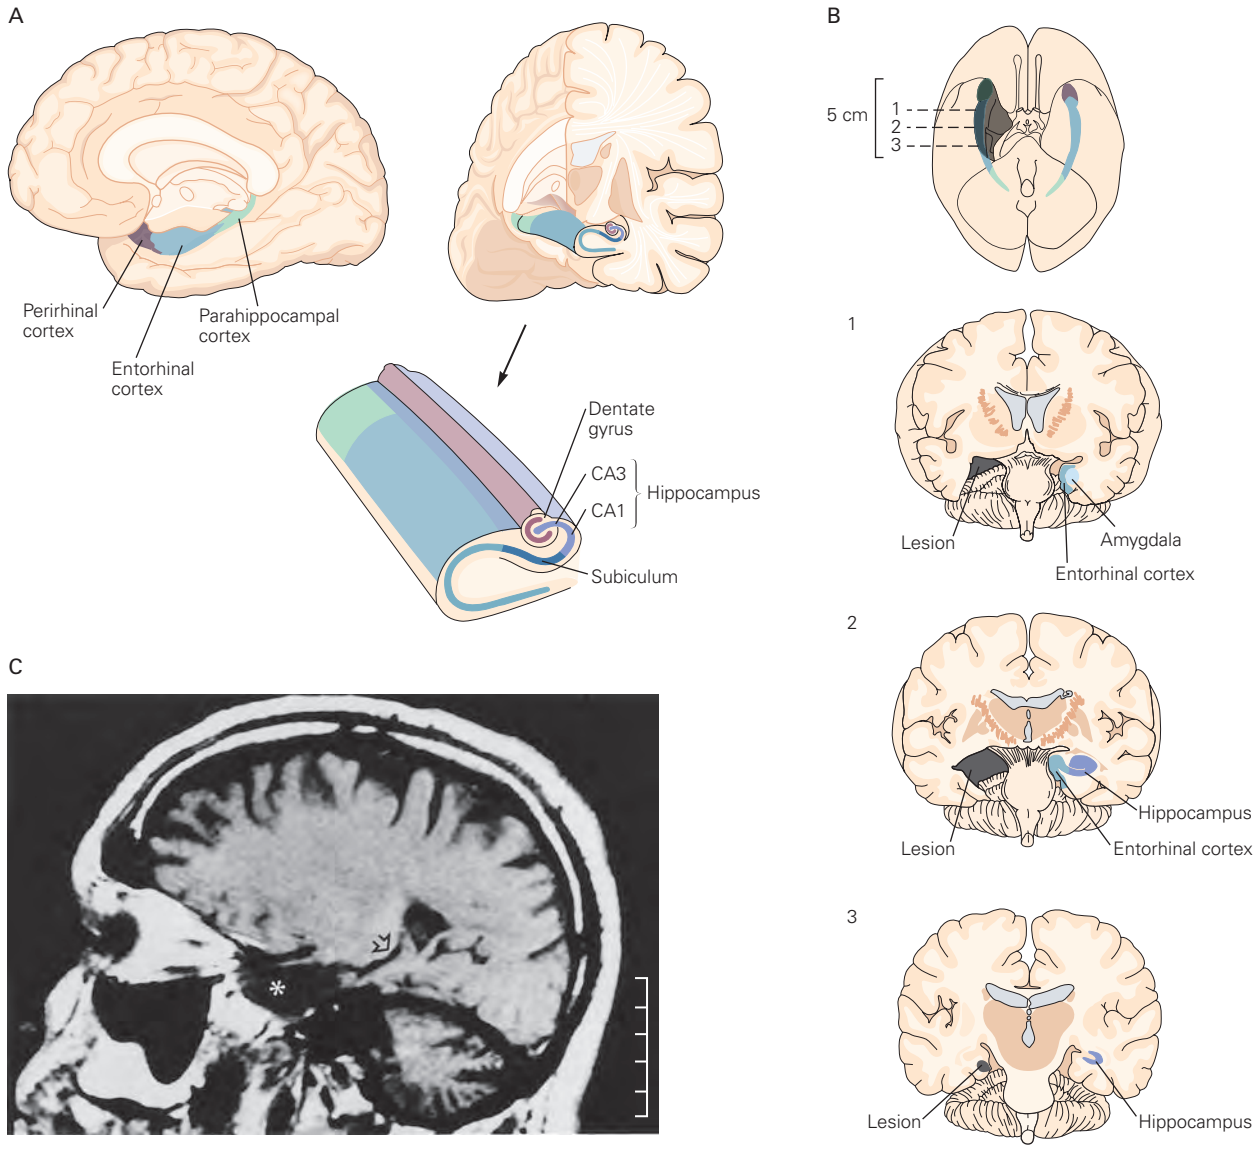

Figure 52–2 The medial temporal lobe and memory storage.

A. The key components of the medial temporal lobe important for memory storage.

B. The areas of temporal lobe resected (**gray shading**) in the patient known as H.M., viewed from the ventral surface of the brain (left hemisphere is on the right side of the image). Surgery was a bilateral, single-stage procedure, but to illustrate the structures that were removed from the left hemisphere (right side of the image), the left hemisphere is shown here intact. The longitudinal extent of the lesion is shown in a ventral view of the brain (top). Cross sections 1 through 3 show the estimated extent of areas of the brain removed from H.M. (Adapted, with permission, from Corkin et al. 1997.)

C. Magnetic resonance image (MRI) scan of a parasagittal section from the left side of H.M.'s brain. The calibration bar at the right of the panel has 1-cm increments. The **asterisk** in the central area of the scan indicates the resected portion of the anterior temporal lobes. The nearby **arrowhead** points to the remaining portion of the intraventricular portion of the hippocampal formation. Approximately 2 cm of preserved hippocampal formation is visible bilaterally. Note also the substantial degeneration in the enlarged folial spaces of the cerebellum. (Adapted, with permission, from Corkin et al. 1997.)

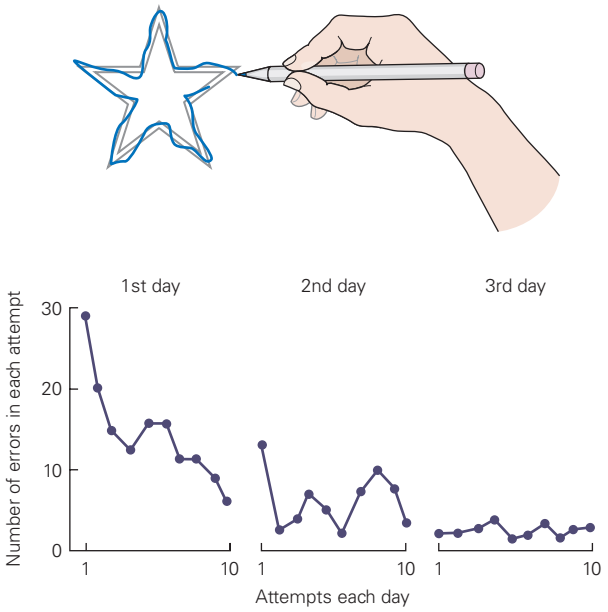

Figure 52–3 The amnesic patient H.M. could learn skilled movements. He was taught to trace between two outlines of a star while viewing his hand in a mirror. The graph plots the number of times, during each attempt, that he strayed outside the outlines as he drew the star. As with healthy subjects, H.M. improved considerably with repeated attempts despite the fact that he had no recollection of performing the task. (Reproduced, with permission, from Blakemore 1977.)

lobe are often referred to as *explicit* (or *declarative*) memory. Explicit memory can be further classified into episodic memory (the memory of personal experiences or autobiographical memory) and semantic memory (memory for facts). *Episodic memory* refers to our ability to remember rich details of moments in time, including information about what happened, when, and where. For example, episodic memory is used to recall that we saw the first flowers of spring yesterday or that we heard Beethoven's "Moonlight Sonata" several months ago. *Semantic memory* is used to recall the meanings of words or concepts, among other facts.

Cognitive psychologists found a similar distinction between different forms of memory in healthy subjects by using tasks that differ in how memories are expressed. One type is a nonconscious form of memory that is evident in the performance of a task. This form of memory is often referred to as *implicit* memory (also referred to as *nondeclarative* or procedural memory). Implicit memory is typically manifested in an automatic manner, with little conscious processing on the part of the subject. Different forms give rise to priming, skill learning, habit memory, and conditioning (Figure 52–5). Explicit memory is considered to be highly flexible; multiple pieces of information can be associated under different circumstances. Implicit memory, however, is tightly connected to the original conditions under which the learning occurred.

The terms "explicit memory" and "implicit memory" are used to describe two broad forms of memory that differ in their hallmark behavioral characteristics and in their neural underpinnings. These forms of memory can be acquired in parallel. For example, one might form an explicit memory of how good a bakery smelled upon entering it yesterday, while at the same time, one might develop an automatic conditioned response of increased salivation upon viewing a picture of the bakery. Moreover, we now believe that these forms of memory, while distinct, normally interact to support behavior, although the precise

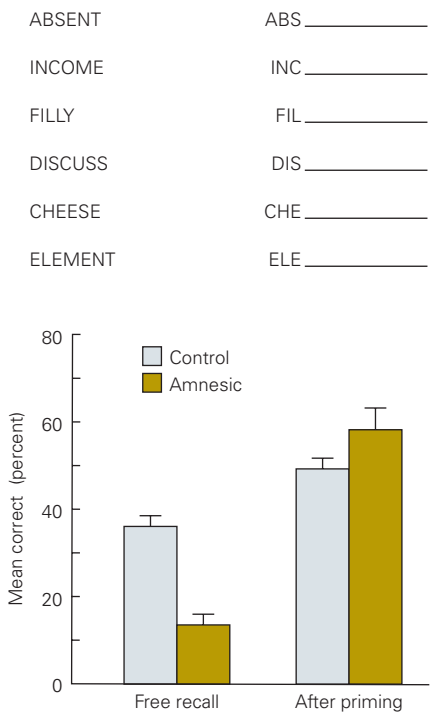

Figure 52–4 Amnesic subjects differ in their ability to recall words under two conditions. Subjects were presented with common words and then asked to recall the words. Amnesic patients did not do well on this test during free recall. However, when subjects were given the first three letters of a word that had been presented and instructed to form the first word that came to mind (word completion), the amnesic subjects performed as well as normal subjects. The baseline guessing rate in the word completion condition for words not previously presented was 9%. (Adapted from Squire 1987.)

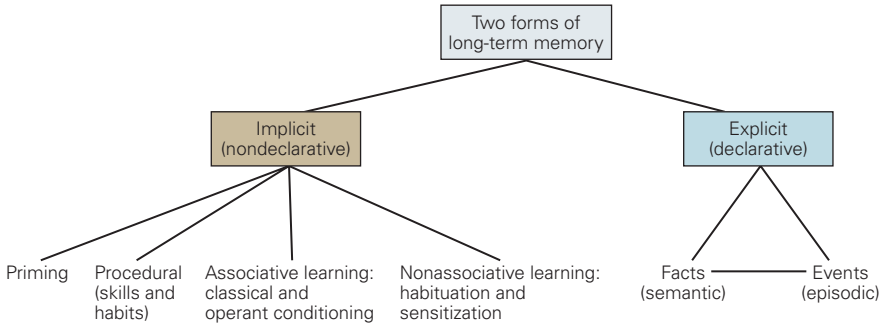

Figure 52–5 Long-term memory is commonly classified as either explicit (the memory is reported verbally) or implicit (the memory is expressed through behavior without conscious awareness).

nature and extent of their interactions are a topic of ongoing investigation.

There are also ongoing debates about the role of conscious awareness in memory and about whether it is indeed a necessary feature of memories supported by the medial temporal lobe. These debates are driven by a growing body of work showing that the same medial temporal circuits necessary for explicit memory are also necessary for some forms of implicit memory (as described below). Indeed, although episodic memory is typically assessed by asking subjects to report the content of their memory, it remains unknown whether conscious accessibility is an integral feature of the memories themselves. Nonetheless, the distinction between implicit and explicit memory played an important historical role in differentiating forms of memory and still offers a productive framework for considering the neural bases of memory. Thus, we use the terms "explicit memory" and "implicit memory" here to distinguish these two forms of memory and the classes of subjective experience and behaviors that they are based on. In the following sections, we focus on episodic memory, which has been the target of a great deal of cognitive neuroscience research in both amnesic patients and healthy individuals.

Episodic Memory Processing Involves Encoding, Storage, Retrieval, and Consolidation

Episodic memory has been studied extensively and offers a window into understanding how the brain builds, stores, and retrieves details about episodes in our lives. We now know that the brain does not have a single long-term store of episodic memories. Instead, the storage of any item of knowledge is widely distributed among many brain regions that process different aspects of the content of the memory and can be accessed independently (by visual, verbal, or other sensory clues). Second, episodic memory is mediated by at least four related but distinct types of processing: encoding, storage, consolidation, and retrieval.

Encoding is the process by which new information is initially acquired and processed during the formation of a new memory. The extent of this processing is critically important for determining how well the learned material will be remembered. For a memory to persist and be well remembered, the incoming information must undergo what the psychologists Fergus Craik and Robert Lockhart called "deep" encoding. This is accomplished by attending to the information and associating it with memories that were already established. Memory encoding is also stronger when one is motivated to remember, whether because the information has particular emotional or behavioral relevance (eg, a memory for a particularly delicious meal on an enjoyable first date) or whether the information itself is neutral but is associated with something meaningful (eg, remembering the location of that restaurant).

Storage refers to the neural mechanisms and sites by which the newly acquired information is retained as a lasting memory over time. One of the remarkable features about long-term storage is that it seems to have an almost unlimited capacity. In contrast, working memory storage is very limited; psychologists believe that human working memory can hold only a few pieces of information at any one time.

Consolidation is the process that transforms temporarily stored and still labile information into a more stable form. As we shall learn in the next two chapters, consolidation involves expression of genes and protein synthesis that give rise to structural changes at synapses.

Finally, *retrieval* is the process by which stored information is recalled. It involves bringing back to mind different kinds of information that are stored in different sites. Retrieval of memory is much like perception; it is a constructive process and therefore subject to distortion much as perception is subject to illusions (Box 52–1). When a memory is retrieved, it becomes active again, providing an opportunity for an old memory to be encoded again. Because retrieval is constructive, re-encoding of a retrieved memory can differ from the original memory. For example,

Box 52–1 Episodic Memories Are Subject to Change During Recall

How accurate is episodic memory? This question was explored by the psychologist Frederic Bartlett in a series of studies in the 1930s in which subjects were asked to read stories and then retell them. The recalled stories were shorter and more coherent than the original stories, reflecting reconstruction and condensation of the original.

The subjects were unaware that they were editing the original stories and often felt more certain about the edited parts than about the unedited parts of the retold stories. They were not confabulating; they were merely interpreting the original material so that it made sense on recall.

Observations such as these demonstrate that episodic memory is malleable. Moreover, the fact that people incorporate later edits into their original memories leads us to believe that episodic memory is a constructive process in the sense that individuals perceive the environment from the standpoint of a specific point in space as well as a specific point in their own history. Much like sensory perception, episodic memory is not a passive recording of the external world but an active process in which incoming bottom-up sensory information is shaped by top-down signals, representing prior experience, along the afferent pathways. Likewise, once information is stored, recall is not an exact copy of the information stored. Past experiences are used in the present as cues that help the brain reconstruct a past event. During recall, we use a variety of cognitive strategies, including comparison, inference, shrewd guessing, and supposition, to generate a memory that seems coherent to us, that is consistent with other memories, and that is consistent with our "memory of the memory."

re-encoding can include information from the old memory together with the new context in which it was retrieved. This re-encoding allows memories of separate moments in time to be connected in memory, but it also opens the door to errors in memory, as discussed later in the chapter.

Retrieval of information is most efficient when a retrieval cue reminds individuals of the episodic nature of the events linking the elements of the encoded experience. For example, in a classic behavioral experiment, Craig Barclay and colleagues asked some subjects to encode sentences such as "The man lifted the piano." On a later retrieval test, "something heavy" was a more effective cue for recalling piano than "something with a nice sound." Other subjects, however, encoded the sentence "The man tuned the piano." For them, "something with a nice sound" was a more effective retrieval cue for piano than "something heavy" as it reflected better the initial experience. Retrieval, particularly of explicit memories, also is partially dependent on working memory.

Episodic Memory Involves Interactions Between the Medial Temporal Lobe and Association Cortices

Although studies of amnesic patients during the past few decades have refined our understanding of various types of memory, medial temporal lobe damage affects all four operations of memory—encoding, storage, consolidation, and retrieval—and thus it is often difficult to discern how the medial temporal lobe contributes to each. fMRI allows us to scan brain activity in the process of building new memories or retrieving existing memories, and thus to identify specific regions that are active during different processes (Chapter 6).

A common method for studying encoding with fMRI is the *subsequent memory paradigm*. In a typical subsequent memory task, a human subject views a series of stimuli (eg, words or pictures) one at a time while being scanned with fMRI, often while engaged in a cover task (eg, determining whether the pictures are in color or black and white). A subject's memory for the stimuli is then tested outside of the scanner, allowing the researchers to sort all the encoding events into those that were later remembered compared to those that were later forgotten. fMRI scans show that remembered items, compared with forgotten items, are associated with greater activity in the hippocampus during encoding. This difference is also evident in simultaneous activity in other parts of the brain, including prefrontal, retrosplenial, and parietal cortices. Often, the activity of these regions covaries on a moment-to-moment basis with the activity in the hippocampus during memory encoding, suggesting that these regions are functionally connected (Figure 52–6).

These fMRI findings, together with findings from patients with amnesia, provide strong support for an

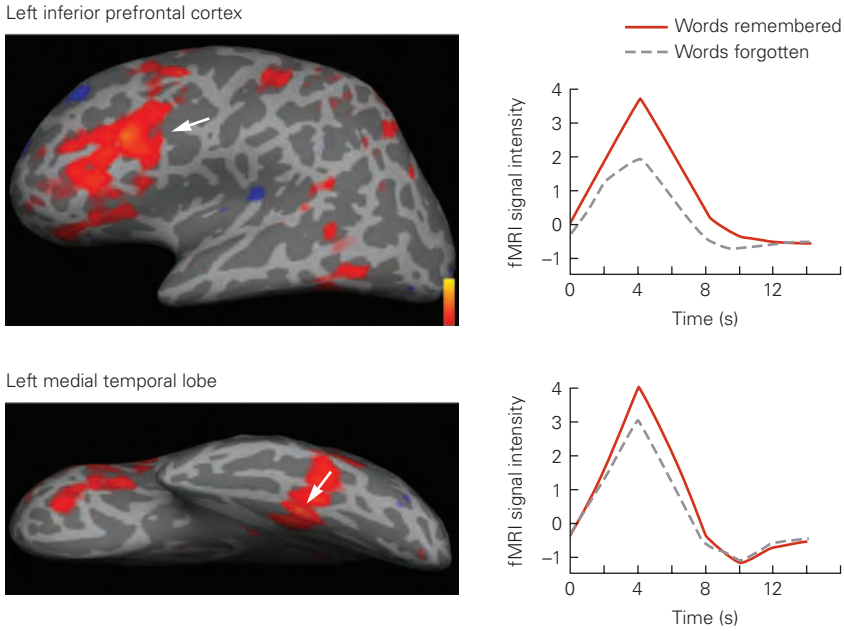

Figure 52–6 In the study illustrated here, neural activity during encoding of visual events (presentation of words) was measured using functional magnetic resonance imaging (fMRI). Subsequently, recall of the studied words was tested, and each word was classified as either remembered or forgotten. The scans taken during encoding were then sorted into two groups: those made during encoding of words that were later remembered and those made during encoding of words that were later forgotten. The activity in regions of the left prefrontal cortex and medial temporal lobe was greater during the encoding of words later remembered than those later forgotten (locations denoted by white arrows). At right are the observed fMRI responses in these regions for words later remembered and those later forgotten. (Adapted, with permission, from Wagner et al. 1998.)

important role of the hippocampus in encoding episodic memories. The fMRI findings also extend the findings from amnesic patients, showing that successful formation of episodic memories depends on interaction between frontoparietal networks and the medial temporal lobe. However, as the medial temporal lobe is a large structure, a key goal is to understand the role of its different subregions. Such information is being provided by higher-resolution fMRI studies that use more powerful brain scanning technologies. These studies reveal that distinct subregions within and outside the hippocampus contribute to different aspects of memory encoding. Thus, whereas some cortical areas surrounding the hippocampus are particularly important for object recognition (perirhinal cortex), others are important for encoding spatial context (parahippocampal cortex). These cortical regions provide strong (but indirect) inputs to the hippocampus proper, which is thought to bind together spatial and object information, forming a unified memory.

Interaction between the medial temporal lobe and widely separated cortical regions is also central in memory consolidation and retrieval. It was initially thought that the hippocampus was not important for retrieval, since patient H.M., whose medial temporal lobe was surgically removed, could still recall childhood memories. In fact, early observations suggested that H.M. could recall many of the experiences of his life up until several years before his operation. These observations of H.M. and other amnesic patients with damage to the medial temporal lobe suggested that old memories must be ultimately stored in various other cortical regions through interaction with the medial temporal lobe. However, even though patients with hippocampal damage like H.M. have some ability to recall older memories, there is evidence that the extent of memory recall may be impaired in these patients. Current thinking suggests that there is a distributed circuit for consolidation and retrieval involving several brain regions, with the hippocampus playing an essential role in the binding of associations during both encoding and retrieval. The cortical regions serve as the long-term repository of the separate elements of information that constitute a memory and in the controlled retrieval and reactivation of the content of the memory itself.

As with studies of encoding, studies of retrieval of episodic knowledge have implicated specific regions of association cortex, frontoparietal networks, and the medial temporal lobe. The retrieval of contextual or event details associated with an episodic memory also involves activity in the hippocampus, with medial temporal lobe retrieval processes facilitating the activation of neocortical representations that were present during encoding.

fMRI scans have a fairly limited time resolution due to the relatively slow time course of changes in blood flow associated with brain activity. To achieve higher temporal resolution of brain activity, researchers can record electrical activity from the human brain using extracellular electrodes. Such recordings are rare and possible only in human patients who are already

undergoing brain surgery for medical reasons, such as severe epilepsy, when electrode implantation is used to localize the site of seizure generation. In one study, intracranial electroencephalography (iEEG) signals were measured using subdural electrodes placed in the medial temporal lobe and other areas of cortex. A subject first learned associations between pairs of words and then had to retrieve memories of those associations. The retrieval of memories was associated with neural activity in the hippocampus, coupled with neural activity in temporal association cortex, a region involved in language and multisensory integration. This coupled neural activity was associated with a reactivation of cortical patterns that were initially observed when participants first memorized word pairs. This finding provides a link between the neural activity observed in the hippocampus during initial encoding of a memory and the later coupled activity in the temporal association cortex during retrieval. Related observations of reactivation of encoding patterns during retrieval have been reported in numerous human functional imaging studies, documenting the ubiquity of such effects. As with encoding of episodic memory, retrieval involves a complex interaction between the medial temporal lobe and distributed cortical regions, including frontoparietal networks and other high-level association areas.

Episodic Memory Contributes to Imagination and Goal-Directed Behavior

Memory enables us to use our past experience to predict future events, thus promoting adaptive behavior. Like retrieval of memories, imagination of future events involves construction of details from memory. The first report of a possible connection between memory and imagination came from the case study of patient K.C., as reported by Endel Tulving in 1985. Patient K.C. displayed typical and devastating amnesia as a result of damage to his hippocampus and medial temporal lobe. Similar to patient H.M., he had a complete lack of episodic memory while language and nonepisodic functions were unimpaired. Tulving's studies revealed further that such brain damage was associated with the loss of the ability to imagine events in the future. When asked what he would be doing the next day, K.C. was unable to provide details.

The importance of the hippocampus in imagining future events is also seen with fMRI studies. Such studies examined brain activity of healthy individuals, comparing activity when subjects were asked to remember an event from the past (eg, think of your birthday last year) with activity when they imagined events in the future (eg, imagine a beach vacation next summer). The subjects were asked to report any vivid details of the event that came to mind. The MRI scans showed a striking overlap in the network of brain regions that were active during memory retrieval and imagination of future events. This network included the hippocampus, prefrontal cortex, posterior cingulate cortex, retrosplenial cortex, and lateral parietal and temporal areas (Figure 52–7).

Further evidence supporting the view that episodic memory and hippocampal function are necessary for planning future behavior comes from a study on human performance of a spatial navigation task using virtual reality simulations. High-resolution fMRI and multivoxel pattern analysis (Chapter 6) showed that activity in the hippocampus was related to simulation of navigation goals. Moreover, hippocampal activity during planning covaried with goal-related activity in prefrontal, medial temporal, and medial parietal cortex (Figure 52–8).

Episodic memory encoding and storage are also influenced by the adaptive value of events. Alison Adcock and colleagues showed that the anticipation of a potential reward can enhance memory by eliciting coordinated activity between the medial temporal lobe and midbrain regions that are rich in dopamine neurons. Reward can also retroactively enhance memories. When human participants navigate a maze for a reward, they have better memory for neutral events that happened right before the reward. The ability to retroactively shape episodic memory based on outcomes is important because the relevance of a specific episode may only become known after the fact. Together with the role of episodic memory in constructing the retrieval of past events and in imagining and simulating future events, the findings on reward support the view that a major function of episodic memory is to guide adaptive behaviors.

The Hippocampus Supports Episodic Memory by Building Relational Associations

In addition to the broad role of the hippocampus in episodic memory, future thinking, and goal-directed behavior, studies of rodents first pointed to a role for the hippocampus in spatial navigation (Chapter 54), findings that were later supported by studies of nonhuman primates and humans. In rodents, single neurons in the hippocampus encode specific spatial information, and lesions of the hippocampus interfere with the animal's memory for spatial location. Functional imaging of the brain in healthy humans shows that activity increases in the right hippocampus when spatial information is recalled and in the left hippocampus when words,

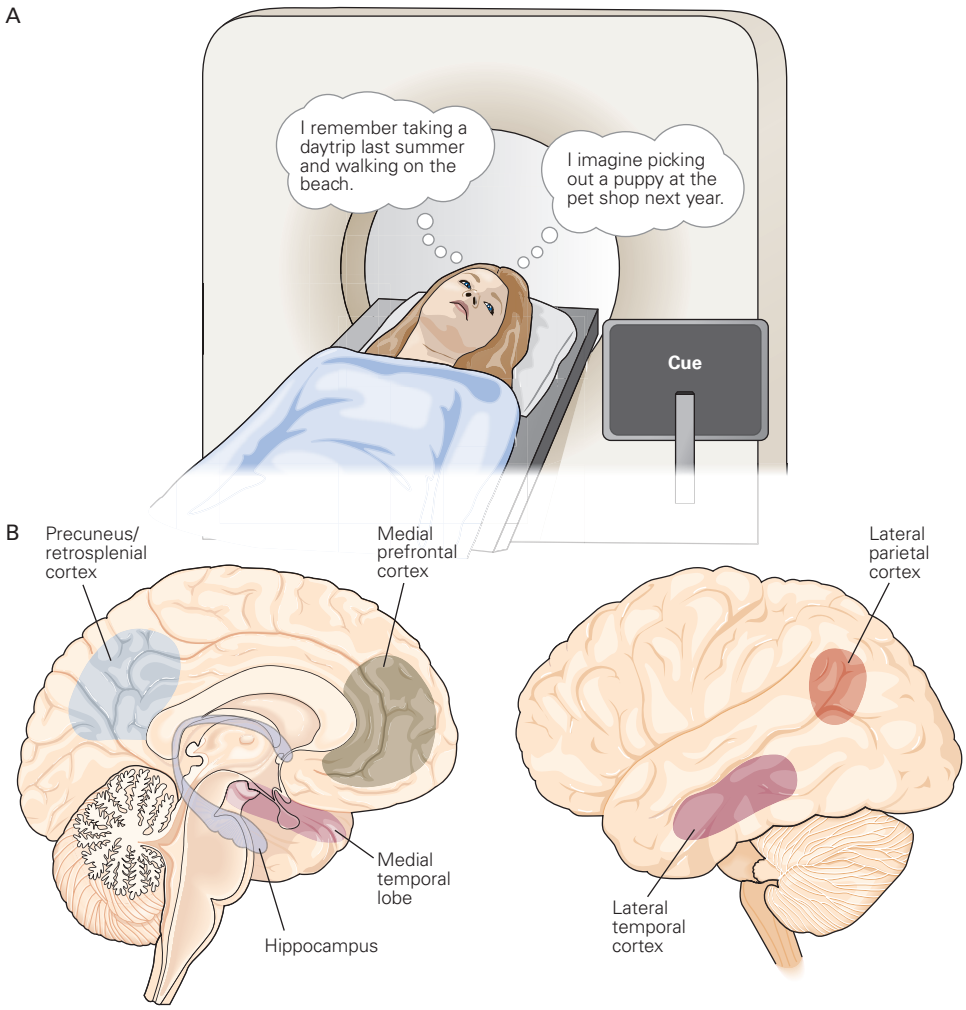

Figure 52–7 Brain regions supporting retrieval of memories for past events and imagination of future events. (Adapted, with permission, from Schacter, Addis, and Buckner 2007.)

A. Subjects were instructed to either remember a personally experienced event in their past or imagine a plausible event in their future while lying inside a functional magnetic resonance imaging scanner. Events are elicited by a cue word (eg, "beach" or "birthday"). Subjective ratings of event phenomenology (eg, vividness and emotionality of the episode) and detailed event descriptions are often obtained in an interview following the scanning in order to confirm that an episodic event was successfully generated.

B. The core brain system that mediates past and future thinking is consistently activated while remembering the past, when envisioning the future, and during related forms of mental simulation. Prominent components of this network include medial prefrontal regions, posterior regions in the medial and lateral parietal cortex (extending into the precuneus and retrosplenial cortex), the lateral temporal cortex, and the medial temporal lobe. Moreover, regions within this core brain system are functionally correlated with each other and with the hippocampus. This core brain system is thought to function adaptively to integrate information about relationships and associations from past experiences to construct mental simulations about possible future events.

objects, or people are recalled. These physiological findings are consistent with the clinical observation that lesions of the right hippocampus differentially give rise to problems with spatial orientation, whereas lesions of the left hippocampus differentially cause deficits in verbal memory.

The fact that the hippocampus supports spatial processing, semantic memory, and episodic memory raises questions about how the hippocampus contributes to such different behaviors. One compelling theory, proposed by Howard Eichenbaum and Neal Cohen, suggests that the hippocampus provides a general mechanism for forming and storing complex multimodal associations. According to this view, the hippocampus binds in memory the separate elements of experiences, encoding events as relational maps of

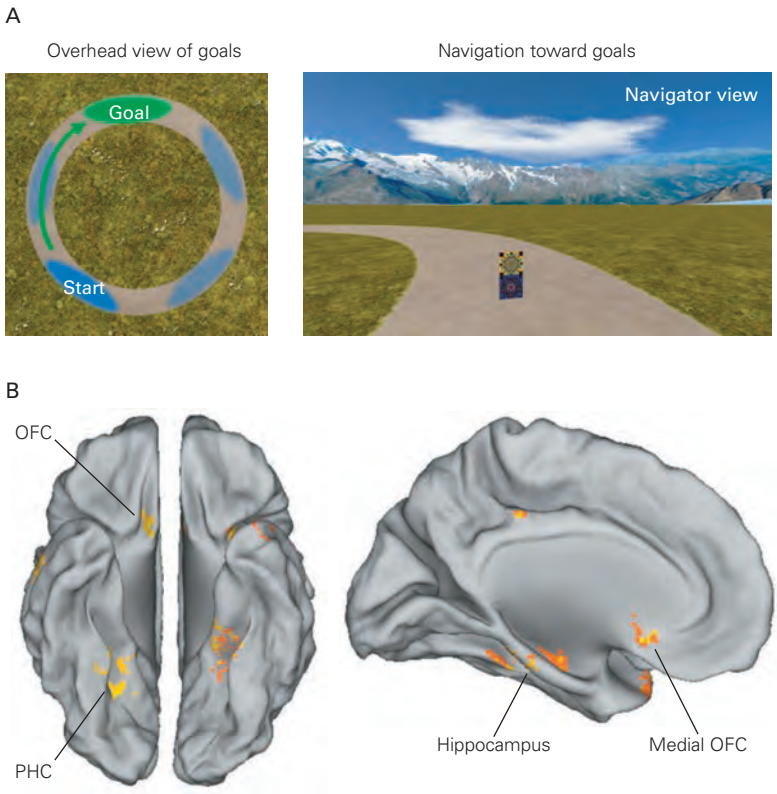

Figure 52–8 **Neural circuits supporting memory-based goal-directed navigation.** (Reproduced, with permission, from Brown et al. 2016.)

A. Human participants navigate to goals in a virtual reality environment while being scanned with functional magnetic resonance imaging. They first explore the space and learn where goals are located and then are tested on their ability to navigate to specific goals.

B. Navigational planning elicits goal-related activity in a core network including the hippocampus, medial temporal lobe, parahippocampal cortex (**PHC**), and orbitofrontal cortex (**OFC**).

items within spatial and temporal contexts, thus composing a "memory space" that can distinguish distinct episodes, or sequences of events, even when the same (or similar) events occur in different episodes (Figure 52–9). As discussed later in this chapter, the view that the hippocampus encodes relations offers insights into the mechanism by which memories are built and explains why, in some cases, the hippocampus may contribute to memory processes that are not consciously accessible but do encode relations.

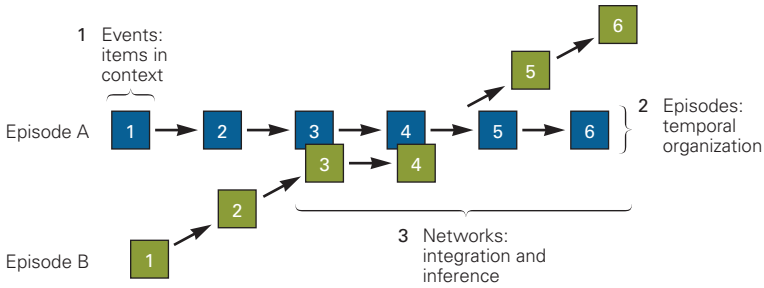

Figure 52–9 **The hippocampus supports relational processing underlying episodic memory.** A conceptual illustration of a memory space designating three key types of relational processing: events, episodes, and networks. The schematic illustrates processing of two distinct episodes (Episode A and Episode B), which have both distinct and overlapping elements. For example, the episodes might be two distinct visits to an Italian restaurant on separate evenings with the same friend. The evenings are experienced as distinct (different days, different weather, different moods), yet they share some overlap (the company of the same friend at the same restaurant). *Events* (**1**) are defined as items (objects, behaviors) that are associated with the context in which they occurred (denoted here as events 1 to 6 in each episode, such as the specific table you sat at, the food you ordered, etc.). *Episodes* (**2**) are defined in this view as the temporal organization of these events. While most of the items in each episode are unique, some of them overlap (here, items 3 and 4; in the example, your friend and the restaurant). Relational *networks* (**3**) are formed via associations between events and episodes by way of the overlapping events, supporting the capacity for links between indirectly related events. Implicit Memory Supports a Range of Behaviors in Humans and Animals

Just as there are many ways in which explicit memory guides behavior, there are also many ways in which nonexplicit forms of memory, those without conscious awareness, can influence behavior. Implicit memory refers to forms of knowledge that guide behavior without conscious awareness. Priming, for example, is the automatic influence of exposure to one cue on processing of a later cue.

Priming can be classified as conceptual or perceptual. *Conceptual priming* provides enhanced access to task-relevant semantic knowledge because that knowledge has been used before. It is correlated with decreased activity in left prefrontal regions that subserve initial retrieval of semantic knowledge. In contrast, *perceptual priming* occurs within a specific sensory modality and depends on cortical modules that operate on sensory information about the form and structure of words and objects.

Damage to unimodal sensory regions of cortex impairs modality-specific perceptual priming. For example, one patient with an extensive surgical lesion of the right occipital lobe failed to demonstrate visual priming for words but had normal explicit memory (Figure 52–10). This condition is the reverse of that found in amnesic patients such as H.M., suggesting that the neural mechanisms of priming are distinct from those for explicit memory. The fact that perceptual priming can be intact in patients with amnesia due to medial temporal damage further suggests that it is distinct from explicit memory.

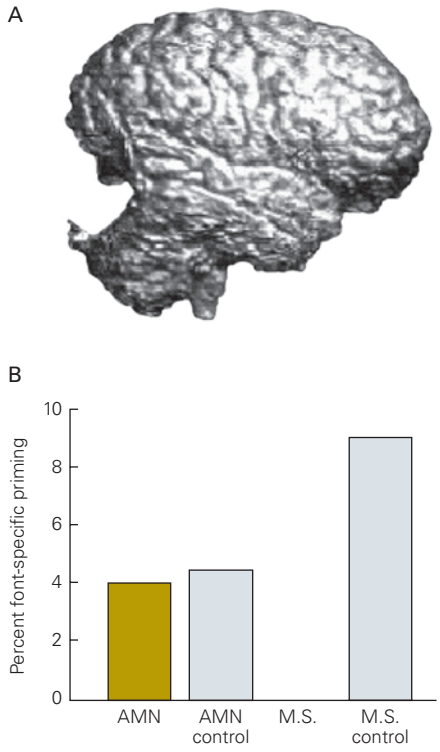

Figure 52–10 The right occipital cortex is required for visual priming for words. (Adapted from Vaidya et al. 1998.)

A. Structural magnetic resonance imaging depicts the near-complete removal of the right occipital cortex in a patient, M.S., who suffered pharmacologically intractable epilepsy with a right occipital cortical focus.

B. Font-specific priming is a form of visual priming in which the individual is better able to identify a briefly flashed word when the type font is identical to an earlier presentation, compared to identification when the font is different. Priming is measured as performance when the font is the same minus performance when the font is different. Font-specific priming is intact in amnesic patients (**AMN**) and their controls as well as in the controls for patient M.S., but not in M.S. himself. The patient M.S. has normal explicit memory, even for visual cues (data not shown), but lacks implicit memory for specific properties of visually presented words.

Different Forms of Implicit Memory Involve Different Neural Circuits

Other forms of implicit memory subserve the learning of habits and motor, perceptual, and cognitive skills and the formation and expression of conditioned responses. In general, these forms of implicit memory are characterized by incremental learning, which proceeds gradually with repetition and, in some cases, is driven by reinforcement.

The learning of habits, motor skills, and conditioned responses can take place independently of the medial temporal lobe system. For example, H.M. was able to acquire new visuomotor skills, like the mirror-tracing task (see Figure 52–3). Therefore, early theories posited that these forms of memory generally do not depend on the medial temporal lobe but, rather, depend on the basal ganglia and cerebellum (see Chapters 37 and 38). However, subsequent work suggested that this is not a general rule and that the medial temporal lobe is required for forms of implicit learning that store relational associations, even when such associations are learned through repetition and appear to take place without conscious awareness.

It is now thought that several kinds of incremental implicit learning involve the medial temporal lobes. For example, Turk-Browne and colleagues investigated implicit learning of regularities between visual cues, called statistical learning. In a typical statistical learning task, human subjects are presented with a

stream of sounds or images that follow a structured sequence or "grammar" of repetitions. Learning of the sequence is typically measured by a faster reaction time to repeated compared to nonrepeated sequences. At first glance, it would appear that statistical learning should not involve the medial temporal lobe: The learning is nonverbal, it does not require conscious thought and is therefore implicit, and it is assumed to reflect the accumulated computation of probabilistic relationships across multiple episodes, rather than the specific memory of one episode. Yet fMRI studies show that the hippocampus is active during statistical learning, and damage to the medial temporal lobe has been found to impair performance on this implicit task.

Statistical learning is an example of how learning takes place through repetition. New perceptual, motor, or cognitive abilities are also learned through repetition. With practice, performance becomes more accurate and faster, and these improvements generalize to learning novel information. Skill learning moves from a cognitive stage, where knowledge is represented explicitly and the learner must pay a great deal of attention to performance, to an autonomous stage, where the skill can be executed without much conscious attention. As an example, driving a car initially requires that one be consciously aware of each component of the skill, but after practice, one no longer attends to the individual components.

The learning of sensorimotor skills depends on numerous brain regions that vary with the specific associations being learned. As we learned in Chapter 38, these include the basal ganglia, cerebellum, and neocortex. Dysfunction of the basal ganglia in patients with Parkinson and Huntington disease impairs learning of motor skills. Patients with cerebellar lesions also have difficulties acquiring some motor skills. Functional imaging of healthy individuals during sensorimotor learning shows changes in the activity of the basal ganglia and cerebellum and their connectivity with cortical regions. Danielle Bassett and colleagues have used network-analysis algorithms applied to whole-brain fMRI data to characterize dynamic changes in network functional connectivity that take place during motor skill learning. Finally, skilled behavior can depend on structural changes in motor neocortex, as seen by the expansion of the cortical representation of the fingers in musicians (Chapter 53).

Habits emerge from the repeated association of cues or actions with rewarding outcomes. Habit learning in humans is studied with tasks that involve incremental learning of stimulus–reward associations. In a typical task, subjects perform a series of trials in which they are asked to choose among visual cues and receive trial-by-trial feedback on their choice. The relationship between the cues and the feedback varies probabilistically over the course of the task so that participants must keep updating their responses based on the feedback. Because learning takes place over numerous trials, explicit memory of any one specific trial may not be as useful for successful performance as the gradual accumulation of feedback-driven learning of stimulus–outcome associations.

fMRI studies demonstrate that incremental learning of stimulus–reward associations depends on the striatum, the area of the basal ganglia that receives input from neocortex, and its modulatory dopaminergic inputs. Patients with a loss of striatal dopamine, as occurs in Parkinson disease, are less effective at learning based on trial-by-trial reinforcement. These findings are consistent with other studies that indicate dopamine has an important role in modulating cortico-striatal circuitry for reinforcement learning (see Chapter 38).

At first glance, stimulus-reward learning appears to be precisely the sort of learning that does not depend on the medial temporal lobe: It is implicit rather than explicit, and it occurs gradually rather than through an explicit memory for a single event. Indeed, early theories posited that learning probabilistic stimulus–reward associations does not depend on the medial temporal lobe. However, subsequent work has revealed that the hippocampus does contribute to stimulus–reward learning under some circumstances, such as when the task demands learning of more complex stimulus–stimulus associations (Figure 52–11). The contribution of the hippocampus to implicit learning takes place via interactions with other cortical and subcortical circuits. fMRI studies show functional connectivity between the hippocampus and the striatum in support of learning across a variety of tasks. Interactions between the hippocampus and the striatum are sometimes competitive and sometimes cooperative, depending on the demands of the task.

Implicit Memory Can Be Associative or Nonassociative

Some forms of implicit memory have also been studied in nonhuman animals, and these animal studies have distinguished two types of implicit memory: nonassociative and associative. With nonassociative learning, an animal learns about the properties of a single stimulus. With associative learning, the animal learns about the relationship between two stimuli or between a stimulus and a behavior. We consider the cellular mechanisms of implicit memory in animals in the next chapter.

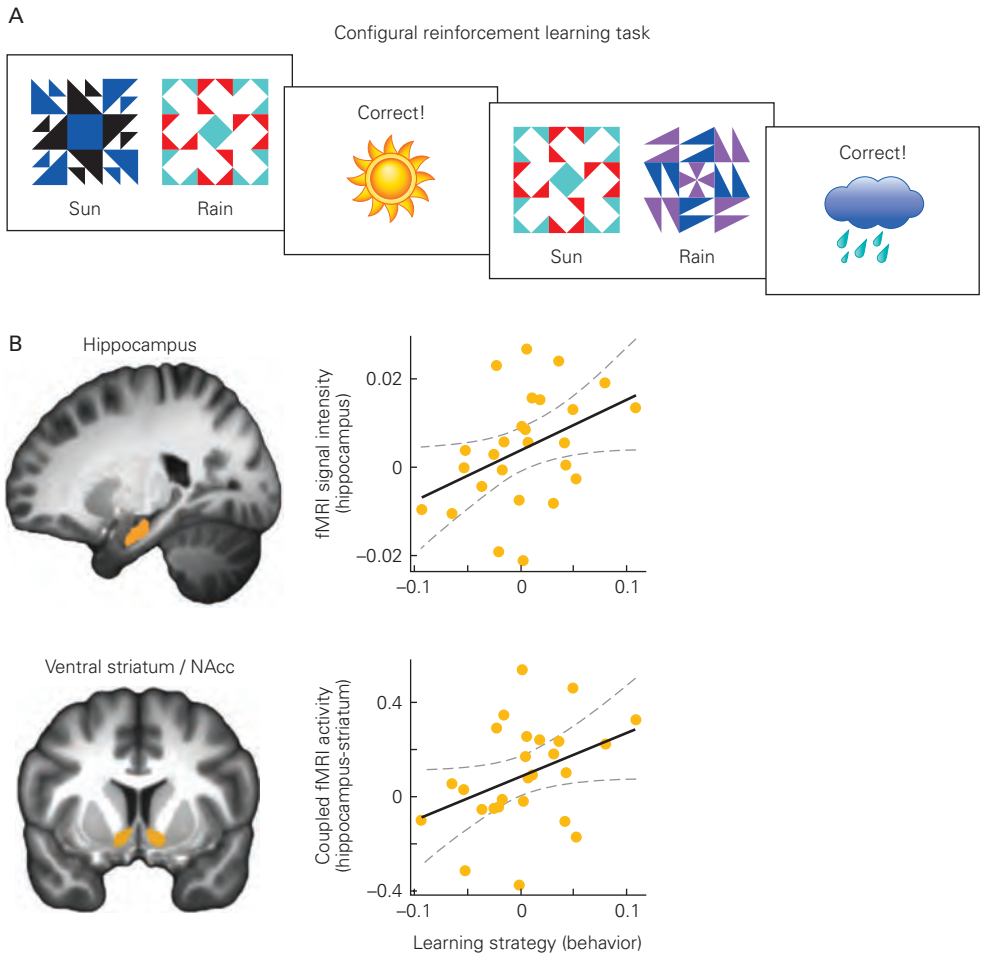

Figure 52–11 Learning stimulus–response associations involves both the striatum and the hippocampus. (Adapted, with permission, from Duncan et al. 2018.)

A. Participants use trial-by-trial reinforcement to learn to predict outcomes (rain or sun) based on cues (colorful shapes). The cues have a probabilistic relation to each weather outcome that the viewer learns by trial and error. The weather can be predicted based either on each individual cue or on the combined presentation of the two cues (their configuration). Reinforcement learning models can discern which strategy each subject uses.

B. The striatum is known to play a critical role in learning to update choices based on reinforcement. When subjects learn about the configuration, this same task also elicits activity in the hippocampus and increased coupling of activity in the hippocampus and the striatum. Scatter plots show that the extent to which subjects use a configural learning strategy correlates with blood oxygenation level–dependent activity in the hippocampus and with functional coupling between the hippocampus and the striatum. The images show activity in hippocampus and the nucleus accumbens (**NAcc**), a region in the ventral portion of the striatum that responds to rewarding stimuli. (Abbreviation: **fMRI**, functional magnetic resonance imaging.)

Nonassociative learning results when a subject is exposed once or repeatedly to a single type of stimulus. Two forms of nonassociative learning are common in everyday life: habituation and sensitization. Habituation is a decrease in a response that occurs when a benign stimulus is presented repeatedly. For example, most people in the United States are startled when they first hear the sound of a firecracker on Independence Day, but as the day progresses, they become accustomed to the noise and do not respond. Sensitization (or pseudo-conditioning) is an enhanced response to a wide variety of stimuli after the presentation of an intense or noxious stimulus. For example, an animal will respond more vigorously to a mild tactile stimulus after receiving a painful pinch. Moreover, a sensitizing stimulus can override the effects of habituation, a process called dishabituation. For example, after the startle response to a noise has been reduced by habituation,

one can restore the intensity of response to the noise by delivering a strong pinch.

With sensitization and dishabituation, the timing of stimuli is not important because no association between stimuli must be learned. In contrast, with two forms of associative learning, the timing of the stimuli to be associated is critical. Classical conditioning involves learning a relationship between two stimuli, whereas operant conditioning involves learning a relationship between the organism's behavior and the consequences of that behavior.

Classical conditioning was first described in the early 1900s by the Russian physiologist Ivan Pavlov. The essence of classical conditioning is the pairing of two stimuli: a conditioned stimulus and an unconditioned stimulus. The conditioned stimulus (CS), such as a light, a tone, or a touch, is chosen because it produces either no overt response or a weak response usually unrelated to the response that eventually will be learned. The unconditioned stimulus (US), such as food or a shock, is chosen because it normally produces a strong and consistent response (the unconditioned response), such as salivation or withdrawal of a limb. Unconditioned responses are innate; they are produced without learning. Repeated presentation of a CS followed by a US gradually elicits a new or different response called the conditioned response.

One way of explaining conditioning is that repeated pairing of the CS and US causes the CS to become an anticipatory signal for the US. With sufficient experience, an animal will respond to the CS as if it were anticipating the US. For example, if a light is followed repeatedly by the presentation of meat, eventually the sight of the light itself will make the animal salivate. Thus, classical conditioning is one way an animal learns to predict events.

The probability that an established conditioned response will occur decreases if the CS is repeatedly presented without the US. This process is known as extinction. If a light that has been paired with food is later repeatedly presented in the absence of food, it will gradually cease to evoke salivation. Extinction is an important adaptive mechanism; it would be maladaptive for an animal to continue to respond to cues that are no longer meaningful. The available evidence indicates that extinction is not the same as forgetting; instead, something new is learned—the CS now signals that the US will not occur.

For many years, psychologists thought that classical conditioning resulted as long as the CS preceded the US within a critical time interval. According to this view, each time a CS is followed by a US (reinforcing stimulus), a connection is strengthened between the internal representations of the stimulus and response or between the representations of one stimulus and another. The strength of the connection was thought to depend on the number of pairings of CS and US. A substantial body of evidence now indicates that classical conditioning cannot be adequately explained simply by the fact that two events or stimuli occur one after the other (Figure 52–12). Indeed, it would not be adaptive to depend solely on sequence. Rather, all animals capable of associative conditioning, from snails to humans, remember the salient relationship between associated events. Thus, classical conditioning, and perhaps all forms of associative learning, enables animals to distinguish events that reliably occur together from those that are only randomly associated.

Lesions in several regions of the brain affect classical conditioning. One well-studied example is conditioning of the protective eyeblink reflex, a form of motor learning. A puff of air to the eye naturally causes an eyeblink. A conditioned eyeblink can be established by pairing the puff with a tone that precedes the puff. Studies in rabbits indicate that the conditioned response (an eyeblink in response to a tone) is abolished by a lesion at either of two sites. Damage to the vermis of the cerebellum abolishes the conditioned response but does not affect the unconditioned response (eyeblink in response to a puff of air). Interestingly, neurons in the same area of the cerebellum show learning-dependent increases in activity that closely parallel the development of the conditioned behavior. A lesion in the interpositus nucleus, a deep cerebellar nucleus, also abolishes the conditioned eyeblink. Thus, both the vermis and the deep nuclei of the cerebellum play an important role in conditioning the eyeblink, and perhaps other simple forms of classical conditioning involving skeletal muscle movement.

Another well-studied example is fear conditioning, which depends on the amygdala. In fear conditioning, a neutral cue, such as a tone, is paired with an aversive outcome, such as a shock. This pairing leads to a conditioned fear response in which the neutral tone alone elicits a behavioral reaction, such as freezing. Fear conditioning depends on plasticity in the inputs to and connections between the subnuclei of the amygdala, particularly the basolateral amygdala, as we will discuss in the next chapter.

Operant Conditioning Involves Associating a Specific Behavior With a Reinforcing Event

A second major paradigm of associative learning, discovered by Edgar Thorndike and systematically studied by B. F. Skinner and others, is operant conditioning

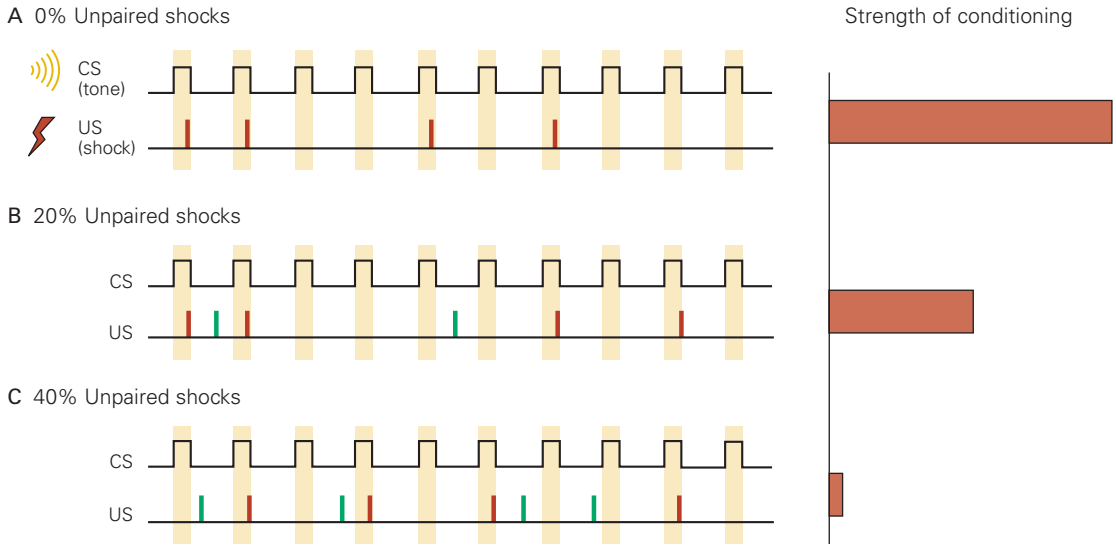

Figure 52–12 Classical conditioning depends on the degree of correlation of two stimuli. In this experiment with rats, a tone (the conditioned stimulus [**CS**]) was paired with an electric shock (the unconditioned stimulus [**US**]) in four out of 10 of the trials (**red ticks**). In some trial blocks, the shock was presented without the tone (**green ticks**). Suppression of lever-pressing to obtain food is a sign of freezing, a conditioned defensive response. The degree of conditioning was evaluated by determining how effective the tone alone was in suppressing lever-pressing to obtain food. (Adapted from Rescorla 1968.)

A. Maximal conditioning occurred when the US was presented only with the CS.

B–C. Little or no conditioning occurred when the shock was presented without the tone almost as often as with it (40%). Some conditioning occurred when the shock occurred without the tone 20% of the time.

(also called trial-and-error learning). In a typical laboratory example of operant conditioning, a hungry rat or pigeon is placed in a test chamber in which the animal is rewarded for a specific action. For example, the chamber may have a lever protruding from one wall. Because of previous learning, or through play and random activity, the animal will occasionally press the lever. If the animal promptly receives a positive reinforcer (eg, food) after pressing the lever, it will begin to press the lever more often than the spontaneous rate. The animal can be described as having learned that among its many behaviors (eg, grooming, rearing, and walking) one behavior is followed by food. With this information, the animal is likely to press the lever whenever it is hungry.

If we think of classical conditioning as the formation of a predictive relationship between two stimuli (the CS and the US), operant conditioning can be considered as the formation of a predictive relationship between an action and an outcome. Unlike classical conditioning, which tests the responsiveness of a reflex to a stimulus, operant conditioning tests behavior that occurs either spontaneously or without an identifiable stimulus. Thus, operant behaviors are said to be emitted rather than elicited. In general, actions that are rewarded tend to be repeated, whereas actions followed by aversive, although not necessarily painful, consequences tend not to be repeated. Many experimental psychologists think that this simple idea, called the law of effect, governs much voluntary behavior.

Operant and classical conditioning involve different kinds of association—an association between an action and a reward or between two stimuli, respectively. However, the laws of operant and classical conditioning are quite similar. For example, timing is critical in both. In operant conditioning, the reinforcer usually must closely follow the operant action. If the reinforcer is delayed too long, only weak conditioning occurs. Similarly, classical conditioning is generally poor if the interval between the CS and US is too long or if the US precedes the CS.

Associative Learning Is Constrained by the Biology of the Organism

Animals generally learn to associate stimuli that are relevant to their survival. For example, animals readily learn to avoid certain foods that have been followed by a negative reinforcement (eg, nausea produced by a poison), a phenomenon termed *taste aversion*.

Unlike most other forms of conditioning, taste aversion develops even when the unconditioned response (poison-induced nausea) occurs after a long delay, up to hours after the CS (specific taste). This makes biological sense because the ill effects of infected foods and naturally occurring toxins usually follow ingestion only after some delay. For most species, including humans, taste-aversion conditioning occurs only when certain tastes are associated with illness. Taste aversion develops poorly if a taste is followed by a painful stimulus that does not produce nausea. Also, animals do not develop an aversion to a visual or auditory stimulus that has been paired with nausea.

Errors and Imperfections in Memory Shed Light on Normal Memory Processes

Memory allows us to revisit our personal past; provides access to a vast network of facts, associations, and concepts; and supports learning and adaptive behavior. But memory is not perfect. We often forget events rapidly or gradually, sometimes distort the past, and occasionally remember events that we would prefer to forget. In the 1930s, the British psychologist Frederic Bartlett reported experiments in which people read and tried to remember complex stories. He showed that people often misremember many features of the stories, often distorting information based on their expectations of what should have happened. Forgetting and distortion can provide important insights into the workings of memory.

Memory's imperfections have been classified into seven basic categories, dubbed the "seven sins of memory": transience, absent-mindedness, blocking, misattribution, suggestibility, bias, and persistence. Here, we focus on six of these.

Absent-mindedness results from a lack of attention to immediate experience. Absent-mindedness during encoding is a likely source of common memory failures such as forgetting where one recently placed an object. Absent-mindedness also occurs when we forget to carry out a particular task such as picking up groceries on the way home from the office, even though we initially encoded the relevant information.

Blocking refers to a temporary inability to access information stored in memory. People often have partial awareness of a sought-after word or image but are nonetheless unable to recall the entire word accurately or completely. Sometimes, it feels like a blocked word is on "the tip of the tongue"—we are aware of the initial letter of the word, the number of syllables in it, or a like-sounding word. Determining which information is correct and which is incorrect requires a great deal of conscious effort.

Absent-mindedness and blocking are sins of omission: At a moment when we need to remember information, it is inaccessible. However, memory is also characterized by sins of commission, situations in which some form of memory is present but wrong.

Misattribution refers to the association of a memory with an incorrect time, place, or person. False recognition, a type of misattribution, occurs when individuals report that they "remember" items or events that never happened. Such false memories have been documented in controlled experiments where people claim to have seen or heard words or objects that had not been presented previously but are similar in meaning or appearance to what was actually presented. Studies using positron emission tomography imaging and fMRI have shown that many brain regions show similar levels of activity during both true and false recognition, which may be one reason why false memories sometimes feel like real ones.

Suggestibility refers to the tendency to incorporate new information into memory, usually as a result of leading questions or suggestions about what may have been experienced. Research using hypnotic suggestion indicates that various kinds of false memories can be implanted in highly suggestible individuals, such as remembering hearing loud noises at night. Studies with young adults have also shown that repeated suggestions about a childhood experience can produce memories of events that never occurred. These findings are important theoretically because they highlight that memory is not simply a "playback" of past experiences (Box 52–1). Despite these important theoretical and practical implications, next to nothing is known about the neural bases of suggestibility.

Bias refers to distortions and unconscious influences on memory that reflect one's general knowledge and beliefs. People often misremember the past to make it consistent with what they presently believe, know, or feel. This idea is consistent with the idea of "predictive coding" supported by studies showing that even low-level neural mechanisms of perception and sensation are shaped by expectations. The specific brain mechanisms by which expectations influence memory are not well understood.

Persistence refers to obsessive memory, constant remembering of information or events that we might want to forget. Neuroimaging studies have illuminated some neurobiological factors that contribute to persistent emotional memories. Some key results implicate the amygdala, the almond-shaped structure near the hippocampus long known to be involved in emotional

processing (Chapter 42). Studies indicate that the level of recall of emotional components of a story is correlated with the level of activity in the amygdala during presentation of the story. Related studies implicate the amygdala in the encoding and retrieval of emotionally charged experiences that can repeatedly intrude into consciousness.

Although persistence can be disabling, it also has adaptive value. The persistence of memories of disturbing experiences increases the likelihood that we will recall information about arousing or traumatic events at times when it may be crucial for survival.

Indeed, many memory imperfections may have adaptive value. False memories and suggestibility may both be related to one of the most basic adaptive functions of memory: the integration of experiences separated in time into a network of learned associations. For memory to play an important role in guiding future behavior, it must be flexible so that we can leverage past experiences to make inferences about future events even when the circumstances have changed. Similarly, although the various forms of forgetting (transience, absent-mindedness, and blocking) can be annoying, a memory system that automatically retains every detail of every experience could result in an overwhelming clutter of useless trivia. This is exactly what happened in the fascinating case of Shereshevski, a mnemonist studied by the Russian neuropsychologist Alexander Luria and described in the book *The Mind of a Mnemonist*. Shereshevski was filled with highly detailed memories of his past experiences but was unable to generalize or to think at an abstract level. A healthy memory system does not encode, store, and retrieve all the details of every experience. Thus, transience, absent-mindedness, and blocking allow us to avoid the unfortunate fate of Shereshevski.

Highlights

1. Different forms of learning and memory can be distinguished behaviorally and neurally. Working memory maintains goal-relevant information for short periods. Explicit (or declarative) memory involves two classes of knowledge: episodic memory, which represents personal experiences, and semantic memory, which represents general knowledge and facts. Implicit memory includes forms of perceptual and conceptual priming, as well as the learning of motor and perceptual skills, perceptual regularities, and reinforced habits.
2. Encoding, storage, retrieval, and consolidation of new explicit memories depend on interactions between specific regions within the neocortex and medial temporal lobe and specific hippocampal subregions. The initiation of long-term storage of explicit memory requires the temporal lobe system, as highlighted by studies of amnesic patients such as H.M. Consolidation processes stabilize stored representations, rendering explicit memories less dependent on the medial temporal lobe. Retrieval of explicit memories involves the medial temporal lobe, as well as frontoparietal networks that subserve attention and cognitive control.
3. Multiple processes interact to support memory-guided behavior. Retrieval of episodic memory guides the imagining of future events, which is important for making decisions about future choices and actions. Motivationally significant events are prioritized in memory through the enhancement of encoding, storage, and consolidation processes. Motivation also impacts retrieval, perhaps through different mechanisms of prioritization.
4. Implicit memory emerges automatically in the course of perceiving, thinking, and acting. It tends to be inflexible and expressed in the performance of tasks even without conscious awareness. Implicit memory involves a wide variety of brain regions and circuits, including cortical areas that support the specific perceptual, conceptual, or motor systems recruited to process a stimulus or perform a task, as well as the striatum and the amygdala. Implicit learning that involves the encoding of relational associations additionally involves the hippocampus.
5. Imperfections and errors in remembering provide telltale clues about learning and memory mechanisms. The past can be forgotten or distorted, indicating that memory is not a faithful record of all details of every experience. Retrieved memories are the result of a complex interplay among various brain regions and can be reshaped over time by multiple influences. Various forms of forgetting and distortion tell us much about the flexibility of memory that allows the brain to adapt to the physical and social environment.

Cellular Mechanisms of Implicit Memory Storage and the Biological Basis of Individuality

Throughout this book we have emphasized that all behavior is a function of the brain and that malfunctions of the brain produce characteristic disturbances of behavior. Behavior is also shaped by experience. How does experience act on the neural circuits of the brain to change behavior? How is new information acquired by the brain, and once acquired, how is it stored, retrieved, and remembered?

In the previous chapter, we saw that memory is not a single process but has at least two major forms. Implicit memory operates unconsciously and automatically, as in the memory for conditioned responses, habits, and perceptual and motor skills, whereas explicit memory operates consciously, as in the memory for people, places, and objects. The circuitry for long-term memory storage differs between explicit and implicit memory. Long-term storage of explicit memory begins in the hippocampus and the medial temporal lobe of the neocortex, whereas long-term storage of different types of implicit memory requires a family of neural structures: the neocortex for priming, the striatum for skills and habits, the amygdala for Pavlovian threat conditioning (also known as fear conditioning), the cerebellum for learned motor skills, and certain reflex pathways for nonassociative learning such as habituation and sensitization (Figure 53–1).

Over time, explicit memories are transferred to different regions of the neocortex. In addition, many cognitive, motor, and perceptual skills that we initially store as explicit memory ultimately become so ingrained with practice that they become stored as implicit memory. The transference from explicit to implicit memory and the difference between them is dramatically demonstrated in the case of the English musician and conductor Clive Waring, who in 1985 sustained a viral infection of his brain (herpes encephalitis) that affected

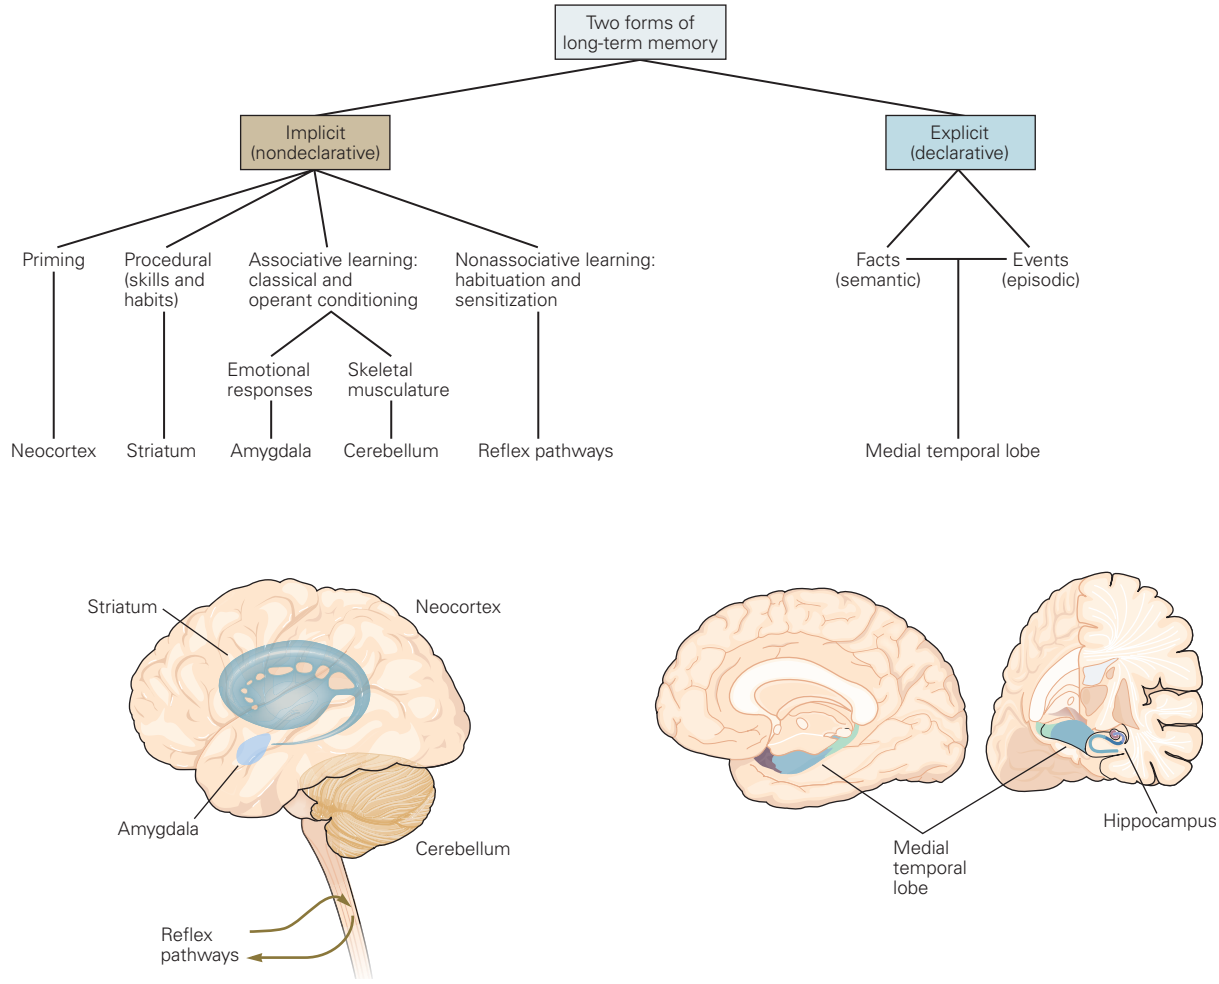

Figure 53–1 Two forms of long-term memory involve different brain systems. Implicit memory involves the neocortex, striatum, amygdala, cerebellum, and, in the simplest cases, the reflex pathways themselves. Explicit memory requires the medial temporal lobe and the hippocampus, as well as certain areas of neocortex (not shown).

the hippocampus and temporal cortex. Waring was left with a devastating loss of memory for events or people he had encountered even a minute or two earlier, but his ability to read music, play the piano, or conduct a chorale was unaffected. Once a performance was completed, however, he could not remember a thing about it.

Similarly, the abstract expressionist painter William de Kooning developed severe disturbances of explicit memory as a result of Alzheimer disease. As the disease progressed and his memory for people, places, and objects deteriorated, he nevertheless continued to produce important and interesting paintings. This aspect of his creative personality was relatively untouched.

In this chapter, we examine the cellular and molecular mechanisms that underlie implicit memory storage in invertebrate and vertebrate animals. We focus on learning about threats (sometimes called fear learning). Implicit memory for motor skills and habits in mammals involving the cerebellum and basal ganglia was considered in Chapters 37 and 38. In the next chapter, we examine the biology of explicit memory in mammals.

Storage of Implicit Memory Involves Changes in the Effectiveness of Synaptic Transmission

Studies of elementary forms of implicit learning—habituation, sensitization, and classical conditioning—provided the conceptual framework for investigating the neural mechanisms of memory storage. Such learning has been analyzed in simple invertebrates and in a variety of vertebrate behaviors, such as the flexion and

eye blink reflexes, and also defensive behaviors such as freezing. These simple forms of implicit memory involve changes in the effectiveness of the synaptic pathways that mediate the behavior.

Habituation Results From Presynaptic Depression of Synaptic Transmission

Habituation is the simplest form of implicit learning. It occurs, for example, when an animal learns to ignore a novel stimulus. An animal reacts to a new stimulus with a series of orienting responses. If the stimulus is neither beneficial nor harmful, the animal learns to ignore it after repeated exposure.

The physiological basis of this behavior was first investigated by Charles Sherrington while studying posture and locomotion in cats. Sherrington observed a decrease in the intensity of certain reflexes in response to repeated electrical stimulation of the motor pathways. He suggested that this decrease, which he called *habituation*, is caused by diminished synaptic effectiveness in the stimulated pathways.

Habituation was later investigated at the cellular level by Alden Spencer and Richard Thompson. They found close cellular and behavioral parallels between habituation of a spinal flexion reflex in cats (the withdrawal of a limb from a noxious stimulus) and habituation of more complex human behaviors. They showed that during habituation the strength of the input from local excitatory interneurons onto motor neurons in the spinal cord decreased, whereas the input to the same interneurons from sensory neurons innervating the skin was unchanged.

Because the organization of interneurons in the vertebrate spinal cord is quite complex, it was difficult to analyze further the cellular mechanisms of habituation in the flexion reflex. Progress required a simpler system. The marine mollusk *Aplysia californica*, which has a simple nervous system of about 20,000 central neurons, proved to be an excellent system for studying implicit forms of memory.

Aplysia has a repertory of defensive reflexes for withdrawing its respiratory gill and siphon, a small fleshy spout above the gill used to expel seawater and waste (Figure 53–2A). These reflexes are similar to the withdrawal reflex of the leg studied by Spencer and Thompson. Mild touching of the siphon elicits reflex withdrawal of both the siphon and gill. With repeated stimulation, these reflexes habituate. As we shall see, these responses can also be dishabituated, sensitized, and classically conditioned.

The neural circuit mediating the gill-withdrawal reflex in *Aplysia* has been studied in detail. Touching the siphon excites a population of mechanoreceptor sensory neurons that innervate the siphon. The release of glutamate from sensory neuron terminals generates fast excitatory postsynaptic potentials (EPSPs) in interneurons and motor cells. The EPSPs from the sensory cells and interneurons summate on motor cells both temporally and spatially, causing them to discharge strongly, thereby producing vigorous withdrawal of the gill. If the siphon is repeatedly touched, however, the monosynaptic EPSPs produced by sensory neurons in both interneurons and motor cells decrease progressively, paralleling the habituation of gill withdrawal. In addition, repeated stimulation also leads to a decrease in the strength of synaptic transmission from the excitatory interneurons to the motor neurons; the net result is that the reflex response diminishes (Figure 53–2B,C).

What reduces the effectiveness of synaptic transmission between the sensory neurons and their postsynaptic cells during repeated stimulation? Quantal analysis (Chapter 15) revealed that the amount of synaptic glutamate released from presynaptic terminals of sensory neurons decreases. That is, fewer synaptic vesicles are released with each action potential in the sensory neuron; the sensitivity of the postsynaptic glutamate receptors does not change. Because the reduction in transmission occurs in the activated pathway itself and does not require another modulatory cell, the reduction is referred to as *homosynaptic depression*. This depression lasts many minutes.

An enduring change in the functional strength of synaptic connections thus constitutes the cellular mechanism mediating short-term habituation. As change of this type occurs at several sites in the gill-withdrawal reflex circuit, *memory is distributed and stored throughout the circuit*. Depression of synaptic transmission by sensory neurons, interneurons, or both is a common mechanism underlying habituation of escape responses of crayfish and cockroaches as well as startle reflexes in vertebrates.

How long can the effectiveness of a synapse change last? In *Aplysia*, a single session of 10 stimuli leads to short-term habituation of the withdrawal reflex lasting minutes. Four sessions separated by periods ranging from several hours to 1 day produce long-term habituation, lasting as long as 3 weeks (Figure 53–3).

Anatomical studies indicate that long-term habituation is caused by a decrease in the number of synaptic contacts between sensory and motor neurons. In naïve animals, 90% of the sensory neurons make physiologically detectable connections with identified motor neurons. In contrast, in animals trained for

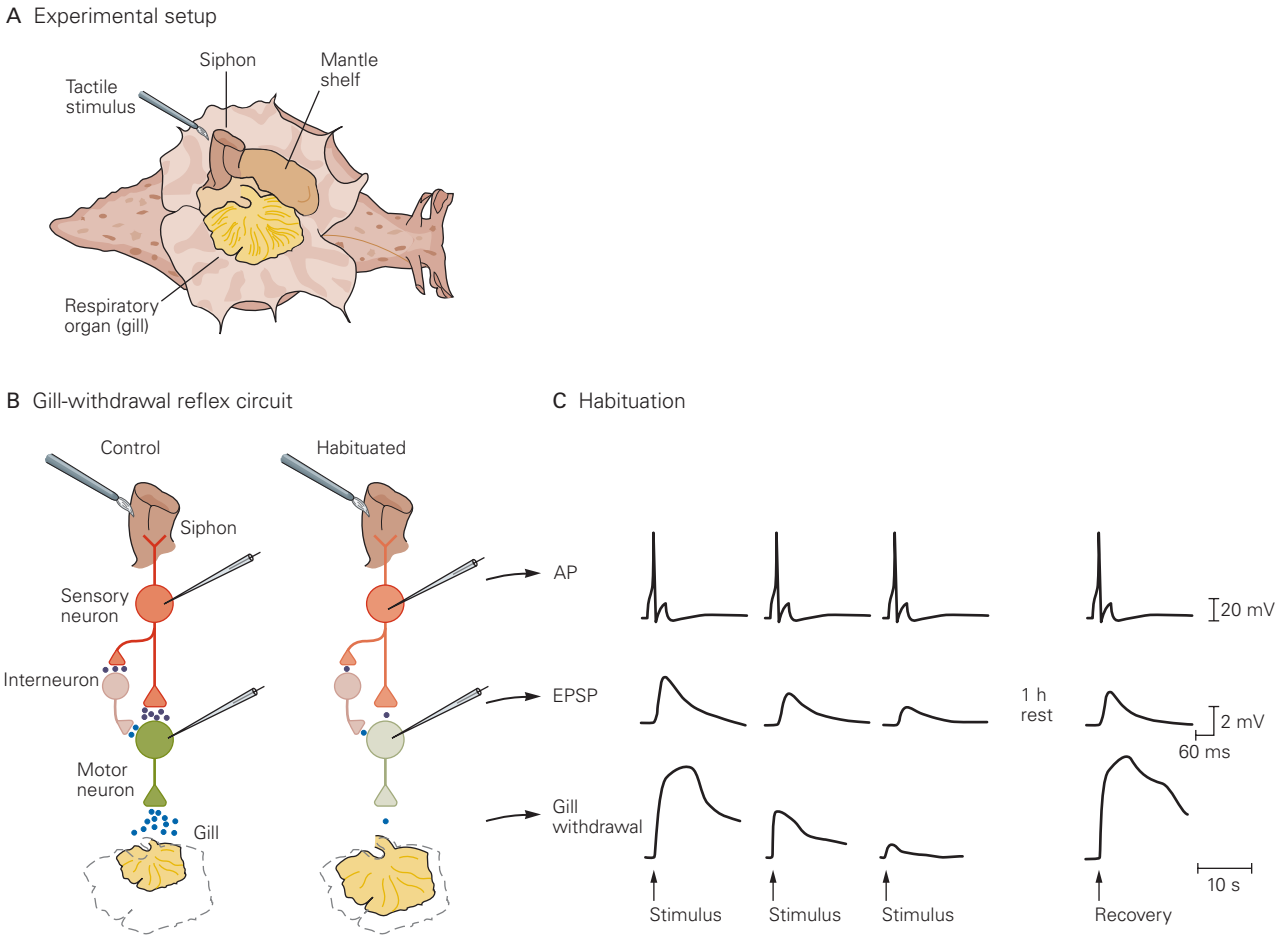

Figure 53–2 Short-term habituation of the gill-withdrawal reflex of the marine snail *Aplysia*.

A. A dorsal view of *Aplysia* illustrates the respiratory organ (gill) and the mantle shelf, which ends in the siphon, a fleshy spout used to expel seawater and waste. Touching the siphon elicits the gill-withdrawal reflex. Repeated stimulation leads to habituation.

B. Simplified diagrams of the gill-withdrawal reflex circuit and sites involved in habituation. Approximately 24 mechanoreceptor neurons in the abdominal ganglion innervate the siphon skin. These sensory cells make excitatory synapses onto a cluster of six motor neurons that innervate the gill, as well as on interneurons that modulate the firing of the motor neurons. (For simplicity, only one of each type of neuron is illustrated here.) Touching the siphon leads to withdrawal of the gill (**dashed outline** shows original gill size; **solid outline** shows maximal withdrawal).

C. Repeated stimulation of the siphon sensory neuron (**top traces**) leads to a progressive depression of synaptic transmission between the sensory and motor neurons. The size of the motor neuron excitatory postsynaptic potential (**EPSP**) gradually decreases despite no change in the presynaptic action potential (**AP**). In a separate experiment, repeated stimulation of the siphon results in a decrease in gill withdrawal (habituation). One hour after repetitive stimulation, both the EPSP and gill withdrawal have recovered. Habituation involves a decrease in transmitter release at many synaptic sites throughout the reflex circuit. (Adapted, with permission, from Pinsker et al. 1970; Castellucci and Kandel 1974.)

long-term habituation, the incidence of connections is reduced to 30%; the reduction in number of synapses persists for a week and does not fully recover even 3 weeks later (see Figure 53–9). As we shall see, the converse occurs with long-term sensitization, where synaptic transmission is associated with an *increase* in the number of synapses between sensory and motor neurons.

Not all classes of synapses are equally modifiable. In *Aplysia*, the strength of some synapses rarely changes, even with repeated activation. In synapses specifically involved in learning (such as the connections between sensory and motor neurons in the withdrawal reflex circuit), a relatively small amount of training can produce large and enduring changes in synaptic strength.

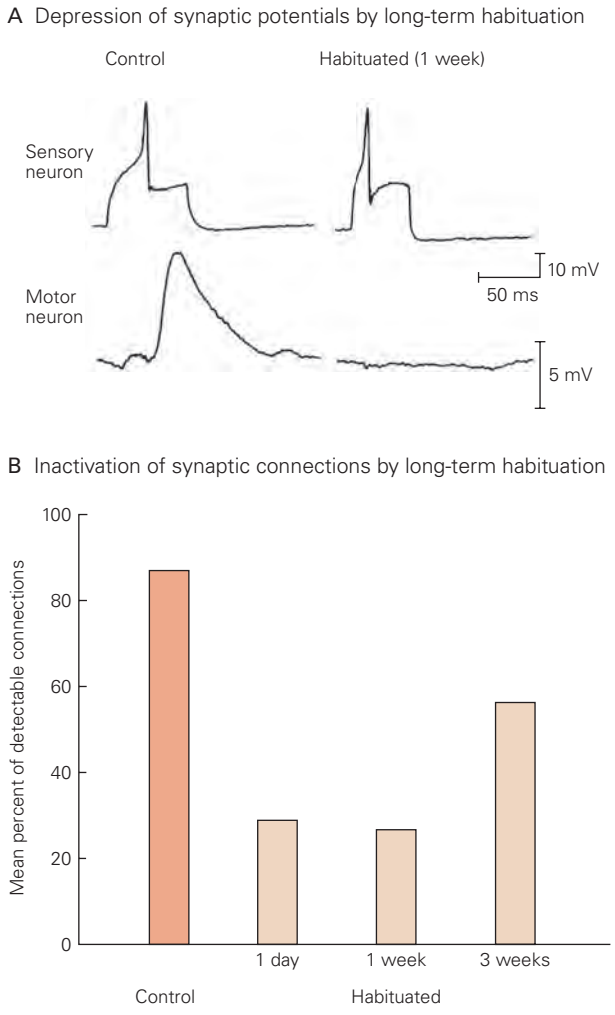

Figure 53–3 Long-term habituation of the gill-withdrawal reflex in *Aplysia.* (Adapted, with permission, from Castellucci, Carew, and Kandel 1978.)

A. Comparison of action potentials in sensory neurons and the postsynaptic potential in motor neurons in an untrained animal (control) and one that has been subjected to long-term habituation. In the habituated animal 1 week after training, no synaptic potential occurs in the motor neuron in response to the sensory neuron action potential.

B. After long-term habituation training, the mean percentage of sensory neurons making physiologically detectable connections with motor neurons is reduced even at 3 weeks.

Sensitization Involves Presynaptic Facilitation of Synaptic Transmission

The ability to recognize and respond to danger is necessary for survival. Not only snails and flies, but all animals, including humans, must distinguish predators from prey and hostile environments from safe ones. Because the ability to respond to threats is a universal requirement of survival, it has been conserved throughout evolution, allowing studies of invertebrates to shed light on neural mechanisms in mammals.

At the beginning of the 20th century, both Freud and Pavlov appreciated that anticipatory defensive responses to danger signals are biologically adaptive, a fact that likely accounts for the profound conservation of this capacity throughout vertebrates and invertebrates. In the laboratory, threat (fear) conditioning is typically studied by presenting a neutral stimulus, such as a tone, prior to the onset of an aversive stimulus, such as electrical shock. The two stimuli become associated such that the tone leads to the elicitation of defensive behaviors that protect against the harmful consequences predicted by the tone. Freud called this "signal anxiety," which prepares the individual for fight or flight when there is even the suggestion of external danger.

When an animal repeatedly encounters a harmless stimulus, its responsiveness to the stimulus habituates, as seen above. In contrast, when the animal confronts a *harmful* stimulus, it typically learns to respond more vigorously to a subsequent presentation of the same stimulus. Presentation of a harmful stimulus can even cause an animal to mount a defensive response to a subsequent *harmless* stimulus. As a result, defensive reflexes for withdrawal and escape become heightened. This enhancement of reflex responses is called *sensitization.*

Like habituation, sensitization can be transient or long lasting. A single shock to the tail of an *Aplysia* produces short-term sensitization of the gill-withdrawal reflex that lasts minutes; five or more shocks to the tail produce sensitization lasting days to weeks. Tail shock is also sufficient to overcome the effects of habituation and enhance a habituated gill-withdrawal reflex, a process termed *dishabituation*.

Sensitization and dishabituation result from an enhancement in synaptic transmission at several connections in the neural circuit of the gill-withdrawal reflex, including the connections made by sensory neurons with motor neurons and interneurons—the same synapses depressed by habituation (Figure 53–4A). Typically, modifiable synapses can be regulated bidirectionally, participate in more than one type of learning, and store more than one type of memory. The bidirectional synaptic changes that underlie habituation and sensitization are the result of different cellular mechanisms. In *Aplysia*, the same synapses that are weakened by habituation through a homosynaptic process can be strengthened by sensitization through a *heterosynaptic* process that depends on modulatory

interneurons activated by the harmful stimulus to the tail.

At least three groups of modulatory interneurons are involved in sensitization. The best studied use serotonin as a transmitter (Figure 53–4B). The serotonergic interneurons form synapses on many regions of the sensory neurons, including axo-axonic synapses on the presynaptic terminals of the sensory cells. After a single tail shock, the serotonin released from the interneurons binds to a receptor in the sensory neurons that is coupled to a stimulatory G protein that increases the activity of adenylyl cyclase. This action produces the second messenger cyclic adenosine monophosphate (cAMP), which in turn activates the cAMP-dependent protein kinase (PKA) (Chapter 14). Serotonin also activates a second type of G-protein–coupled receptor that leads to the hydrolysis of phospholipids and the activation of protein kinase C (PKC).

The protein phosphorylation mediated by PKA and PKC enhances the release of transmitter from sensory neurons through at least two mechanisms (Figure 53–4B). In one action, PKA phosphorylates a K^+ channel, causing it to close. This broadens the action potential and thus enhances the duration of Ca^{2+} influx through voltage-gated Ca^{2+} channels, which in turn enhances transmitter release. In a second action, protein phosphorylation through PKC enhances the functioning of the release machinery directly. Presynaptic facilitation in response to release of serotonin by a tail shock lasts for a period of many minutes. Repeated noxious stimuli can strengthen synaptic activity for days (by a mechanism we consider below).

Classical Threat Conditioning Involves Facilitation of Synaptic Transmission

Classical conditioning is a more complex form of learning. Rather than learning about the properties of one stimulus, as in habituation and sensitization, the animal learns to associate one type of stimulus with another. As described in Chapter 52, an initial weak conditioned stimulus (eg, the ringing of a bell) becomes highly effective in producing a response when paired with a strong unconditioned stimulus (eg, presentation of food). In reflexes that can be enhanced by both classical conditioning and sensitization, such as the defensive withdrawal reflexes of *Aplysia*, classical conditioning results in greater and longer-lasting enhancement.

Although aversive classical conditioning is traditionally referred to as fear conditioning, we will use the more neutral term *threat conditioning* to avoid the implication that animals have subjective states comparable to those that humans experience and label as "fear." This distinction is important because humans can respond to threats behaviorally and physiologically in the absence of any reported feeling of fear. This terminology allows the findings from research on implicit learning in all animals, from the simplest worm to humans, to be interpreted in an objective manner without invoking empirically unverifiable subjective fear states in animals.

For classical conditioning of the *Aplysia* gill-withdrawal reflex, a weak touch to the siphon serves as the conditioned stimulus while a strong shock to the tail serves as the unconditioned stimulus. When the gill-withdrawal reflex is classically conditioned, gill withdrawal in response to siphon stimulation alone is greatly enhanced. This enhancement is even more dramatic than the enhancement produced in an unpaired pathway by tail shock alone (sensitization). In classical conditioning, the timing of the conditioned and unconditioned stimuli is critical. To be effective, the conditioned stimulus (siphon touch) must *precede* (and thus predict) the unconditioned stimulus (tail shock), often within an interval of about 0.5 seconds.

The convergence in individual sensory neurons of the signals initiated by the conditioned and unconditioned stimuli is critical. Alone, a strong shock to the tail (unconditioned stimulus) will excite serotonergic interneurons that form synapses on presynaptic terminals of the siphon sensory neurons, resulting in presynaptic facilitation (Figure 53–5A). However, when the tail shock immediately follows a slight tap on the siphon (conditioned stimulus), the serotonin from the interneurons produces even greater presynaptic facilitation, a process termed *activity-dependent facilitation* (Figure 53–5B).

How does this work? During conditioning, the modulatory interneurons activated by tail shock release serotonin shortly *after* the action potential produced in the siphon sensory neurons by the tap on the siphon. The action potential triggers an influx of Ca^{2+} into the presynaptic terminals of the sensory neurons, and the Ca^{2+} binds to calmodulin, which in turn binds to the enzyme, adenylyl cyclase. This primes the adenylyl cyclase so that it responds more vigorously to the serotonin released following the tail shock. This in turn enhances the production of cAMP, which increases the amount of presynaptic facilitation. If the order of stimuli is reversed so that serotonin release precedes Ca^{2+} influx in the presynaptic sensory terminals, there is no potentiation and no classical conditioning.

Thus, the cellular mechanism of classical conditioning in the monosynaptic pathway of the withdrawal reflex is largely an elaboration of the mechanism of

sensitization, with the added feature that the adenylyl cyclase serves as a *coincidence detector* in the presynaptic sensory neuron, recognizing the temporal order of the physiological responses to the tail shock (unconditioned stimulus) and the siphon tap (conditioned stimulus).

In addition to the presynaptic component of activity-dependent facilitation, a postsynaptic component is triggered by Ca^{2+} influx into the motor neuron when it is highly excited by the siphon sensory neurons. The properties of this postsynaptic mechanism are similar to those of long-term potentiation of synaptic transmission in the mammalian brain (discussed later in this chapter and in Chapters 13 and 54).

Long-Term Storage of Implicit Memory Involves Synaptic Changes Mediated by the cAMP-PKA-CREB Pathway

Cyclic AMP Signaling Has a Role in Long-Term Sensitization

In all forms of learning, practice makes perfect. Repeated experience converts short-term memory into a long-term form. In *Aplysia*, the form of long-term memory that has been most intensively studied is long-term sensitization. Like the short-term form, long-term sensitization of the gill-withdrawal reflex involves changes in the strength of connections at several synapses. But in addition, it also recruits the growth of new synaptic connections.

Five spaced training sessions (or repeated applications of serotonin) over approximately 1 hour produce long-term sensitization and long-term synaptic facilitation lasting 1 or more days. Spaced training over several days produces sensitization that persists for 1 or more weeks. Long-term sensitization, like the short-term form, requires protein phosphorylation that is dependent on increased levels of cAMP (Figure 53–6).

The conversion of short-term memory into long-term memory, called *consolidation*, requires synthesis of messenger RNAs and proteins in the neurons in the circuit. Thus, activation of specific gene expression is required for long-term memory. The transition from short-term to long-term memory depends on the prolonged rise in cAMP that follows repeated applications of serotonin. The increase in cAMP leads to prolonged activation of PKA, allowing the catalytic subunit of the kinase to translocate into the nucleus of the sensory neurons. It also leads indirectly to activation of a second protein kinase, the mitogen-activated protein kinase (MAPK), a kinase commonly associated with cellular growth (Chapter 14). Within the nucleus, the catalytic subunit of PKA phosphorylates and thereby activates the transcription factor CREB-1 (*c*AMP *r*esponse *e*lement *b*inding protein 1), which binds a promoter element called CRE (*c*AMP *r*ecognition *e*lement) (Figures 53–6 and 53–7).

To turn on gene transcription, phosphorylated CREB-1 recruits a transcriptional coactivator, CREB-binding protein (CBP), to the promoter region. CBP has two important properties that facilitate transcriptional activation: It recruits RNA polymerase II to the

Figure 53–4 (Opposite) Short-term sensitization of the gill-withdrawal reflex in *Aplysia*.

A. Sensitization of the gill-withdrawal reflex is produced by applying a noxious stimulus to another part of the body, such as the tail. A shock to the tail activates tail sensory neurons that excite facilitating (modulatory) interneurons, which form synapses on the cell body and terminals of the mechanoreceptor sensory neurons that innervate the siphon. Through these axo-axonic synapses, the modulatory interneurons enhance transmitter release from the siphon sensory neurons onto their postsynaptic gill motor neurons (presynaptic facilitation), thus enhancing gill withdrawal. Presynaptic facilitation results, in part, from a prolongation of the sensory neuron action potential (**AP**; **bottom traces**). (Abbreviation: **EPSP**, excitatory postsynaptic potential.) (Adapted, with permission, from Pinsker et al. 1970; Klein and Kandel 1980.)

B. Presynaptic facilitation in the sensory neuron is thought to occur by means of two biochemical pathways. The diagram shows details of the synaptic complex in the dashed box in part **A**.

Pathway 1: A facilitating interneuron releases serotonin (**5-HT**), which binds to metabotropic receptors in the sensory neuron terminal. This action engages a G protein (G_s), which in turn increases the activity of adenylyl cyclase. The adenylyl cyclase converts adenosine triphosphate to cyclic adenosine monophosphate (**cAMP**), which binds to the regulatory subunit of protein kinase A (**PKA**), thus activating its catalytic subunit. The catalytic subunit phosphorylates certain K^+ channels, thereby closing the channels and decreasing the outward K^+ current. This prolongs the action potential, thus increasing the influx of Ca^{2+} through voltage-gated Ca^{2+} channels and thereby augmenting transmitter release.

Pathway 2: Serotonin binds to a second class of metabotropic receptor that activates the $G_{q/11}$ class of G protein that enhances the activity of phospholipase C (**PLC**). The PLC activity leads to production of diacylglycerol, which activates protein kinase C (**PKC**). The PKC phosphorylates presynaptic proteins, resulting in the mobilization of vesicles containing glutamate from a reserve pool to a releasable pool at the active zone, thus increasing the efficiency of transmitter release.

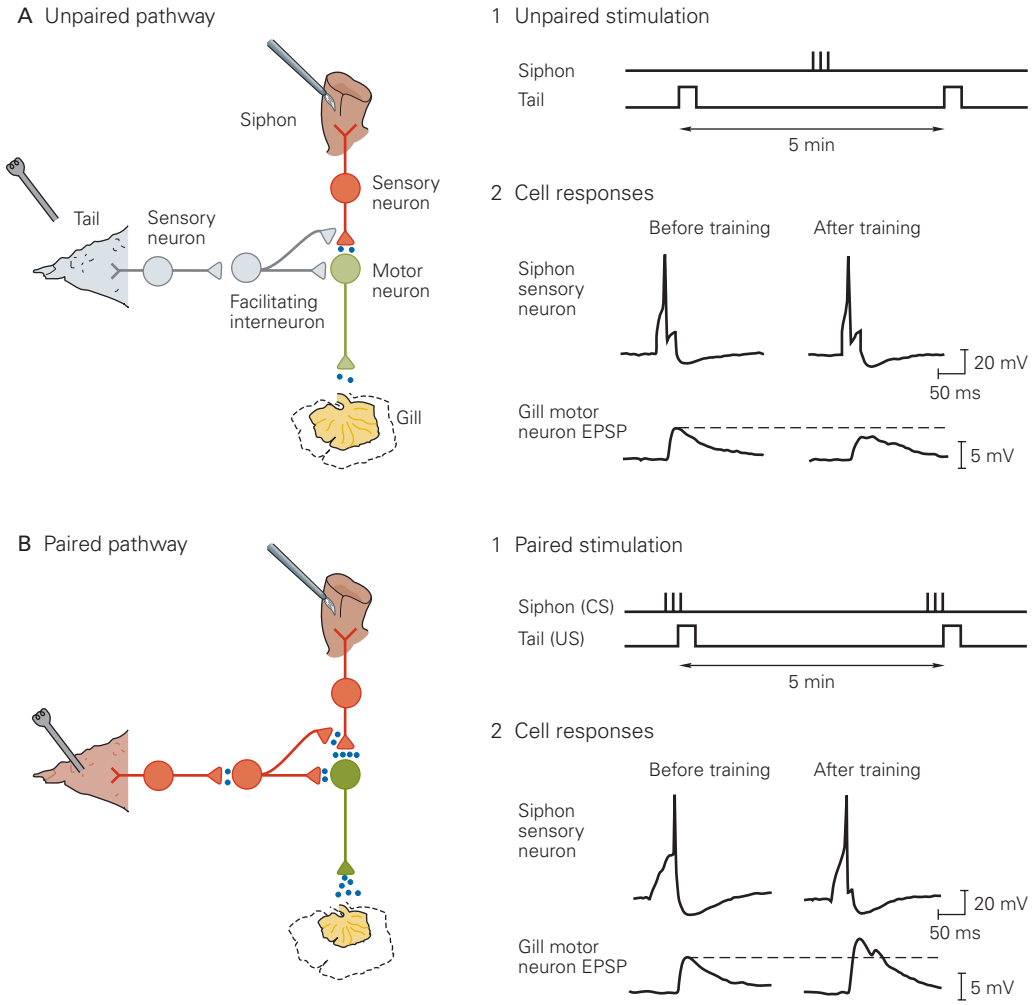

Figure 53–5 Classical conditioning of the gill-withdrawal reflex in *Aplysia*. (Adapted, with permission, from Hawkins et al. 1983.)

A. The siphon is stimulated by a light tap and the tail is shocked, but the two stimuli are not paired in time. The tail shock excites facilitatory interneurons that form synapses on the presynaptic terminals of sensory neurons innervating the mantle shelf and siphon. This is the mechanism of sensitization. **1.** The pattern of unpaired stimulation during training. **2.** Under these conditions, the size of the motor neuron test excitatory postsynaptic potential (**EPSP**) is only weakly facilitated by the tail shock. Often, as in this example, the EPSP actually decreases slightly despite the tail shock because repeated unpaired stimulation of the siphon leads to synaptic depression due to habituation.

B. The tail shock is paired in time with stimulation of the siphon. **1.** The siphon is touched (conditioned stimulus [**CS**]) immediately prior to shocking the tail (unconditioned stimulus [**US**]). As a result, the siphon sensory neurons are primed to be more responsive to input from the facilitatory interneurons in the unconditioned pathway. This is the mechanism of classical conditioning; it selectively amplifies the response of the conditioned pathway. **2.** Recordings of test EPSPs in an identified motor neuron produced by a siphon sensory neuron before training and 1 hour after training. After training with paired sensory input, the EPSP in the siphon motor neuron is considerably greater than either the EPSP before training or the EPSP following unpaired tail shock (shown in part **A2**). This synaptic amplification produces a more vigorous gill withdrawal.

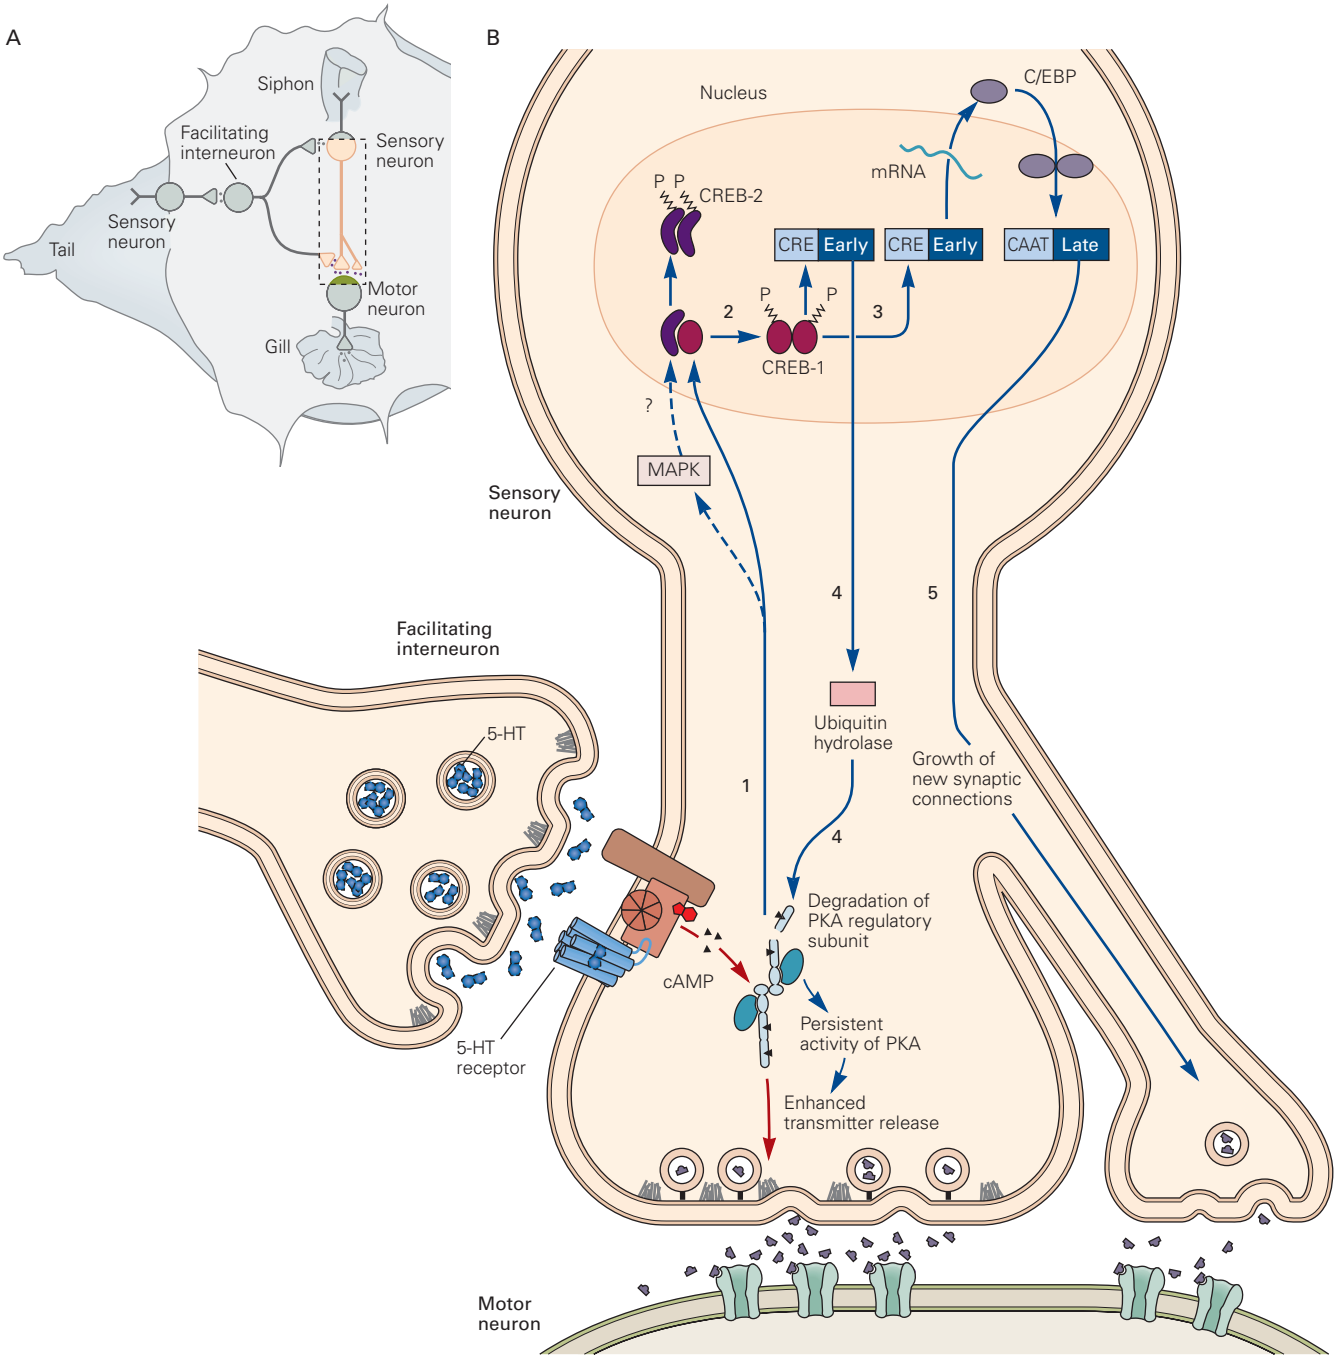

Figure 53–6 Long-term sensitization involves synaptic facilitation and the growth of new synaptic connections.

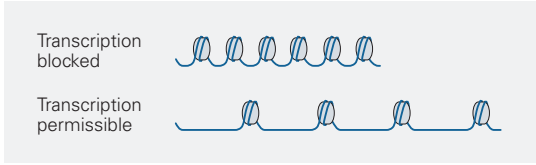
A. Long-term sensitization of the gill-withdrawal reflex of *Aplysia* involves long-lasting facilitation of transmitter release at the synapses between sensory and motor neurons.

B. Long-term sensitization of the gill-withdrawal reflex leads to persistent activity of protein kinase A (**PKA**), resulting in the growth of new synaptic connections. Repeated tail shock leads to more pronounced elevation of cyclic adenosine monophosphate (**cAMP**), producing long-term facilitation (lasting 1 or more days) that outlasts the increase in cAMP and recruits the synthesis of new proteins. This inductive mechanism is initiated by translocation of PKA to the nucleus (**pathway 1**), where PKA phosphorylates the transcriptional activator cAMP response element binding protein 1 (**CREB-1**) (**pathway 2**). CREB-1 binds cAMP regulatory elements (**CRE**) located in the upstream region of several cAMP-inducible genes, activating gene transcription (**pathway 3**). PKA also activates the mitogen-activated protein kinase (**MAPK**), which phosphorylates the transcriptional repressor cAMP response element binding protein 2 (**CREB-2**), thus removing its repressive action. One gene activated by CREB-1 encodes a ubiquitin hydrolase, a component of a specific ubiquitin proteasome that leads to the proteolytic cleavage of the regulatory subunit of PKA, resulting in persistent activity of PKA, even after cAMP has returned to its resting level (**pathway 4**). CREB-1 also activates the expression of the transcription factor C/EBP, which leads to expression of a set of unidentified proteins important for the growth of new synaptic connections (**pathway 5**).



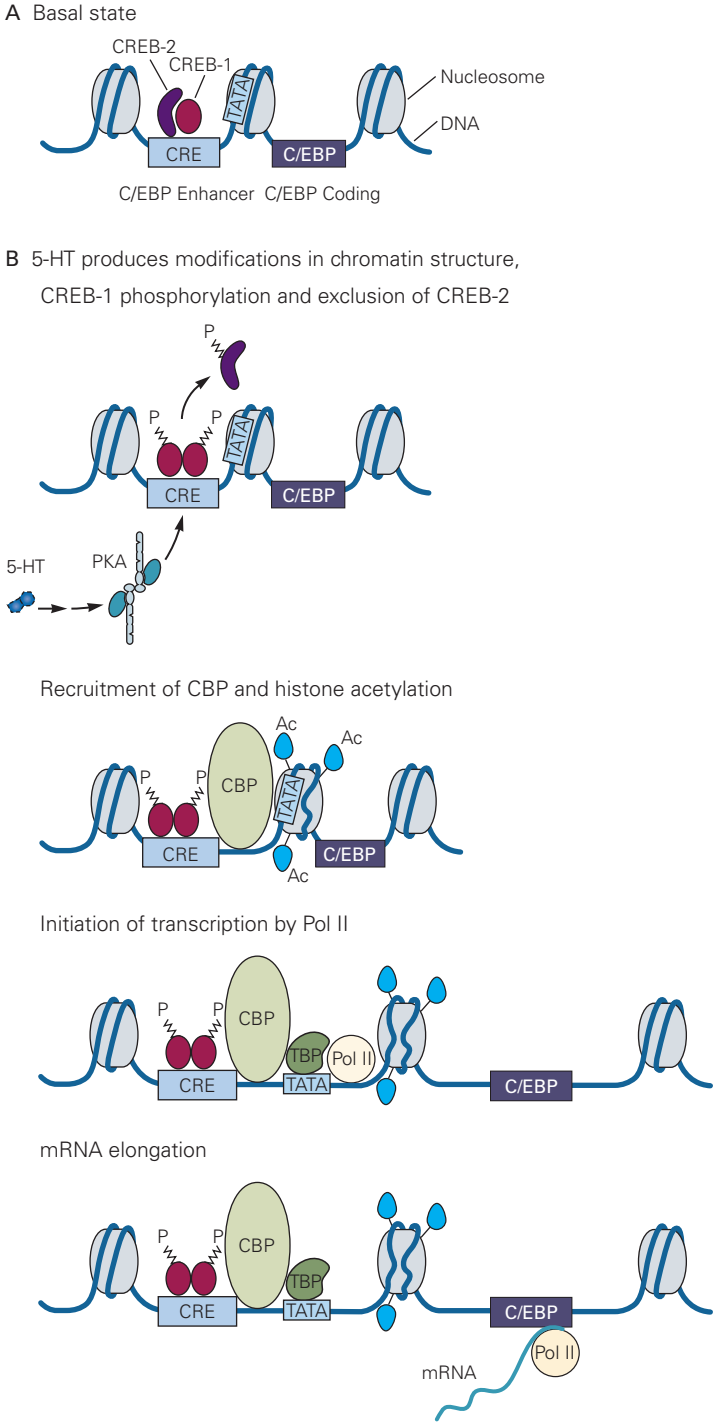


Figure 53–7 Regulation of histone acetylation by serotonin, CREB-1, and CBP.

A. Under basal conditions, the activator CREB-1 (here in complex with CREB-2) occupies the binding site for cAMP recognition element (**CRE**) within the promoter region of its target genes. In the example shown here, CREB-1 binds to the CRE within the C/EBP promoter. In the basal state, CREB-1 binding is not able to activate transcription because the TATA box, the core promoter region responsible for recruiting RNA polymerase II (**Pol II**) during transcription initiation, is inaccessible because the DNA is tightly bound to histone proteins in the nucleosome.

B. Serotonin (**5-HT**) activates protein kinase A (**PKA**), which phosphorylates CREB-1 and indirectly enhances CREB-2 phosphorylation by MAPK, causing CREB-2 to dissociate from the promoter. This allows CREB-1 to form a complex at the promoter with CREB binding protein (**CBP**). Activated CBP acetylates specific lysine residues of the histones, causing them to bind less tightly to DNA. Along with other changes in chromatin structure, acetylation facilitates the repositioning of the nucleosome that previously blocked access of the Pol II complex to the TATA box. This repositioning allows Pol II to be recruited to initiate transcription of the C/EBP gene. (Abbreviation: **TBP**, TATA binding protein.)

promoter, and it functions as an acetyltransferase, adding acetyl groups to certain lysine residues on its substrate proteins. One of the most important substrates of CBP are DNA-binding histone proteins, which are components of nucleosomes, the fundamental building blocks of chromatin. The histones contain a series of positively charged basic residues that strongly interact with the negatively charged phosphates of DNA. This interaction causes DNA to become tightly wrapped around the nucleosomes, much like string is wrapped around a spool, thereby preventing necessary transcription factors from accessing their gene targets.

The binding of CBP to CREB-1 leads to histone acetylation, which causes a number of important structural and functional changes at the level of the nucleosome. For example, acetylation neutralizes the positive charge of lysine residues in the histone tail domains, decreasing the affinity of histones for DNA. Also, specific classes of transcriptional activators can bind to acetylated histones and facilitate the repositioning of nucleosomes at the promoter region. Together, these and other types of chromatin modifications serve to regulate the accessibility of chromatin to the transcriptional machinery, and thus enhance the ability of a gene to be transcribed. This type of modification of DNA structure is termed *epigenetic* regulation. As we will see in Chapter 54, a mutation in the gene encoding CBP underlies Rubinstein-Taybi syndrome, a disorder associated with mental retardation.

The turning on of transcription by PKA also depends on its ability to indirectly activate the MAPK pathway (Chapter 14). MAPK phosphorylates the transcription factor CREB-2, relieving its inhibitory action on transcription (Figure 53–6B). The combined effects of CREB-1 activation and relief of CREB-2 repression induce a cascade of new gene expression important for learning and memory (Figure 53–7).

The presence of both a repressor (CREB-2) and an activator (CREB-1) of transcription at the first step in long-term facilitation suggests that the threshold for long-term memory storage can be regulated. Indeed, we see in everyday life that the ease with which short-term memory is transferred into long-term memory varies greatly with attention, mood, and social context.

The Role of Noncoding RNAs in the Regulation of Transcription

There are other targets of transcription and chromatin regulation in memory consolidation and reconsolidation besides messenger RNAs. Of particular interest are noncoding RNAs such as microRNAs (miRNAs), PIWI-interacting RNAs (piRNAs), and long noncoding RNAs. These are also targeted to specific genetic sites, and their expression in turn regulates transcriptional and posttranscriptional mechanisms.

Studies in *Aplysia* show that miRNAs and piRNAs are both regulated by neuronal activity and contribute to long-term facilitation. MicroRNAs are a class of conserved noncoding RNAs, 20 to 23 nucleotides in length, that contribute to transcriptional and posttranscriptional regulation of gene expression through a specific set of RNA–protein machinery. In *Aplysia*, the most abundant and conserved brain species of these miRNAs are present in sensory neurons, where one of them—miRNA-124—normally constrains serotonin-induced synaptic facilitation by inhibiting the translation of CREB-1 mRNA, suppressing levels of CREB-1 protein. Serotonin inhibits the synthesis of miRNA-124, thereby leading to the disinhibition of the translation of CREB-1 mRNA, enabling the initiation of CREB-1–mediated transcription. The piRNAs are 28 to 32 nucleotides in length, slightly longer than miRNAs, and bind to a protein called Piwi. Individual piRNAs promote the methylation of specific DNA sequences, thereby silencing the genes, providing another example of epigenetic regulation. One piRNA, piRNA-F, increases in response to serotonin, which leads to the methylation of the promoter of CREB-2, reducing CREB-2 gene transcription.

Thus, we see here an example of integrative action at the transcriptional level. Serotonin regulates both piRNA and microRNA in a coordinated fashion: Serotonin rapidly decreases levels of miRNA-124 and facilitates the activation of CREB-1, which begins the process of memory consolidation. After a delay, serotonin also increases levels of piRNA-F, resulting in the methylation and silencing of the promoter of the transcription repressor CREB-2. The decrease in CREB-2 increases the duration of action of CREB-1, thereby consolidating a stable form of long-term memory in the sensory neuron (Figure 53–8).

Two of the genes expressed in the wake of CREB-1 activation and the consequential alteration in chromatin structure are important in the early development of long-term facilitation. One is a gene for ubiquitin carboxyterminal hydrolase, the other a gene for a transcription factor, CAAT box enhancer binding protein (C/EBP), a component of a gene cascade necessary for synthesizing proteins needed for the growth of new synaptic connections (Figures 53–6 and 53–7).

The hydrolase facilitates ubiquitin-mediated protein degradation (Chapter 7) and helps enhance activation of PKA. PKA is made up of four subunits; two regulatory subunits inhibit two catalytic subunits (Chapter 14). With long-term training and the

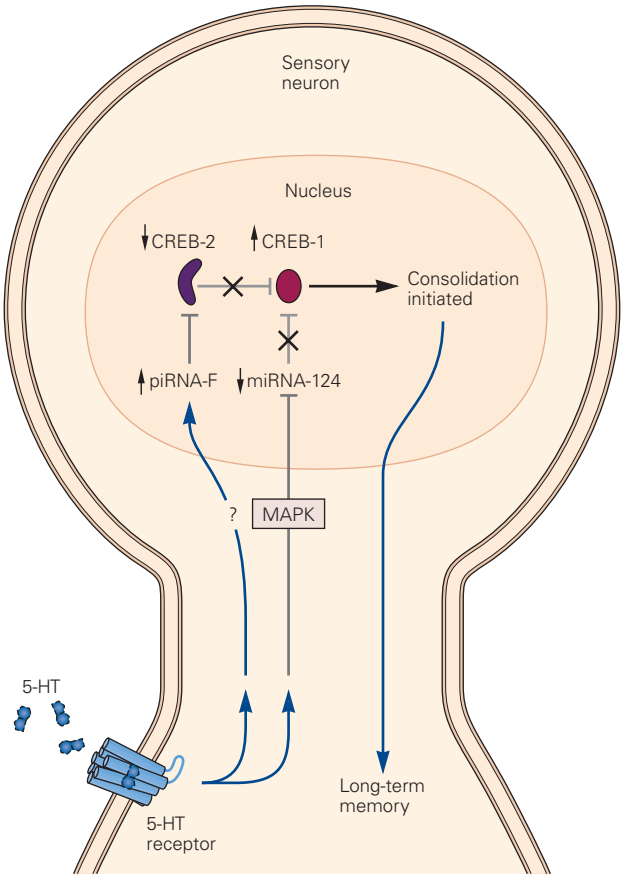

Figure 53–8 Small non-coding RNA molecules contribute to the memory consolidation switch. Long-term facilitation of the sensory to motor neuron synapses is consolidated through the action of two distinct classes of small noncoding RNA molecules. miRNA-124 normally acts to suppress levels of the CREB-1 transcription factor by binding to its mRNA and inhibiting its translation. Serotonin (**5-HT**) downregulates miRNA-124 levels through a mechanism requiring mitogen-activated protein kinase (**MAPK**). This enhances the levels of CREB-1, promoting activation of CREB-1–dependent transcription of gene products necessary for memory consolidation. In a complementary pathway, 5-HT enhances with a delay the synthesis of several piRNAs, including piRNA-F, which bind to the Piwi protein. The piRNA-F/Piwi complex leads to enhanced methylation of the *CREB-2* gene, resulting in long-lasting transcriptional repression of *CREB-2* and decreased levels of CREB-2 protein. Because CREB-2 normally inhibits the action of CREB-1, the increased levels of piRNA-F in response to 5-HT enhance and prolong CREB-1 activity, resulting in more effective memory consolidation.

induction of the hydrolase, approximately 25% of the regulatory subunits are degraded in the sensory neurons. As a result, free catalytic subunits can continue to phosphorylate proteins important for the enhancement of transmitter release and the strengthening of synaptic connections, including CREB-1, long after cAMP has returned to its resting level (Figure 53–6B). Formation of a constitutively active enzyme is therefore the simplest molecular mechanism for long-term memory. With repeated training, a second-messenger kinase critical for short-term facilitation can remain persistently active for up to 24 hours without requiring a continuous activating signal.

The second and more enduring consequence of CREB-1 activation is the activation of the transcription factor C/EBP. This transcription factor forms both a homodimer with itself and a heterodimer with another transcription factor called *activating factor*. Together, these factors act on downstream genes that trigger the growth of new synaptic connections that support long-term memory.

With long-term sensitization, the number of presynaptic terminals in the sensory neurons in the gill-withdrawal circuit doubles (Figure 53–9). The dendrites of the motor neurons also grow to accommodate the additional synaptic input. Thus, long-term structural changes in both post- and presynaptic cells increase the number of synapses. Long-term habituation, in contrast, leads to *pruning* of synaptic connections, as described above. Long-term disuse of functional connections between sensory and motor neurons reduces the number of terminals of each sensory neuron by one-third (Figure 53–9A).

Long-Term Synaptic Facilitation Is Synapse Specific

A typical pyramidal neuron in the mammalian brain makes 10,000 presynaptic connections with a wide range of target cells. It is therefore generally thought that long-term memory storage should be synapse specific—that is, only those synapses that actively participate in learning should be enhanced. However, the finding that long-term facilitation involves gene expression—which occurs in the nucleus, far removed from a neuron's synapses—raises some fundamental questions regarding information storage.

Is long-term memory storage indeed synapse specific, or do the gene products recruited during long-term memory storage alter the strength of every presynaptic terminal in a neuron? And if long-term memory is synapse specific, what are the cellular mechanisms that enable the products of gene transcription to selectively strengthen just some synapses and not others?

Kelsey Martin and her colleagues addressed these questions for long-term facilitation by using a cell culture system consisting of an isolated *Aplysia* sensory neuron with a bifurcated axon that makes separate synaptic contacts with two motor neurons. The sensory

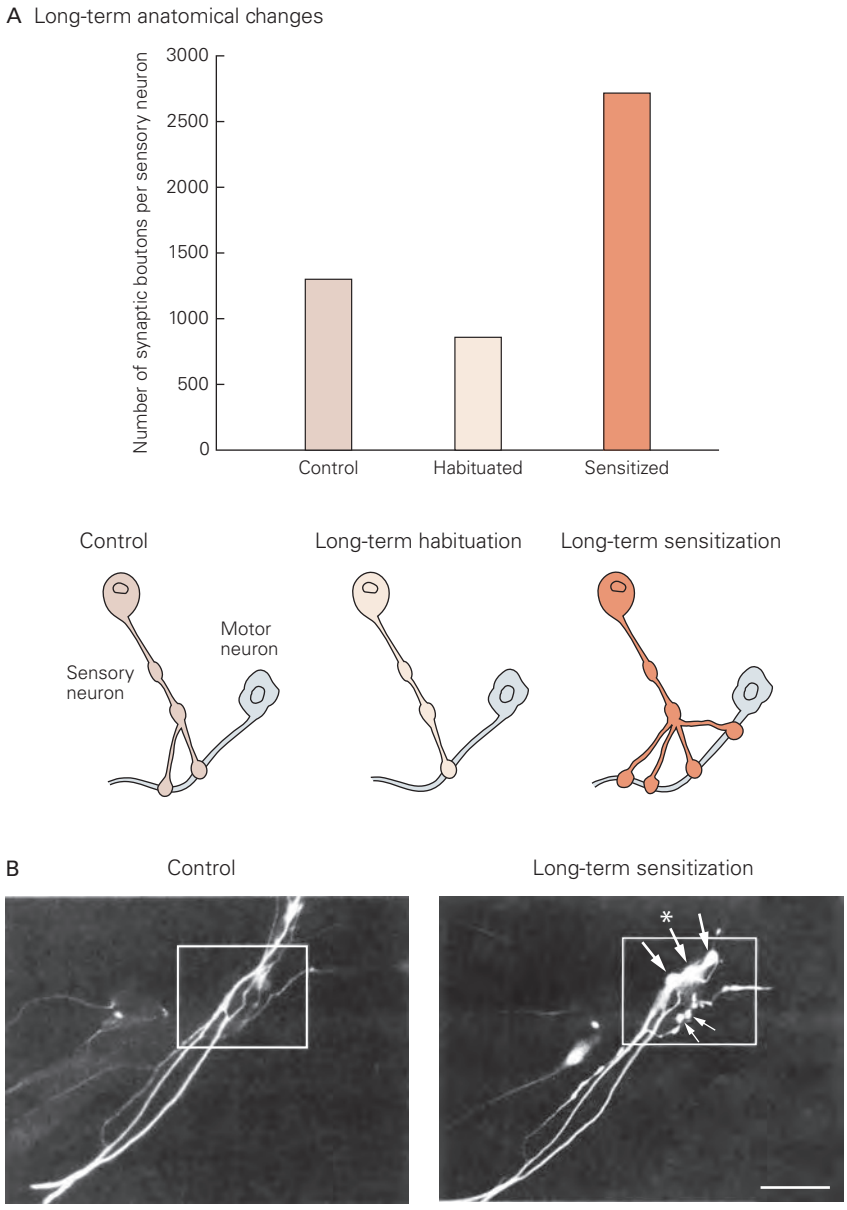

Figure 53–9 Long-term habituation and sensitization involve structural changes in the presynaptic terminals of sensory neurons.

A. Long-term habituation leads to a loss of synapses, and long-term sensitization leads to an increase in the number of synapses. When measured either 1 day (shown here) or 1 week after training, the number of presynaptic terminals relative to control levels is greater in sensitized animals and less in habituated animals. The drawings below the graph illustrate changes in the number of synaptic contacts. The swellings or varicosities on the sensory neuron processes are called synaptic boutons; they contain all the specialized structures necessary for transmitter release. (Adapted, with permission, from Bailey and Chen 1983. Copyright © 1983 AAAS.)

B. Fluorescence images of a sensory neuron axon contacting a motor neuron in culture before (*left*) and 1 day after (*right*) five brief exposures to serotonin. The resulting increase in varicosities simulates the synaptic changes associated with long-term sensitization. Prior to serotonin application, no presynaptic varicosities are visible in the outlined area (*left*). After serotonin, several new boutons are apparent (**arrows**), some of which contain a fully developed active zone (**asterisk**) or have small immature active zones. Scale bar = 50 µm. (Reproduced, with permission, from Glanzman, Kandel, and Schacher 1990.)

neuron terminals on one of the two motor neurons were activated by focal pulses of serotonin, thus mimicking the neural effects of a shock to the tail. When only one pulse of serotonin was applied, those synapses showed short-term facilitation. The synapses on the second motor neuron, which did not receive serotonin, showed no change in synaptic transmission.

When five pulses of serotonin were applied to the same synapses, those synapses displayed both short-term and long-term facilitation, and new synaptic connections were formed with the motor neuron. Although long-term facilitation and synaptic growth require gene transcription and protein synthesis, the synapses that did not receive serotonin showed no enhancement of synaptic transmission (Figure 53–10). Thus, both short-term and long-term synaptic facilitation are synapse specific and manifested only by those synapses that receive the modulatory serotonin signal.

But how are the nuclear products able to enhance transmission at only certain synapses and not others of the same neuron? Are the newly synthesized proteins somehow targeted to only those synapses that receive serotonin? Or are they shipped out to all synapses but used productively for the growth of new synaptic connections only at those synapses that have been marked by at least a single pulse of serotonin?

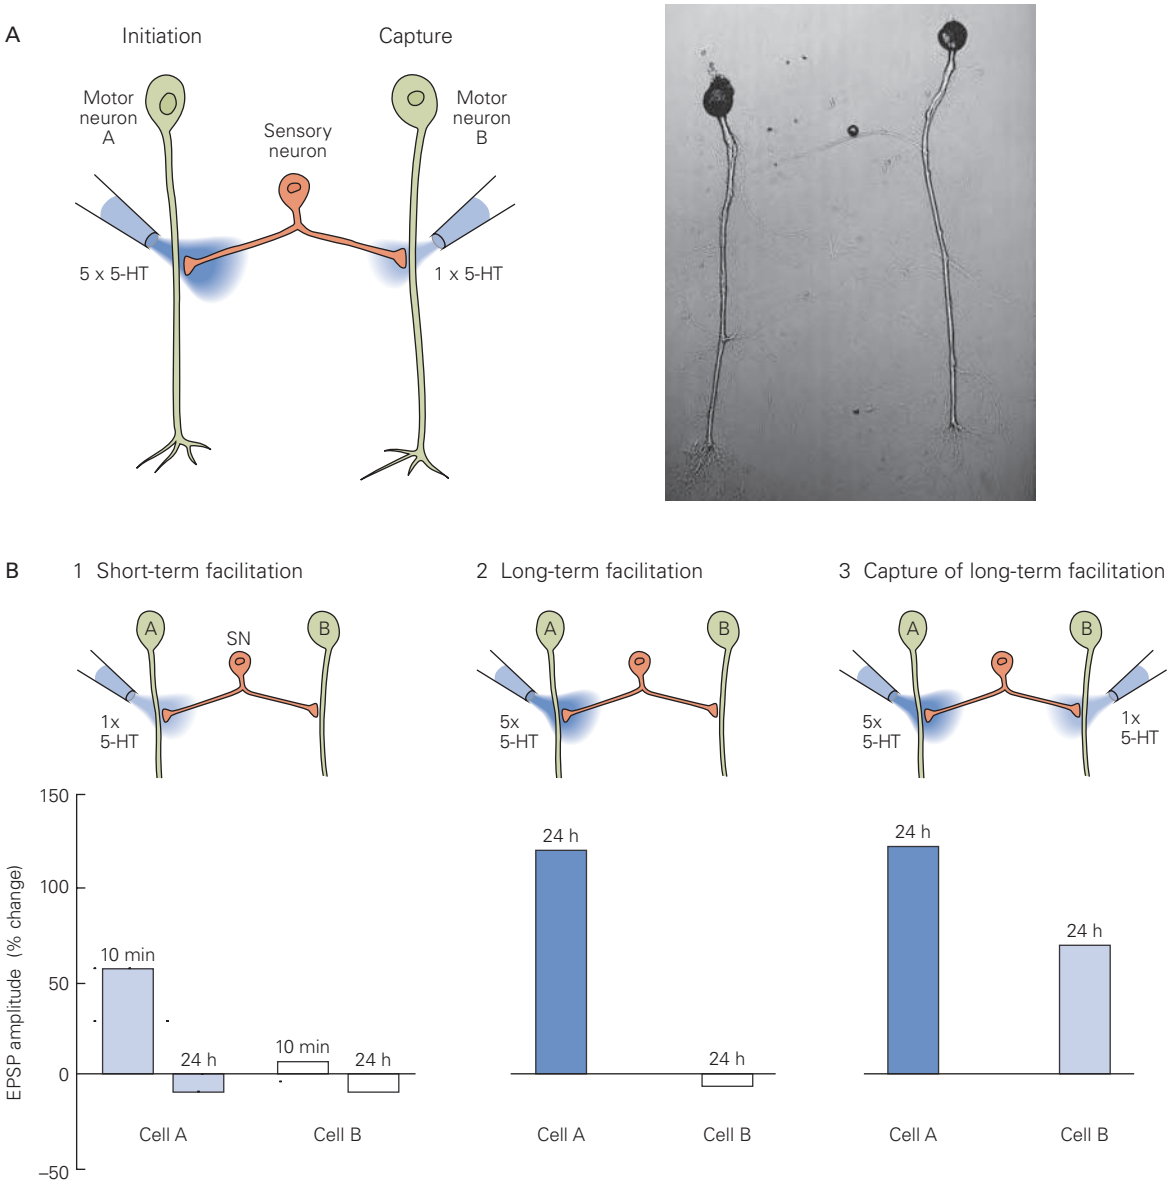

Figure 53–10 **The long-term facilitation of synaptic transmission is synapse specific.** (Adapted, with permission, from Martin et al. 1997.)

A. The experiment uses a single presynaptic sensory neuron that contacts two postsynaptic motor neurons A and B. The pipette on the left is used to apply five pulses of serotonin (**5-HT**) to a sensory neuron synapse with motor neuron A, initiating long-term facilitation at that synapse. The pipette on the right is used to apply one pulse of 5-HT to a sensory neuron synapse with motor neuron B, allowing this synapse to make use of (capture) new proteins produced in the cell body in response to the five pulses of 5-HT at the synapse with motor neuron A. The image at the right shows the actual appearance of the cells in culture.

B. 1. One pulse of 5-HT applied to the synapse with motor neuron A produces only short-term (10-minute) facilitation of the excitatory postsynaptic potential (**EPSP**) in the neuron. By 24 hours, the EPSP has returned to its normal size. There is no significant change in EPSP size in cell B. **2.** Application of five pulses of 5-HT to the synapses with cell A produces long-term (24-hour) facilitation of the EPSP in that cell but no change in the size of the EPSP in cell B. **3.** When five pulses of 5-HT onto the synapse with cell A are paired with a single pulse of 5-HT onto the synapses with cell B, cell B now displays long-term facilitation and an increase in EPSP size after 24 hours.

To test this question, Martin and her colleagues again selectively applied five pulses of serotonin to the synapses made by the sensory neuron onto one of the motor neurons. This time, however, the synapses with the second motor neuron were simultaneously activated by a single pulse of serotonin (which by itself produces only short-term synaptic facilitation lasting minutes). Under these conditions, the single pulse of serotonin was sufficient to induce long-term facilitation and growth of new synaptic connections at the contacts between the sensory neuron and the second motor neuron. Thus, application of the single pulse of serotonin onto the synapses at the second branch enabled those synapses to use the nuclear products produced in response to the five pulses of serotonin onto the synapses of the first branch, a process called *capture*.

These results suggest that newly synthesized gene products, both mRNAs and proteins, are delivered by fast axonal transport to all the synapses of a neuron but are functional only at synapses that have been marked by previous synaptic activity, that is, by presynaptic release of serotonin. Although one pulse of serotonin at a synapse is insufficient to turn on new gene expression in the cell body, it is sufficient to mark that synapse, allowing it to make use of new proteins generated in the cell body in response to five pulses of serotonin at another synapse. This idea, developed by Martin and her colleagues for *Aplysia* and independently by Frey and Morris for the hippocampus in rodents, is called *synaptic capture* or *synaptic tagging*.

These findings raise the question, what is the nature of the synaptic mark that allows the capture of the gene products for long-term facilitation? When an inhibitor of PKA was applied locally to the synapses receiving the single pulse of serotonin, those synapses could no longer capture the gene products produced in response to the five pulses of serotonin (Figure 53–11). This indicates that local phosphorylation by PKA is required for synaptic capture.

In the early 1980s, Oswald Steward discovered that ribosomes, the machinery for protein synthesis, are present at synapses as well as in the cell body. Martin examined the importance of local protein synthesis in long-term synaptic facilitation by applying a single pulse of serotonin together with an inhibitor of local protein synthesis onto one set of synapses while simultaneously applying five pulses of serotonin to a second set of synapses. Normally, long-term facilitation and synaptic growth would persist for up to 72 hours in response to synaptic capture. In the presence of the local protein synthesis inhibitor, synaptic capture still occurred, producing long-term synaptic facilitation at the synapses exposed to only one pulse of serotonin. However, the facilitation only lasted 24 hours. After 24 hours, synaptic growth and facilitation at these synapses collapsed, indicating that the maintenance of learning-induced synaptic growth requires new local protein synthesis at the synapse (Figure 53–11B).

Martin and her colleagues thus found that regulation of protein synthesis at the synapse plays a major role in controlling synaptic strength at the sensory-to-motor neuron connection in *Aplysia*. As we shall see in Chapter 54, local protein synthesis is also important for the later phases of long-term potentiation of synaptic strength in the hippocampus.

These findings indicate there are two distinct components of synaptic marking in *Aplysia*. The first component, lasting about 24 hours, initiates long-term synaptic plasticity and synaptic growth, requires transcription and translation in the nucleus, and recruits local PKA activity, but does not require local protein synthesis. The second component, which stabilizes the long-term synaptic change after 72 hours, requires local protein synthesis at the synapse. How might this local protein synthesis be regulated?

Maintaining Long-Term Synaptic Facilitation Requires a Prion-Like Protein Regulator of Local Protein Synthesis

The fact that mRNAs are translated at the synapse in response to marking of that synapse by one pulse of serotonin suggests that these mRNAs may initially be dormant and under the control of a regulator of translation recruited by serotonin. Translation of most mRNAs requires that transcripts contain a long tail of adenosine nucleotides at their 3′ end [poly(A) tail]. Joel Richter had earlier found that in *Xenopus* (frog) oocytes the maternal mRNAs only have a short tail of adenine nucleotides and thus are silent until activated by the cytoplasmic polyadenylation element binding protein (CPEB). CPEB binds to a site on mRNAs and recruits poly(A) polymerase, leading to the elongation of the poly(A) tail.

Kausik Si and his colleagues found that serotonin increases the local synthesis of a novel, neuron-specific isoform of CPEB in *Aplysia* sensory neuron terminals. The induction of CPEB is independent of transcription but requires new protein synthesis. Blocking CPEB locally at an activated synapse blocks the long-term maintenance of synaptic facilitation at the synapse but not its initiation and initial 24-hour maintenance.

How might CPEB stabilize the late phase of long-term facilitation? Most biological molecules have a relatively short half-life (hours to days), whereas memory

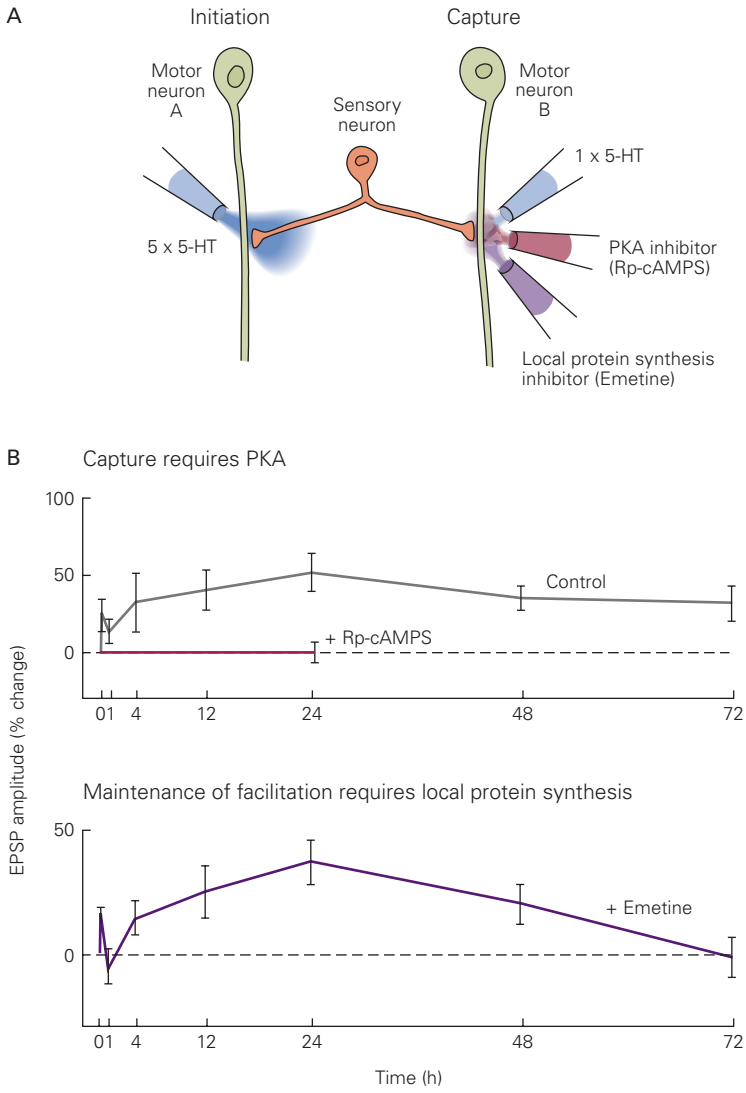

Figure 53–11 Long-term facilitation requires both cyclic adenosine monophosphate (cAMP)-dependent phosphorylation and local protein synthesis. (Adapted, with permission, from Casadio et al. 1999.)

A. Five pulses of serotonin (**5-HT**) are applied to the synapses on motor neuron A, and a single pulse is applied to those of cell B. Inhibitors of protein kinase A (**PKA**; Rp-cAMPS) or local protein synthesis (emetine) are applied to synapses on cell B.

B. Rp-cAMPS blocks the capture of long-term facilitation completely at the synapses on neuron B. Emetine has no effect on the capture of facilitation or the growth of new synaptic connections measured 24 hours after 5-HT application, but by 72 hours, it fully blocks synaptic enhancement. The outgrowth of new synaptic connections is retracted, and long-term facilitation decays after 1 day if capture is not maintained by local protein synthesis. (Abbreviations: **EPSP**, excitatory post-synaptic potential; **Rp-cAMPS**, Rp-diaster-eomer of adenosine cyclic 3′,5′-phosphorothioate.)

lasts days, weeks, or even years. How can learning-induced alterations in the molecular composition of a synapse be maintained for such a long time? Most hypotheses posit some type of self-sustained mechanism that modulates synaptic strength and structure.

Si and his colleagues made the surprising discovery that the neuronal isoform of *Aplysia* CPEB appears to have self-sustaining properties that resemble those of prion proteins. Prions were discovered by Stanley Prusiner, who demonstrated that these proteins were the causative agents of Creutzfeldt-Jakob disease, a devastating neurodegenerative human disease, and mad cow disease. Prion proteins can exist in two forms: a soluble form and an aggregated form that is capable of self-perpetuation. *Aplysia* CPEB also has two conformational states, a soluble form that is inactive and an aggregated form that is active. This switch depends on an N-terminal domain of CPEB that is rich in glutamine, similar to prion domains in other proteins.

In a naïve synapse, CPEB exists in the soluble, inactive state, and its resting level of expression is low. However, in response to serotonin, the local synthesis of CPEB increases until a threshold concentration is reached that switches CPEB to the aggregated, active state, which is then capable of activating the translation of dormant mRNAs. Once the active state is established, it becomes self-perpetuating by recruiting soluble CPEB to the aggregates, maintaining its ability to activate the translation of dormant mRNAs. Although dormant mRNAs are made in the cell body and distributed throughout the cell, they are translated only at synapses that have active CPEB aggregates.

Whereas conventional prion mechanisms are pathogenic—the aggregated state of most prion proteins causes cell death—the *Aplysia* CPEB is a new form of a prion-like protein, one whose aggregated state plays an important physiological function. The active self-perpetuating form of *Aplysia* CPEB maintains long-term molecular changes in a synapse that are necessary for the persistence of memory storage (Figure 53–12).

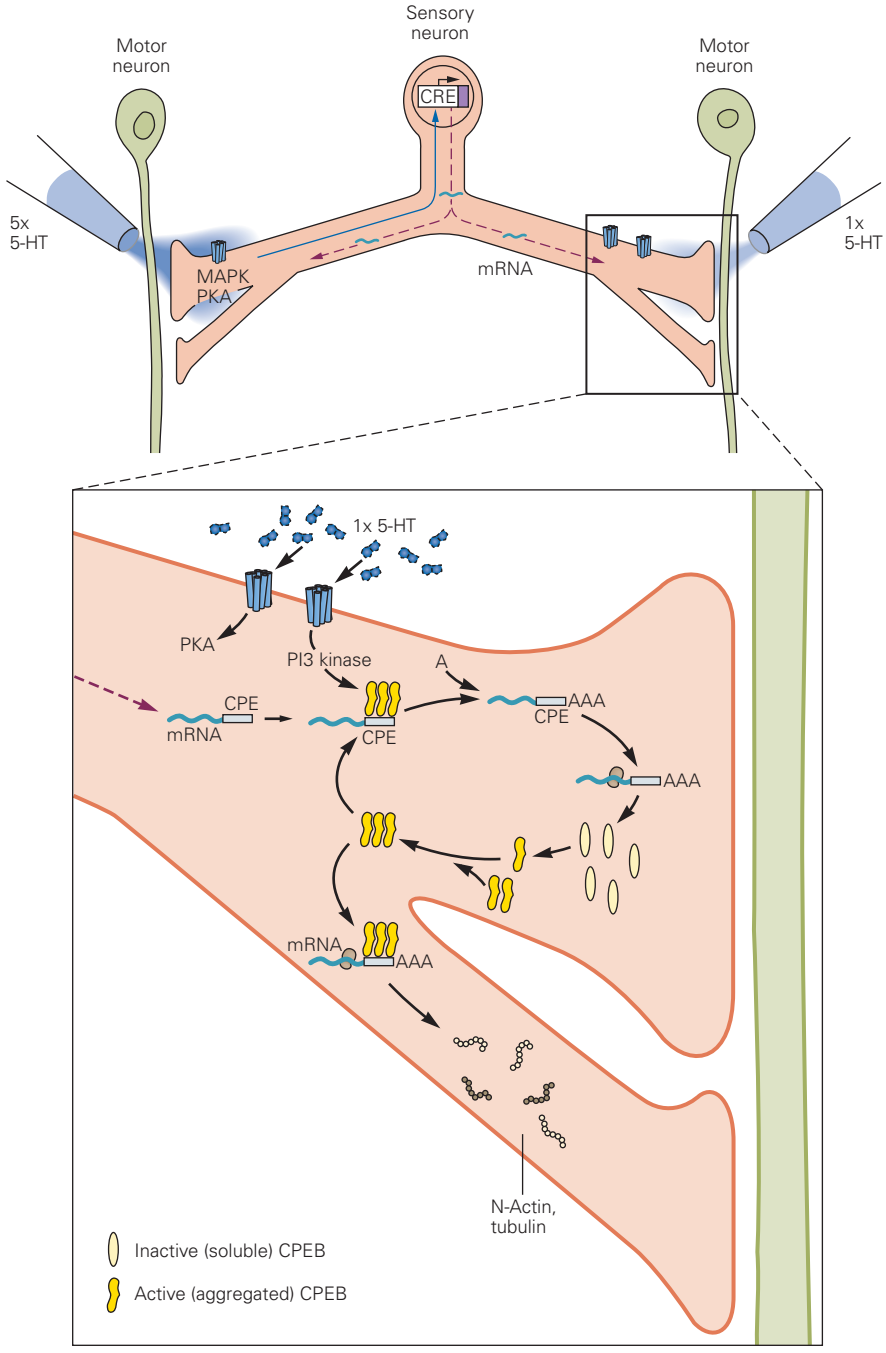

Figure 53–12 A self-perpetuating switch for protein synthesis at axon terminals in *Aplysia* maintains long-term synaptic facilitation. Five pulses of serotonin (**5-HT**) set up a signal that goes back to the nucleus to activate synthesis of mRNA. Newly transcribed mRNAs and newly synthesized proteins in the cell body are then sent to all terminals by fast axonal transport. However, only those terminals that have been marked by at least one pulse of serotonin can use the proteins to grow the new synapses needed for long-term facilitation. The marking of a terminal involves two substances: (1) protein kinase A (**PKA**), which is necessary for the immediate synaptic growth initiated by the proteins transported to the terminals, and (2) phosphoinositide 3 kinase (**PI3 kinase**), which initiates the local translation of mRNAs required to maintain synaptic growth and long-term facilitation past 24 hours. Some of the mRNAs at the terminals encode cytoplasmic polyadenylation element binding protein (**CPEB**), a regulator of local protein synthesis. In the basal state, CPEB is thought to exist in a largely inactive conformation as a soluble monomer that cannot bind to mRNAs. Through some as yet unspecified mechanism activated by serotonin and PI3 kinase, some copies of CPEB convert to an active conformation that forms aggregates. The aggregates function like prions in that they are able to recruit monomers to join the aggregate, thereby activating the monomers. The CPEB aggregates bind the cytoplasmic polyadenylation element (**CPE**) site of mRNAs. This binding recruits the poly(A) polymerase machinery and allows poly(A) tails of adenine nucleotides (**A**) to be added to dormant mRNAs. The polyadenylated mRNAs can now be recognized by ribosomes, allowing the translation of these mRNAs to several proteins. For example, in addition to CPEB, this leads to the local synthesis of N-actin and tubulin, which stabilize newly grown synaptic structures. (Model based on Bailey, Kandel, and Si 2004.)

Memory Stored in a Sensory-Motor Synapse Becomes Destabilized Following Retrieval but Can Be Restabilized

A variety of studies in mammals by Karim Nader and others have found that in its early stages long-term memory storage is dynamic and can be disrupted. In particular, a memory trace can become labile after retrieval and require an additional round of consolidation (so-called *reconsolidation*).

Until recently, it was unclear whether the same set of synapses involved in storing a memory are destabilized and restabilized following retrieval or whether, after synaptic reactivation following a memory, a new set of synapses is regulated. This question was examined for retrieval of long-term sensitization of the gill- and siphon-withdrawal reflex in *Aplysia*. These experiments revealed that a retrieved memory becomes labile as a result of ubiquitin-mediated protein degradation and is then reconsolidated by means new protein synthesis.

Does a similar reconsolidation mechanism occur at sensory-motor synapses that have undergone long-term facilitation? Indeed, when a synapse that has undergone long-term facilitation is reactivated by a brief burst of presynaptic action potentials, that synapse becomes destabilized through protein degradation and requires protein synthesis for restabilization. Such results suggest that reconsolidation of memory involves restabilization of synaptic facilitation at the same synapses at which the initial memory was stored.

Classical Threat Conditioning of Defensive Responses in Flies Also Uses the cAMP-PKA-CREB Pathway

Do the cellular mechanisms for implicit memory storage found in *Aplysia* have parallels in other animals? Studies on aversive learning indicate that the same mechanisms are also used to store memory in the fruit fly *Drosophila* and in rodents, indicating conserved mechanisms throughout Metazoan evolution. The fruit fly is particularly convenient for the study of implicit memory storage because its genome is easily manipulated and, as first demonstrated by Seymour Benzer and his colleagues, the fly can be classically conditioned. In a typical classical conditioning paradigm, an odor is paired with repeated electrical shocks to the feet. The extent of learning is then examined by allowing the flies to choose between two arms of a maze, where one arm contains the odor that had been paired with a shock and the other arm contains an unpaired odor. Following training, a large fraction of wild type flies avoids the arm with the conditioned odor. Several fly mutants have been identified that do not learn to avoid the conditioned odor. These learning-defective mutants have been given imaginatively descriptive names such as *dumb*, *dunce*, *rutabaga*, *amnesiac*, and *PKA-R1*. Of great interest, all of these mutants have defects in the cAMP cascade.

Olfactory conditioning depends on a region of the fly brain called the mushroom bodies. Neurons of the mushroom bodies, called Kenyon cells, receive olfactory input from the antennal lobes, structures similar to the olfactory lobes of the mammalian brain. The Kenyon cells also receive input from dopaminergic neurons that respond to aversive stimuli, such as a foot shock. The dopamine binds to a metabotropic receptor (encoded by the *dumb* gene) that activates a stimulatory G protein and a specific type of Ca^{2+}/calmodulin-dependent adenylyl cyclase (encoded by the *rutabaga* gene), similar to the cyclase involved in classical conditioning in *Aplysia*. The convergent action of dopamine released by the unconditioned stimulus (foot shock) and a rise in intracellular Ca^{2+} triggered by olfactory input leads to the synergistic activation of adenylyl cyclase, producing a large increase in cAMP.

Recent experiments have demonstrated that flies can be classically conditioned when an odorant is paired with direct stimulation of the dopaminergic neurons, bypassing the foot shock. In these experiments, the mammalian P2X receptor (an adenosine triphosphate [ATP]-gated cation channel) is expressed as a transgene in the dopaminergic neurons. The flies are then injected with a caged derivative of ATP. The dopaminergic neurons can then be excited to fire action potentials by shining light on the flies to release ATP from its cage and activate the P2X receptors. When the dopaminergic neurons are activated in this manner in the presence of an odor, the flies undergo aversive conditioning—they learn to avoid the odor. Thus, the unconditioned stimulus activates a dopamine signal that reinforces aversive conditioning, much as serotonin acts as an aversive reinforcement signal for learned defensive responses in *Aplysia.*

A reverse genetic approach has also been used to explore memory formation in *Drosophila.* In these experiments, various transgenes are placed under the control of a promoter that is heat sensitive. The heat sensitivity permits the gene to be turned on at will by elevating the temperature of the chamber housing the flies. This was done in mature animals to minimize any potential effect on the development of the brain. When the catalytic subunit of PKA was blocked by transient expression of an inhibitory transgene, flies were unable

to form short-term memory, indicating the importance of the cAMP signal transduction pathway for associative learning and short-term memory in *Drosophila.*

Long-term memory in *Drosophila* requires new protein synthesis just as in *Aplysia* and other animals. Knockout of a CREB activator gene selectively blocks long-term memory without interfering with short-term memory. Conversely, when the gene is overexpressed, a training procedure that ordinarily produces only short-term memory produces long-term memory.

As in *Aplysia*, certain forms of long-term memory in *Drosophila* also involve CPEB and may depend on prion-like behavior in this protein. Male flies learn to suppress their courtship behavior after exposure to unreceptive females. When the N-terminal domain of CPEB is deleted genetically, there is a loss of long-term courtship memory; the male fly fails to recognize the unreceptive female. This N-terminal domain is rich in glutamine residues and corresponds to the glutamine rich prion-like domain of CPEB in *Aplysia*. Thus several molecular mechanisms involved in implicit memory are conserved from *Aplysia* to flies, and as we will see next, this conservation extends to mammals.

Memory of Threat Learning in Mammals Involves the Amygdala

Research over the past several decades has resulted in a detailed understanding of the neural circuits for both innate and learned defensive responses to threats in mammals, often referred to as "fear learning." In particular, as we have noted in Chapter 42, both types of defensive responses crucially involve the amygdala, which participates in the detection and evaluation of a broad range of significant and potentially dangerous environmental stimuli. The amygdala-based defense system quickly learns about new dangers. It can associate a new neutral stimulus (conditioned stimulus) with a known threat (unconditioned stimulus) after a single paired exposure, and this learned association is often retained throughout life.

The amygdala receives information about threats directly from sensory systems. The input nucleus of the amygdala, the lateral nucleus, is the site of convergence for signals from both unconditioned and conditioned stimuli. Both signals are carried by a rapid pathway that goes directly from the thalamus to the amygdala and a slower indirect pathway that projects from the thalamus to sensory areas of neocortex and from there to the amygdala. These parallel pathways both contribute to conditioning (Figure 53–13). The amygdala also receives higher-order cognitive information by means of connections from cortical associational areas, especially medial cortical regions in the frontal and temporal lobes.

During Pavlovian conditioning, the strength of synaptic transmission is modified in the amygdala. In response to a tone, an extracellular electrophysiological signal proportional to the excitatory synaptic response is recorded in the lateral nucleus. Following pairing of the tone with a shock, the electrophysiological response to the tone is enhanced by an increase in synaptic transmission, which depends on the

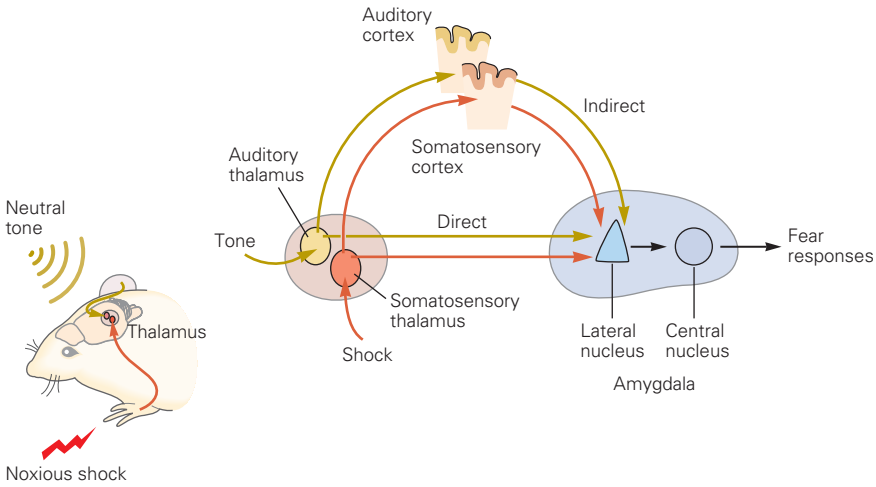

Figure 53–13 Threat learning engages parallel pathways from the thalamus to the amygdala. The signal for the conditioned stimulus, here a neutral tone, is carried by two pathways from the auditory thalamus to the lateral nucleus of the amygdala: by a direct pathway and by an indirect pathway via the auditory cortex. Similarly, the signal for the unconditioned stimulus, here a shock, is conveyed through parallel nociceptive pathways from the somatosensory part of the thalamus to the lateral nucleus, one a direct pathway and one an indirect pathway via the somatosensory cortex. The lateral nucleus in turn projects to the central nucleus, the output nucleus of the amygdala, which activates neural circuits that increase heart rate, produce other autonomic changes, and elicit defensive behaviors that constitute the defensive state. (Reproduced, with permission, from Kandel 2006.)

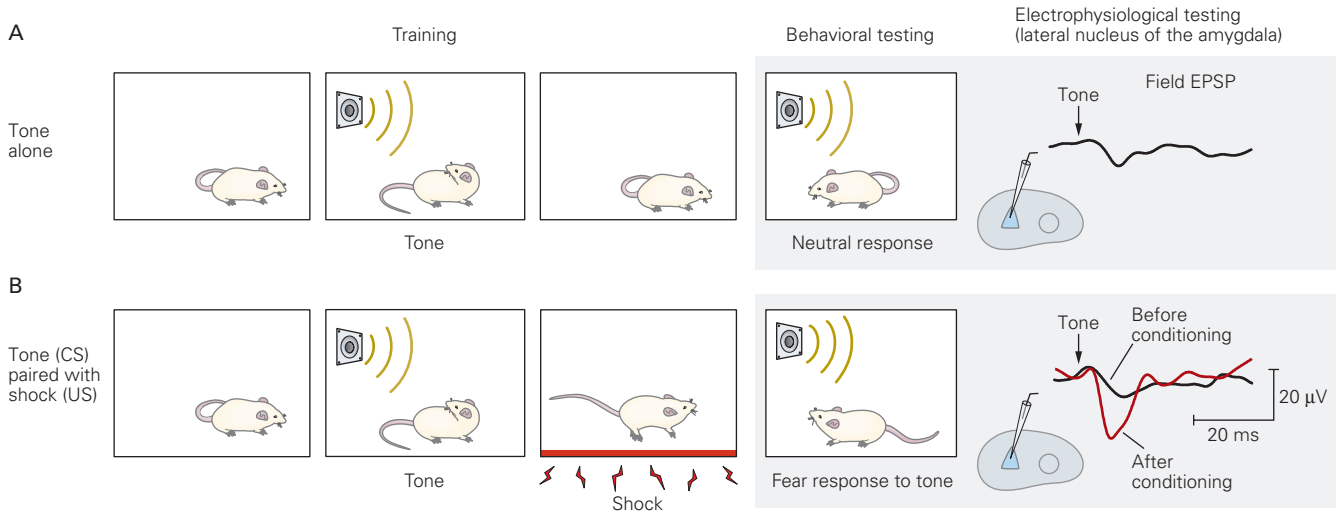

Figure 53–14 Threat learning produces correlated behavioral and electrophysiological changes.

A. An animal ordinarily ignores a neutral tone. The tone produces a small synaptic response in the amygdala recorded by an extracellular field electrode. This field excitatory postsynaptic potential (**field EPSP**) is generated by the small voltage drop between the recording electrode in the amygdala and a second electrode on the exterior of the brain as excitatory synaptic current enters the dendrites of a large population of amygdala neurons.

B. When the tone is presented immediately before a foot shock, the animal learns to associate the tone with the shock. As a result, the tone alone will elicit what the shock previously elicited: It causes the mouse to freeze, an instinctive defense response. After threat conditioning, the electrophysiological response in the lateral nucleus of the amygdala to the tone is greater than the response prior to conditioning. (Abbreviations: **CS**, conditioned stimulus; **US**, unconditioned stimulus.) (Reproduced, with permission, from Rogan et al. 2005.)

convergence of the tone (conditioned stimulus) and the shock (unconditioned stimulus) onto single neurons in the lateral amygdala (Figure 53–14).

It is generally thought that behavioral learning depends on synaptic plasticity. In an effort to understand how such plasticity might occur during learning in the lateral amygdala, researchers have studied *long-term potentiation* (LTP), a cellular model of plasticity. We initially discussed LTP in connection with excitatory synapse function in Chapter 13 and will examine it in detail in Chapter 54 in connection with explicit memory and the hippocampus. In brain slices that include the lateral amygdala, LTP can be induced by high-frequency tetanic stimulation of either the direct or indirect sensory pathways, which produces a long-lasting increase in the excitatory postsynaptic response to these inputs. This change results from a form of homosynaptic plasticity (Figure 53–15).

Long-term potentiation in the lateral nucleus of the amygdala is triggered by Ca^{2+} influx into the postsynaptic neurons in response to strong synaptic activity. The Ca^{2+} entry is mediated by the opening of both *N*-methyl-D-aspartate (NMDA)-type glutamate receptors and L-type voltage-gated Ca^{2+} channels in the postsynaptic cell. Because NMDA receptors are normally blocked by extracellular Mg^{2+}, they require a large synaptic input to generate enough postsynaptic depolarization to relieve this blockade (Chapter 13). L-type channels also require a strong depolarization to open. Thus, LTP is only generated in response to coincident synaptic activity. Calcium influx triggers a biochemical cascade that enhances synaptic transmission through both the insertion of additional α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA)-type glutamate receptors in the postsynaptic membrane and an increase in transmitter release from the presynaptic terminals. As in *Aplysia*, monoamine neurotransmitters, such as norepinephrine and dopamine, released during tetanic stimulation provide a heterosynaptic modulatory signal that contributes to the induction of LTP.

Studies in awake behaving rodents indicate that similar mechanisms contribute to the acquisition of Pavlovian threat conditioning. This form of learning requires postsynaptic NMDA receptors and voltage-gated calcium channels in the lateral amygdala, and it is enhanced by norepinephrine released in lateral amygdala from the locus ceruleus.

In addition, the size of the LTP elicited by electrical stimulation in slices of the amygdala from animals previously trained is less than that found in slices from untrained animals. Because there is an upper limit to the amount by which synapses can be

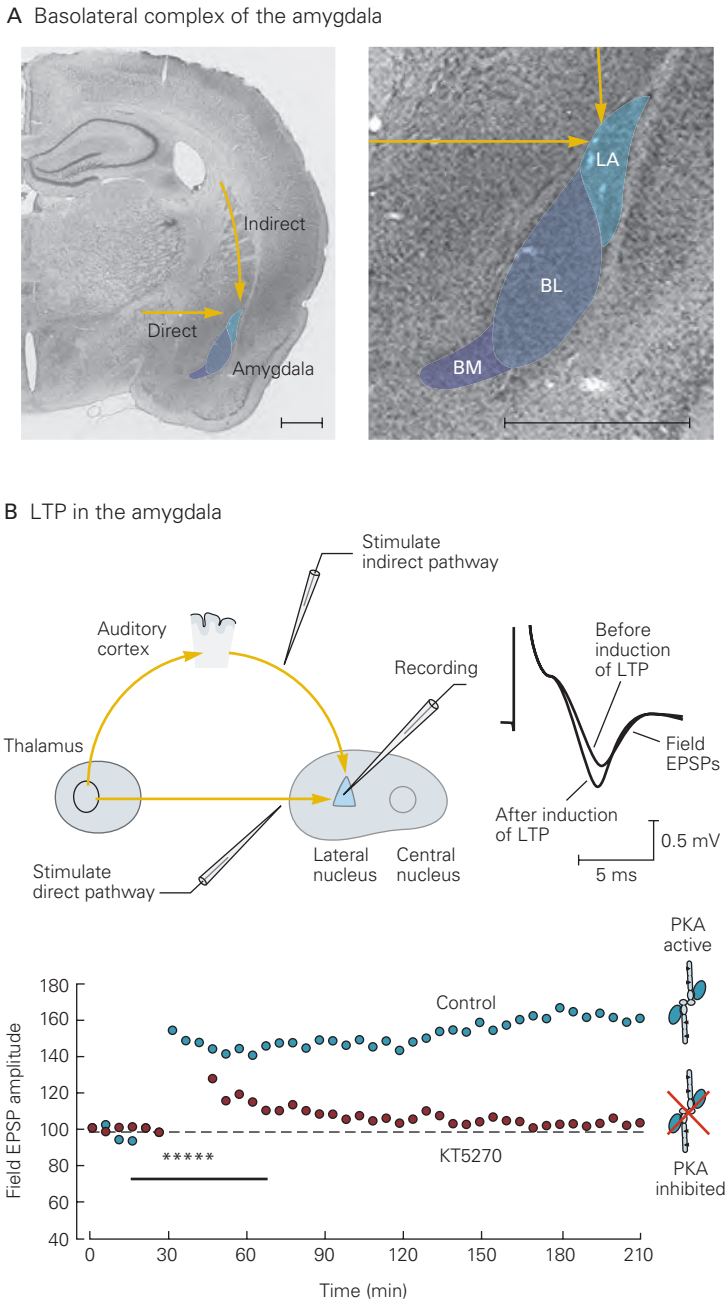

Figure 53–15 Long-term potentiation at synapses in the amygdala may mediate threat conditioning.

A. A coronal brain slice from a mouse shows the position of the amygdala. The enlargement shows three key input nuclei of the amygdala—lateral (**LA**), basolateral (**BL**), and basomedial (**BM**)—which together form the basolateral complex. These nuclei project to the central nucleus, which projects to the hypothalamus and brain stem. (Adapted, with permission, from Maren 1999. Copyright © 1999 Elsevier.)

B. High-frequency tetanic stimulation of the direct or indirect pathway from the thalamus to the lateral nucleus initiates long-term potentiation (**LTP**). The drawing shows the position of the extracellular voltage recording electrode in the lateral nucleus, and the positions of two stimulating electrodes used to activate either the direct pathway or indirect pathway. The plot shows the amplitude of the extracellular field excitatory postsynaptic potential (**EPSP**) in response to stimulation of the indirect cortical pathway during the time course of the experiment. When a pathway is stimulated at a low frequency (once every 30 seconds), the field EPSP is stable. However, when five trains of high-frequency tetanic stimulation are applied (**asterisks**), the response is enhanced for a period of hours. The facilitation depends on protein kinase A (**PKA**) and is compromised when the PKA inhibitor KT5720 is applied (the **bar**). Field EPSPs before and after induction of LTP are also shown. (Adapted, with permission, from Huang and Kandel 1998; Huang, Martin, and Kandel 2000.)

potentiated, this result is taken as evidence that threat conditioning recruits LTP, which precludes further LTP in response to electrical stimulation. Thus, artificially induced LTP and behaviorally induced LTP are closely related.

Two types of genetic experiments also strongly support the idea that an LTP-like phenomenon contributes to the cellular mechanism for storing the memory of a learned threat. First, genetic disruption of the GluN2B (NR2B) subunit of the NMDA receptor interferes both with threat conditioning and the induction of LTP in pathways that transmit the conditioned stimulus signal to the lateral amygdala. Moreover, this mutation affects only learned threats; it does not affect responses to unconditioned threats or routine synaptic transmission. Conversely, overexpression of the GluN2B subunit facilitates learning. Similarly, disruption of CREB signaling, a step downstream from Ca^{2+} influx, interferes with conditioning, whereas enhancement of CREB activity facilitates learning.

Does the LTP important for threat learning involve insertion of new AMPA receptors, as observed in brain slices? To address this question, researchers infected pyramidal neurons in the lateral nucleus with a genetically engineered virus that did not damage the neurons but caused them to express AMPA receptors tagged with a fluorescent label. Threat conditioning led to an increase in insertion of the tagged AMPA receptors into the cell membrane, similar to what is seen during experimentally induced LTP in brain slices. When a different virus was used to express a C-terminal portion of the AMPA receptor that competes with and prevents the insertion of endogenous AMPA receptors, memory for learned threat was substantially reduced, even though the virus infected only 10% to 20% of the neurons in the lateral nucleus. This surprising result suggests that LTP needs to be induced at nearly all activated synapses to effectively support threat learning.

One of the virtues of the Pavlovian paradigm is its amenability to experimental study due to the fact that specific stimuli are transmitted to the amygdala by known pathways. This has allowed experimenters to directly activate conditioned stimulus or unconditioned stimulus pathways, bypassing the normal sensory input. Such studies have provided convincing evidence implicating these pathways to the amygdala in threat learning.

Based on these findings, researchers explored whether threat learning could be induced when they paired an auditory conditioned stimulus (tone) with direct depolarization of lateral amygdala neurons, instead of using an external, pain-eliciting unconditioned shock stimulus to produce the depolarization via the unconditioned stimulus pathway to the lateral amygdala. To accomplish this, they used an optogenetic approach (Chapter 5). They injected a virus into the amygdala to express channelrhodopsin-2, a light-activated excitatory cation channel, in lateral amygdala neurons. Following pairing of the auditory stimulus with a light pulse that depolarized lateral amygdala cells, presentation of the tone alone elicited conditioned freezing. The amount of freezing was greater when norepinephrine was present, which is further evidence that modulatory pathways also have a role in synaptic facilitation in this circuit. Thus, an aversive shock itself is not necessary to induce threat learning. Rather, it is the association of a stimulus with activation of the lateral amygdala that is key.

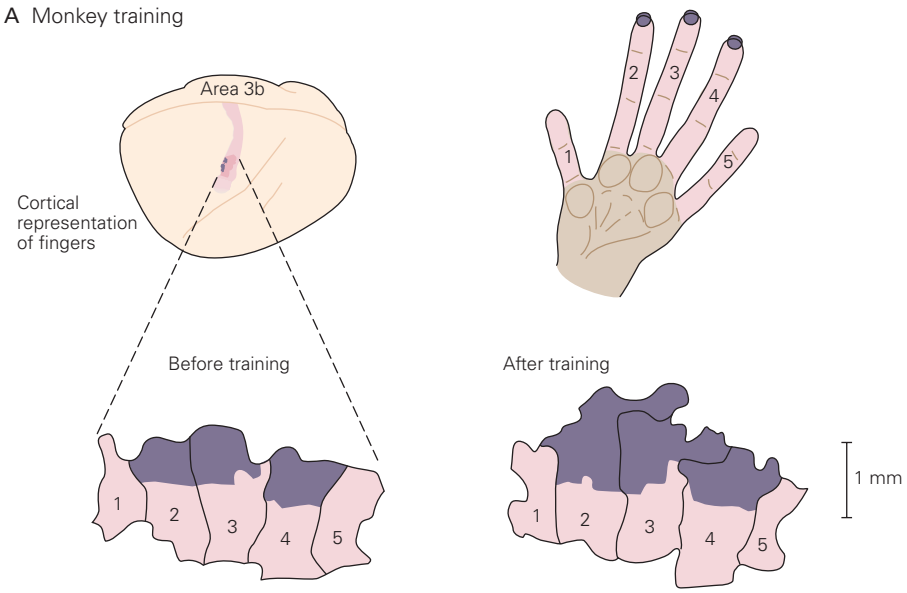
Other studies demonstrated the possibility of artificially manipulating the amygdala to impair as well as to instantiate, threat memory. They first trained animals to associate a foot shock with optogenetic stimulation of auditory inputs to the amygdala. They then delivered a pattern of optogenetic stimulation that generated *long-term depression* (LTD) of the auditory input to the amygdala, a form of synaptic plasticity in which weak, repetitive stimulation decreases the strength of synaptic transmission. Induction of LTD was able to inactivate the memory of the shock. Then, using a pattern of optical stimulation that produced LTP of the same auditory input, they found that the memory of the shock could be reinstated. The findings that inactivation and reactivation of a memory could be engineered using LTD and LTP strengthened the possible causal link between synaptic strength and behavioral memory storage.

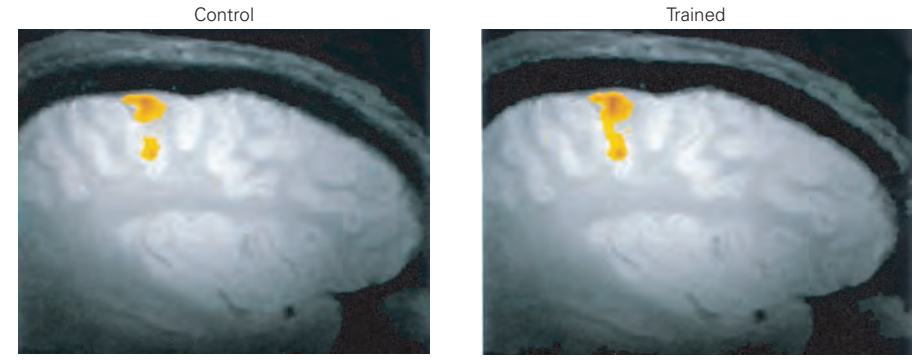
The persistence of the synaptic changes underlying the memory for a threat depend on gene expression and protein synthesis in the amygdala, much like long-term memory in *Aplysia* and *Drosophila*. Thus, cAMP-dependent protein kinase and MAPK activate the transcription factor CREB to initiate gene expression. The importance of CREB is underscored by the finding that different neurons in the lateral amygdala have varying levels of CREB expression prior to threat conditioning. Neurons that express a larger than average amount of CREB are selectively recruited during learning. Conversely, if neurons with a large resting level of CREB are selectively ablated after learning, memory is impaired.

While most of the work on the neural mechanisms of threat conditioning has involved the lateral nucleus of the amygdala, in recent years, evidence has accumulated that plasticity in the central nucleus is also important. The central nucleus receives direct and indirect inputs from the lateral nucleus and forms synaptic connections with neurons in the periaqueductal gray region in the midbrain, which projects to the brain stem to control a number of defensive reactions, including freezing behavior. Within a lateral cell group of the central nucleus, inhibitory cells called PKC delta neurons control the activity of the output neurons in the medial cell group that project to the periaqueductal gray.

Memory for threat conditioning in humans also involves the amygdala. Thus, in humans, damage to the amygdala impairs the implicit memory of threat conditioning but not the explicit memory of having been conditioned. Functional imaging studies have found that the amygdala is activated by threats even when the person is not aware of the presence of the threat because the stimulus was subliminal. Although human studies are limited in their ability to reveal neurobiological details, they demonstrate the relevance of the animal work for human psychopathology.

In summary, Pavlovian threat conditioning has emerged as one of the most useful experimental





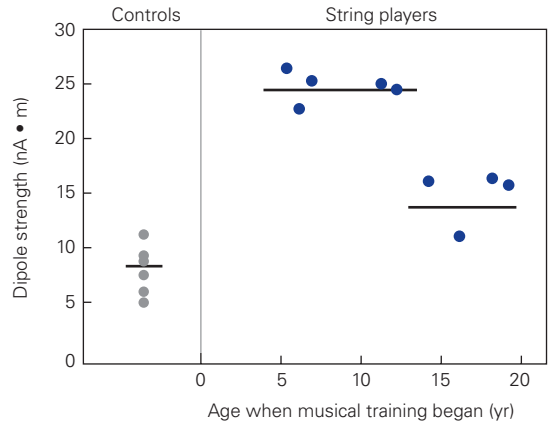


Figure 53–16 Training expands representation of inputs from the fingers in the cortex.

A. A monkey was trained for 1 hour per day to perform a task that required repeated use of the tips of fingers 2, 3, and occasionally 4. After training, the portion of area 3b of the somatosensory cortex representing the tips of the stimulated fingers (**dark color**) is substantially greater than normal (measured 3 months prior to training). (Adapted, with permission, from Jenkins et al. 1990.)

B. 1. A human subject trained to do a rapid sequence of finger movements will improve in accuracy and speed after 3 weeks of daily training (10–20 minutes each day). Functional magnetic resonance imaging scans of the primary motor cortex (based on local blood oxygenation level–dependent signals) after training show that the region activated in trained subjects (**orange region**) is larger than the region activated in untrained (controls). The control subjects received no training and performed unlearned finger movements using the same hand as control subjects. The change in cortical representation in trained subjects persisted for several months. (Reproduced, with permission, from Karni et al. 1998. Copyright © 1998 National Academy of Sciences.)

2. The size of the cortical representation of the fifth finger of the left hand is greater in string players than in nonmusicians. The graph plots the dipole strength obtained from magnetoencephalography, a measure of neural activity. The increase is most pronounced in musicians that began musical training before age 13. (Reproduced, with permission, from Elbert et al. 1995. Copyright © 1995 AAAS.)

models for studying associative learning and memory in the mammalian brain. In part, this is due to the fact that the behavioral paradigm has been applied successfully across diverse species, from flies to humans, and thus builds upon the earlier progress that invertebrate models have made.

Learning-Induced Changes in the Structure of the Brain Contribute to the Biological Basis of Individuality

To what extent do the anatomical alterations in synapses required for long-term memory storage alter the large-scale functional architecture of the mature brain? The answer is well illustrated by the fact that the maps of the body surface in the primary somatic sensory cortex differ among individuals in a manner that reflects their use of specific sensory pathways. This remarkable finding results from the expansion or retraction of the connections of sensory pathways in the cortex according to the specific experience of the individual (Chapter 49).

The reorganization of afferent inputs as a result of behavior is also evident at lower levels in the brain, specifically at the level of the dorsal column nuclei, which contain the first synapses of the somatic sensory system. Therefore, organizational changes probably occur throughout the somatic afferent pathway.

The process by which experience alters the maps of somatosensory inputs in the cortex is illustrated in an experiment in which adult monkeys were trained to use their middle three fingers at the expense of other fingers to obtain food. After several thousand trials of this behavior, the area of cortex devoted to the middle fingers expanded greatly (Figure 53–16A). Thus, practice may expand synaptic connections by strengthening the effectiveness of existing connections.

The normal development of somatosensory input to cortical neurons may depend on the level of activity in neighboring afferent axons. In one experiment using monkeys, the skin surfaces of two adjacent fingers were surgically connected so that the connected fingers were always used together, thus ensuring that their afferent somatosensory axons were normally coactivated. As a result, the normally sharp discontinuity between the zones in the somatosensory cortex that receive inputs from these digits was abolished. Thus, normal development of the boundaries of representation of adjacent fingers in the cortex may be guided not only genetically but also through experience. Fine tuning of cortical connections may depend on associative mechanisms such as LTP, similar to the role of cooperative activity in shaping the development of ocular dominance columns in the visual system (Chapter 49).

This plasticity is evident in humans as well. People trained to perform a task with their fingers show an expansion in the fMRI signal in the primary motor cortex during performance of the task (Figure 53–16B). Thomas Elbert explored the hand representation in the motor cortex of string instrument players. These musicians use their left hand for fingering the strings, manipulating the fingers in a highly individuated way. By contrast, the right hand, used for bowing, is used almost like a fist. The representation of the right hand in the cortex of string instrument players is the same as that of nonmusicians. But the representation of the left hand is greater than in nonmusicians and substantially more prominent in players who started to play their instrument prior to age 13 years (Figure 53–16B).

Because each of us is brought up in a somewhat different environment, experiencing different combinations of stimuli and developing motor skills in different ways, each individual's brain is uniquely modified. This distinctive modification of brain architecture, along with a unique genetic makeup, constitutes a biological basis for individuality.

Highlights

1. Many aspects of personality are guided by implicit memory. A great deal of what we experience—what we perceive, think, fantasize—is not directly controlled by conscious thought.
2. In mammals, both innate and learned defensive responses involve the amygdala. The amygdala-based defense system quickly learns about new dangers. It can associate a new neutral (conditioned) stimulus with a known threatening (unconditioned) stimulus on a single paired exposure, and this learned association is often retained throughout life.
3. During Pavlovian conditioning, the strength of synaptic transmission is modified in the lateral amygdala by pairing the conditioned and unconditioned stimuli. As a result, electrophysiological responses of neurons in the lateral amygdala are enhanced and behavioral learning occurs.
4. Many of the molecular mechanisms underlying threat conditioning in invertebrates also contribute to conditioning in mammals.
5. Damage to the human amygdala impairs implicit threat conditioning but does not affect the explicit memory of having been conditioned.

6. Habits are routines that are acquired gradually by repetition and are the result of a distinct form of implicit learning. As with all forms of implicit learning, habits are expressed in action alone, without conscious control, and independent of verbal reports.
7. As these arguments make clear, the empirical study of unconscious psychic processes was severely limited for many years by the lack of suitable experimental methods. Today, however, biology has a wide range of empirical methods that are providing cellular and molecular insights that are expanding our understanding of a wide range of mental activities.

The Hippocampus and the Neural Basis of Explicit Memory Storage

Explicit memory—the conscious recall of information about people, places, objects, and events—is what people commonly think of as memory. Sometimes called *declarative memory*, it binds our mental life together by allowing us to recall at will what we ate for breakfast, where we ate it, and with whom. It allows us to join what we did today with what we did yesterday or the week or month before that.

Two structures in the mammalian brain are particularly critical for encoding and storing explicit memory: the prefrontal cortex and the hippocampus (Chapter 52). The prefrontal cortex mediates working memory, which can be actively maintained for only very short periods and is then rapidly forgotten, such as a password that is remembered only until it is entered. Information in working memory can be stored elsewhere in the brain as long-term memory for periods ranging from days to weeks to years, and throughout a lifetime. Although long-term storage of explicit memory requires the hippocampus, the ultimate storage site for most declarative memory is thought to be the cerebral cortex.

In this chapter, we focus on the cellular, molecular, and network mechanisms of the hippocampus that underlie the long-term storage of explicit memory. Because the hippocampus receives its major input from a region of the cerebral cortex called the entorhinal cortex, an area that processes many forms of sensory input, we also consider how information from the entorhinal cortex is transformed by the hippocampus. In particular, we examine how neural activity in the entorhinal cortex and hippocampus contributes to

spatial memory by encoding a representation of an animal's location in its environment.

Explicit Memory in Mammals Involves Synaptic Plasticity in the Hippocampus

Unlike working memory, which is thought to be maintained by ongoing neural activity in the prefrontal cortex (Chapter 52), the long-term storage of information is thought to depend on long-lasting changes in the strength of connections among specific ensembles of neurons (neural assemblies) in the hippocampus that encode particular elements of memory.

The idea that memory storage involves long-lasting structural changes in the brain, first referred to as an "engram" by the German biologist Richard Semon in the early 20th century, dates back to the French philosopher Rene Descartes. In an attempt to locate an engram, the American psychologist Karl Lashley examined the effects of lesions in different regions of the neocortex on the ability of a rat to learn to navigate a maze. Since the performance in the maze seemed to be directly proportional to the size of the lesion, rather than its precise location, Lashley concluded that any memory trace must be distributed throughout the brain. Although it is now generally accepted that storage of an explicit memory is distributed throughout the neocortex, it is also clear that the process of storing memory requires the hippocampus, as demonstrated by the pioneering studies of Brenda Milner on patient H.M. (Chapter 52) and subsequent studies in animals with targeted lesions of the hippocampus. Thus, understanding how the brain stores explicit memory depends on an understanding of how the cortico-hippocampal circuit processes and stores information.

The nature of the basic mechanisms for memory storage was and remains the subject of much speculation and debate among psychologists and neuroscientists. One influential theory was proposed by the Canadian psychologist Donald Hebb, who suggested in 1949 that memory-encoding neural assemblies may be generated when synaptic connections are strengthened based on experience. According to *Hebb's rule*: "When an axon of cell A . . . excites cell B and repeatedly or persistently takes part in firing it, some growth process or metabolic change takes place in one or both cells so that A's efficiency as one of the cells firing B is increased." The key element of Hebb's rule is the requirement for coincidence of pre- and postsynaptic firing, and so the rule has sometimes been rephrased as "Cells that fire together, wire together." A similar Hebbian coincidence principle is thought to be involved in fine-tuning synaptic connections during the late stages of development (Chapter 49). Hebb's ideas were later refined by the theoretical neuroscientist David Marr, based on a consideration of the hippocampal circuit.

The hippocampus comprises a loop of connections that process multimodal sensory and spatial information from the superficial layers of the nearby entorhinal cortex. This information passes through multiple synapses before arriving at the hippocampal CA1 region, the major output area of the hippocampus. The critical importance of CA1 neurons in learning and memory is seen in the profound memory loss exhibited by patients with lesions in this region alone, an observation supported by numerous animal studies. Information from the entorhinal cortex reaches CA1 neurons along two excitatory pathways, one direct and one indirect.

In the indirect pathway, the axons of neurons in layer II of the entorhinal cortex project through the *perforant pathway* to excite the granule cells of the dentate gyrus (an area considered part of the hippocampus). Next, the axons of the granule cells project in the *mossy fiber pathway* to excite the pyramidal cells in the CA3 region of the hippocampus. Finally, axons of the CA3 neurons project through the *Schaffer collateral pathway* to make excitatory synapses on more proximal regions of the dendrites of the CA1 pyramidal cells (Figure 54–1). (Because of its three successive excitatory synaptic connections, the indirect pathway is often referred to as the *trisynaptic pathway*). Finally, CA1 pyramidal cells project back to the deep layers of entorhinal cortex and forward to the subiculum, another medial temporal lobe structure that connects the hippocampus with a wide diversity of brain regions.

In parallel with the indirect pathway, the entorhinal cortex also projects directly to CA3 and CA1 hippocampal regions. In the direct pathway to CA1, neurons in layer III of the entorhinal cortex send their axons through the *perforant pathway* to form excitatory synapses on the very distal regions of the apical dendrites of CA1 neurons (such projections are also called the *temporoammonic pathway*). Interactions between direct and indirect inputs at each stage of the hippocampal circuit are likely important for memory storage or recall, although the precise nature of these interactions remains to be determined.

In addition to the above pathways that link different stages of the hippocampal circuit, CA3 pyramidal neurons also make strong excitatory connections with one another. This self-excitation through recurrent collaterals is thought to contribute to associative aspects of memory storage and recall. Under pathological conditions, such self-excitation can lead to seizures.

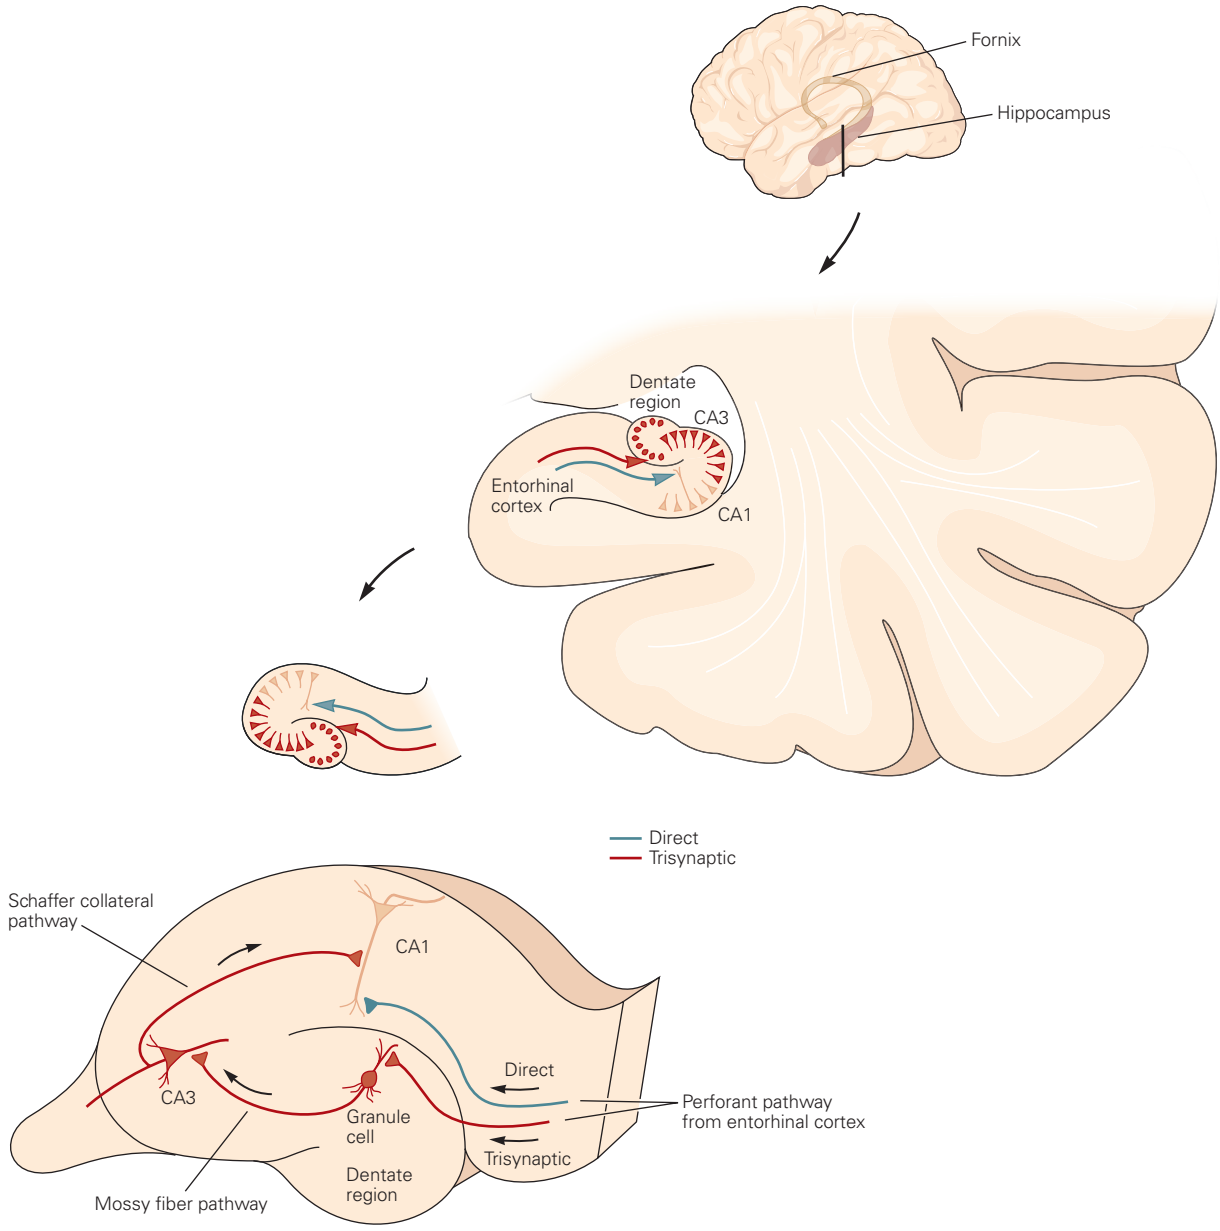

Figure 54–1 The cortico-hippocampal synaptic circuit is important for declarative memory. Information arrives in the hippocampus from the entorhinal cortex through the perforant pathways, which provide both direct and indirect input to pyramidal neurons in area CA1, the major output neurons of the hippocampus. (**Arrows** denote the direction of impulse flow.) The indirect *trisynaptic pathway* has three component connections. Neurons in layer II of the entorhinal cortex send their axons through the perforant path to make excitatory synapses onto the granule cells of the dentate gyrus. The granule cells project through the mossy fiber pathway and make excitatory synapses with the pyramidal cells in area CA3 of the hippocampus. The CA3 cells excite the pyramidal cells in CA1 by means of the Schaffer collateral pathway. In the *direct pathway*, neurons in layer III of the entorhinal cortex project through the perforant path to make excitatory synapses on the distal dendrites of CA3 and CA1 pyramidal neurons without inter vening synapses (shown only for CA1).

Finally, neurons in the relatively small CA2 region, located between CA3 and CA1, receive information from entorhinal cortex layer II through both a direct pathway and an indirect pathway via the dentate gyrus and CA3. The CA2 region also receives strong input from hypothalamic nuclei that release oxytocin and vasopressin, hormones important for social behavior. In turn, CA2 sends a strong output to CA1,

providing CA1 with a third source of excitatory input (in addition to the direct and trisynaptic routes from the entorhinal cortex).

Long-Term Potentiation at Distinct Hippocampal Pathways Is Essential for Explicit Memory Storage

How is information stored in the hippocampal circuit to provide a long-lasting memory trace? In 1973, Timothy Bliss and Terje Lømo discovered that a brief period of high-frequency synaptic stimulation causes a persistent increase in the amplitude of hippocampal excitatory postsynaptic potentials (EPSPs), a process termed *long-term potentiation* or LTP (Chapter 13). The enhancement in the EPSP, in turn, increases the probability that the postsynaptic cell will fire action potentials.

Bliss and Lømo examined the initial stage of the indirect hippocampal pathway—the synapses formed by the perforant pathway from entorhinal cortex layer II neurons with dentate gyrus granule neurons. Subsequent studies showed that brief high-frequency trains of stimulation can induce forms of LTP at nearly all excitatory synapses of this indirect pathway as well as at the direct perforant path synapses with CA3 and CA1 neurons (Figure 54–2). LTP can last for days or even weeks when induced in intact animals using implanted electrodes and can last several hours in isolated slices of hippocampus and in hippocampal neurons in cell culture.

Studies in the different hippocampal pathways have shown that LTP at different synapses is not a single process. Rather, it comprises a family of processes that strengthen synaptic transmission at different hippocampal synapses through distinct cellular and molecular mechanisms. Indeed, even at a single synapse, different forms of LTP can be induced by different patterns of synaptic activity, although these distinct processes share many important similarities.

All forms of LTP are induced by synaptic activity in the pathway that is being potentiated—that is, LTP is homosynaptic. In addition, LTP is synapse specific; only those synapses that are activated by the tetanic stimulation are potentiated. However, the various forms of LTP differ in their dependence on specific receptors and ion channels. In addition, different forms of LTP recruit different second-messenger signaling pathways that act at different synaptic sites. Some forms of LTP result from an enhancement of the postsynaptic response to the neurotransmitter glutamate, whereas other forms of LTP result from the enhancement of glutamate release from the presynaptic terminal, and still other forms of LTP engage both the presynaptic and postsynaptic neurons.

The similarities and differences in the mechanisms of different forms of LTP can be seen by comparing LTP at Schaffer collateral, mossy fiber, and direct entorhinal synapses. In all three pathways, synaptic transmission is persistently enhanced in response to a brief tetanic stimulation. However, the contribution of the *N*-methyl-D-aspartate (NMDA) receptor to the induction of LTP differs in the three pathways. At the Schaffer collateral synapses, the induction of LTP in response to a brief 100-Hz stimulation is completely blocked when the tetanus is applied in the presence of the NMDA receptor antagonist 2-amino-5-phosphonovaleric acid (AP5 or APV). In contrast, APV only partially inhibits the induction of LTP at the direct entorhinal synapses with CA1 neurons and has no effect on LTP at the mossy fiber synapses with CA3 pyramidal neurons (Figure 54–2).

Long-term potentiation in the mossy fiber pathway is largely presynaptic and is triggered by the large Ca^{2+} influx into the presynaptic terminals during the tetanus. The Ca^{2+} influx activates a calcium/calmodulin-dependent adenylyl cyclase, thereby increasing the production of cyclic adenosine monophosphate (cAMP) and activating protein kinase A (PKA; see Chapter 14). This leads to the phosphorylation of presynaptic vesicle proteins that enhance the release of glutamate from the mossy fiber terminals, resulting in an increase in the EPSP. Activity in the postsynaptic cell is not required for this form of LTP. Thus, unlike Hebbian plasticity, mossy fiber LTP is nonassociative.

In the Schaffer collateral pathway, however, LTP is associative, largely as a result of the properties of the NMDA receptors (Figure 54–3; see also Chapter 13). As is the case with most excitatory synapses in the brain, glutamate released from the Schaffer collateral terminals activates both α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) and NMDA receptor-channels in the postsynaptic membrane of CA1 pyramidal neurons. However, unlike the AMPA receptors, activation of the NMDA receptors is associative because it requires simultaneous presynaptic and postsynaptic activity. This is because the pore of the NMDA receptor-channel is normally blocked by extracellular Mg^{2+} at typical negative resting potentials, which prevents these channels from conducting ions in response to glutamate. For the NMDA receptor-channel to function efficiently, the postsynaptic membrane must be depolarized sufficiently to expel the bound Mg^{2+} by electrostatic repulsion. In this manner, the NMDA receptor-channel acts as a coincidence detector: It is functional only when (1) the action potentials in the presynaptic neuron release glutamate that binds to the receptor *and* (2) the membrane of the postsynaptic

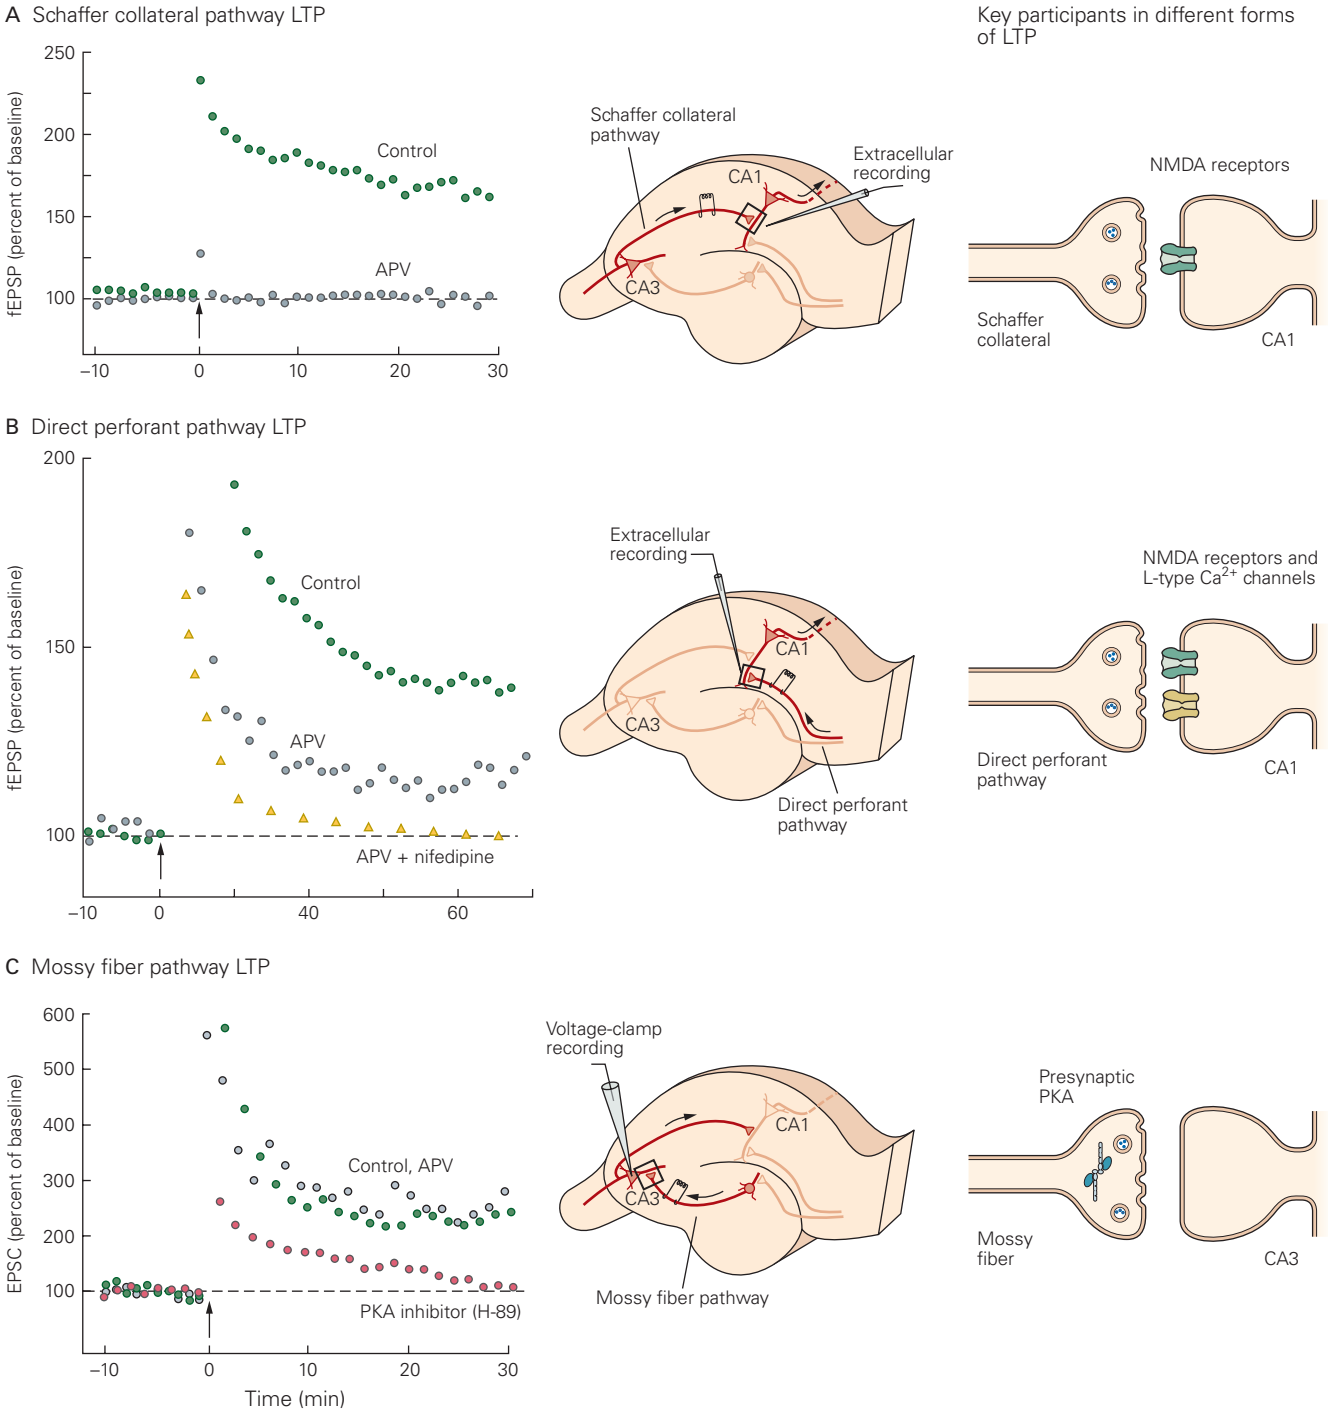

Figure 54–2 Different neural mechanisms underlie long-term potentiation at each of the three synapses in the trisynaptic pathway. Long-term potentiation (**LTP**) occurs at synapses throughout the hippocampus but depends to differing degrees on activation of *N*-methyl-D-aspartate (**NMDA**)-type glutamate receptors.

A. Tetanic stimulation of the Schaffer collateral fibers (at time 0 in the plot) induces LTP at the synapses between presynaptic CA3 pyramidal neurons and postsynaptic CA1 pyramidal neurons. The plot shows the size of the extracellular field excitatory postsynaptic potential (**fEPSP**) as a percentage of the baseline fEPSP prior to induction of LTP. At these synapses, LTP requires activation of the NMDA receptor-channels in the postsynaptic CA1 neurons as it is completely blocked when the tetanus is delivered in the presence of the NMDA receptor antagonist 2-amino-5-phosphonovaleric acid (**APV**). (Adapted from Morgan and Teyler 2001.)

B. Tetanic stimulation of the direct pathway from entorhinal cortex to CA1 neurons generates LTP of the fEPSP that depends partly on activation of the NMDA receptor-channels and partly on activation of L-type voltage-gated Ca^{2+} channels. It is therefore only partially blocked by APV. Addition of APV and nifedipine, a dihydropyridine that blocks L type channels, is needed to fully inhibit LTP.

C. Tetanic stimulation of the mossy fiber pathway induces LTP at the synapses with the pyramidal cells in the CA3 region. In this experiment, the excitatory postsynaptic current (**EPSC**) was measured under voltage-clamp conditions. This LTP does not require activation of the NMDA receptors and so is not blocked by APV. However, it does require activation of protein kinase A (**PKA**) and so is blocked by the kinase inhibitor H-89. (Reproduced, with permission, from Zalutsky and Nicoll 1990. Copyright © 1990 AAAS.)

cell is sufficiently depolarized by strong synaptic activity to relieve the Mg^{2+} block. Thus, the NMDA receptor is able to associate presynaptic and postsynaptic activity to recruit plasticity mechanisms that strengthen connections between pairs of cells, fulfilling Hebb's coincidence requirement for synaptic modification.

What are the functional consequences of the activation of NMDA receptors by strong synaptic excitation? Whereas most AMPA receptor-channels conduct only monovalent cations (Na^+ and K^+), the NMDA receptor-channels have a high permeability to Ca^{2+} (Chapter 13). Thus, the opening of these channels leads to a significant increase in the Ca^{2+}concentration in the postsynaptic cell. The increase in intracellular Ca^{2+} activates several downstream signaling pathways—including calcium/calmodulin–dependent protein kinase II (CaMKII), protein kinase C (PKC), and tyrosine kinases—that lead to changes that enhance the magnitude of the EPSP at Schaffer collateral synapses (Figure 54–3).

Different Molecular and Cellular Mechanisms Contribute to the Forms of Expression of Long-Term Potentiation

Neuroscientists often find it useful to distinguish between the *induction* of LTP (the biochemical reactions activated by the tetanic stimulation) and the *expression* of LTP (the long-term changes responsible for enhanced synaptic transmission). The mechanisms for the induction of LTP at the CA3-CA1 synapse are largely postsynaptic. Is the expression of LTP at this synapse caused by an increase in transmitter release, an increased postsynaptic response to a fixed amount of transmitter, or some combination of the two?

A number of lines of experiments suggest that the form of expression of LTP depends on the type of synapse and precise pattern of activity that induces LTP. In many cases, the expression of LTP in CA1 neurons in response to Ca^{2+} influx through NMDA receptor-channels depends on an increase in the response of the postsynaptic membrane to glutamate. But stronger patterns of stimulation can elicit forms of LTP at the same synapse whose expression depends on presynaptic events that enhance transmitter release.

One of the key pieces of evidence for a postsynaptic contribution to the expression of LTP at Schaffer collateral synapses comes from an examination of so-called "silent synapses." In some recordings from pairs of hippocampal pyramidal neurons, stimulation of an action potential in one neuron fails to elicit a response in the postsynaptic neuron when that neuron is at its resting potential (approximately –70 mV). This result is not surprising, as each hippocampal presynaptic neuron is connected to only a small number of other neurons. What *is* surprising is that in some neuronal pairs that appear unconnected when the postsynaptic membrane is initially at –70 mV, stimulation of the same presynaptic neuron is able to elicit a large excitatory postsynaptic current in the second neuron when the second neuron is depolarized under voltage clamp to +30 mV. In such neuronal pairs, the postsynaptic membrane appears to lack functional AMPA receptors so that the excitatory postsynaptic current (EPSC) is mediated solely by NMDA receptors-channels. As a result, there is no measurable EPSC when the membrane is held at the cell's resting potential (–70 mV) because of the strong Mg^{2+} block of these receptor-channels (the synapse is effectively silent). However, a large EPSC can be generated at +30 mV because the depolarization relieves the block (Figure 54–4).

The key finding from these experiments is seen following the induction of LTP using strong synaptic stimulation. Pairs of neurons initially connected solely by silent synapses now often exhibit large EPSPs at the

Figure 54–3 (Opposite) A model for the induction of long-term potentiation (LTP) at Schaffer collateral synapses. A single high-frequency tetanus induces early LTP. The large depolarization of the postsynaptic membrane (caused by strong activation of the α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid [**AMPA**] receptors) relieves the Mg^{2+} blockade of the *N*-methyl-D-aspartate (**NMDA**) receptor-channels (**1**), allowing Ca^{2+}, Na^+, and K^+ to flow through these channels. The resulting increase of Ca^{2+} in the dendritic spine (**2**) triggers calcium-dependent kinases (**3**)—calcium/calmodulin–dependent kinase (**CaMKII**) and protein kinase C (**PKC**)—leading to induction of LTP. Second-messenger cascades activated during induction of LTP have two main effects on synaptic transmission. Phosphorylation through activation of protein kinases, including PKC, enhances current through the AMPA receptor-channels, in part by causing insertion of new receptors into the spine synapses (**4**). In addition, the postsynaptic cell releases retrograde messengers, such as nitric oxide (**NO**), that activate protein kinases in the presynaptic terminal to enhance subsequent transmitter release (**5**). Repeated bouts of tetanic stimulation induce late LTP. The prolonged increase in Ca^{2+} influx recruits adenylyl cyclase (**6**), which generates cyclic adenosine monophosphate (**cAMP**) that activates protein kinase A (**PKA**). This leads to the activation of MAP kinase, which translocates to the nucleus where it phosphorylates CREB-1. CREB-1 in turn activates transcription of targets (containing the CRE promoter) that are thought to lead to the growth of new synaptic connections (**7**). Repeated stimulation also activates translation of mRNA encoding PKMζ, a constitutively active isoform of PKC (**8**). This leads to a long-lasting increase in the number of AMPA receptors in the postsynaptic membrane.

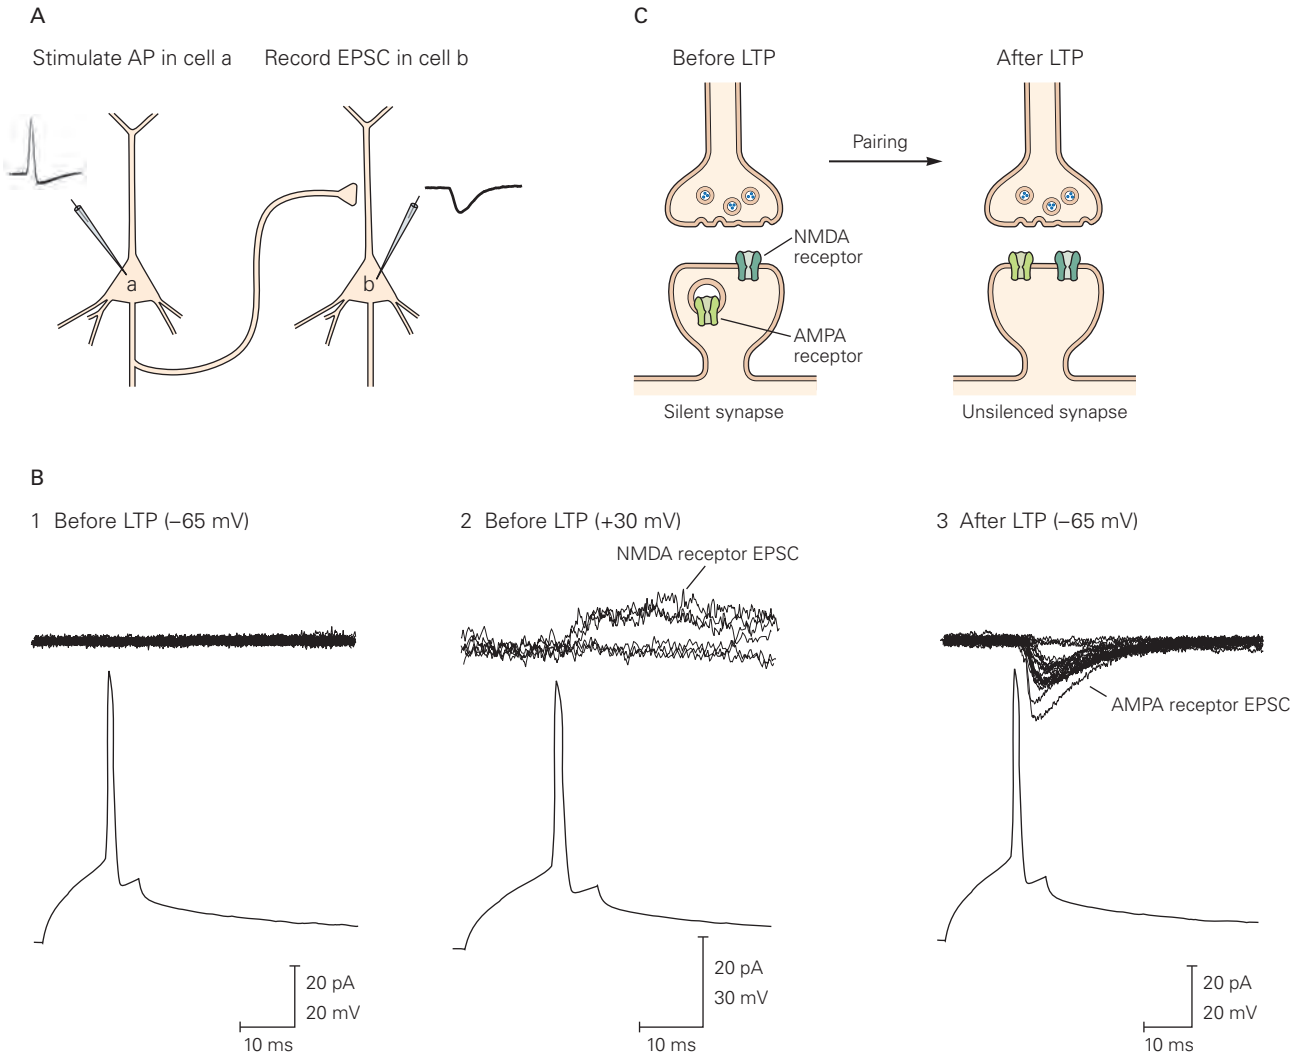

Figure 54–4 Adding α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors to silent synapses during long-term potentiation (LTP).

A. Intracellular recordings are obtained from a pair of hippocampal pyramidal neurons. An action potential (**AP**) is triggered in neuron *a* by a depolarizing current pulse, and the resultant excitatory postsynaptic current (**EPSC**) produced in neuron *b* is recorded under voltage-clamp conditions.

B. Before induction of LTP, there is no EPSC in cell *b* (top traces) in response to an action potential in cell *a* (bottom traces) when the membrane potential of neuron *b* is at its resting value of –65 mV (**1**). However, when neuron *b* is depolarized by the voltage clamp to +30 mV, the *N*-methyl-D-aspartate (**NMDA**) receptors are activated and slow EPSCs characteristic of these receptors are observed (**2**). LTP is then induced by pairing action potentials in neuron *a* with postsynaptic depolarization in neuron *b* to relieve the Mg^{2+} block of the NMDA receptors. After this pairing, fast EPSCs initiated by activation of AMPA receptors are seen in cell *b* (**3**). (Reproduced, with permission, from Montgomery, Pavlidis, and Madison 2001. C. Mechanism of the unsilencing of silent synapses. Prior to LTP, the dendritic spine contacted by a presynaptic CA3 neuron contains only NMDA receptors. Following induction of LTP, intracellular vesicles containing AMPA receptors fuse with the plasma membrane at the synapse, adding AMPA receptors to the membrane.

negative resting potential, and these EPSPs are mediated by AMPA receptors. The simplest interpretation of this result is that LTP somehow recruits new functional AMPA receptors to the silent synapse membrane, a process Roberto Malinow refers to as "AMPAfication."

How does the induction of LTP increase the response of AMPA receptors? The strong synaptic stimulation used to induce LTP triggers glutamate release at both silent and nonsilent synapses on the same postsynaptic neuron. This leads to the opening

of a large number of AMPA receptor-channels at the nonsilent synapses, which in turn produces a large postsynaptic depolarization. The depolarization then propagates throughout the neuron, thus relieving Mg^{2+} block of the NMDA receptor-channels at both the nonsilent and silent synapses. At the silent synapses, the Ca^{2+} influx through the NMDA receptor-channels activates a biochemical cascade that ultimately leads to the insertion of clusters of AMPA receptors in the postsynaptic membrane. These newly inserted AMPA receptors are thought to come from a reserve pool stored in endosomal vesicles within dendritic spines, the site of all excitatory input to pyramidal neurons (Chapter 13). Calcium influx through the NMDA receptor-channels elevates spine Ca^{2+} levels, triggering a postsynaptic signaling cascade that leads to phosphorylation of the cytoplasmic tail of the vesicular AMPA receptors by PKC (Chapter 14), leading to their insertion in the postsynaptic membrane (Figure 54–3).

Because the induction of almost all forms of postsynaptic LTP requires Ca^{2+} influx into the postsynaptic cell, the finding that transmitter release is enhanced during some forms of LTP implies that the presynaptic cell must receive a signal from the postsynaptic cell that LTP has been induced. There is now evidence that calcium-activated second messengers in the postsynaptic cell, or perhaps Ca^{2+} itself, cause the postsynaptic cell to release one or more chemical messengers, including the gas nitric oxide, that diffuse to the presynaptic terminals to enhance transmitter release (Figure 54–3 and Chapter 14). Importantly, these diffusible retrograde signals appear to affect only those presynaptic terminals that have been activated by the tetanic stimulation, thereby preserving synapse specificity.

Long-Term Potentiation Has Early and Late Phases

Long-term potentiation has two phases, early and late, that provide a means of regulating the duration of the enhancement of synaptic transmission. The phase we have focused on up to now lasts for only 1 to 3 hours and is termed early LTP; this phase is typically induced by a single train of 100-Hz tetanic stimulation for 1 second. More prolonged periods of activity (using three or four trains of 100-Hz tetanic stimulation, each lasting 1 second) induce a late phase of LTP that can last 24 hours or even longer. Unlike early LTP, late LTP requires the synthesis of new proteins (Figure 54–5).

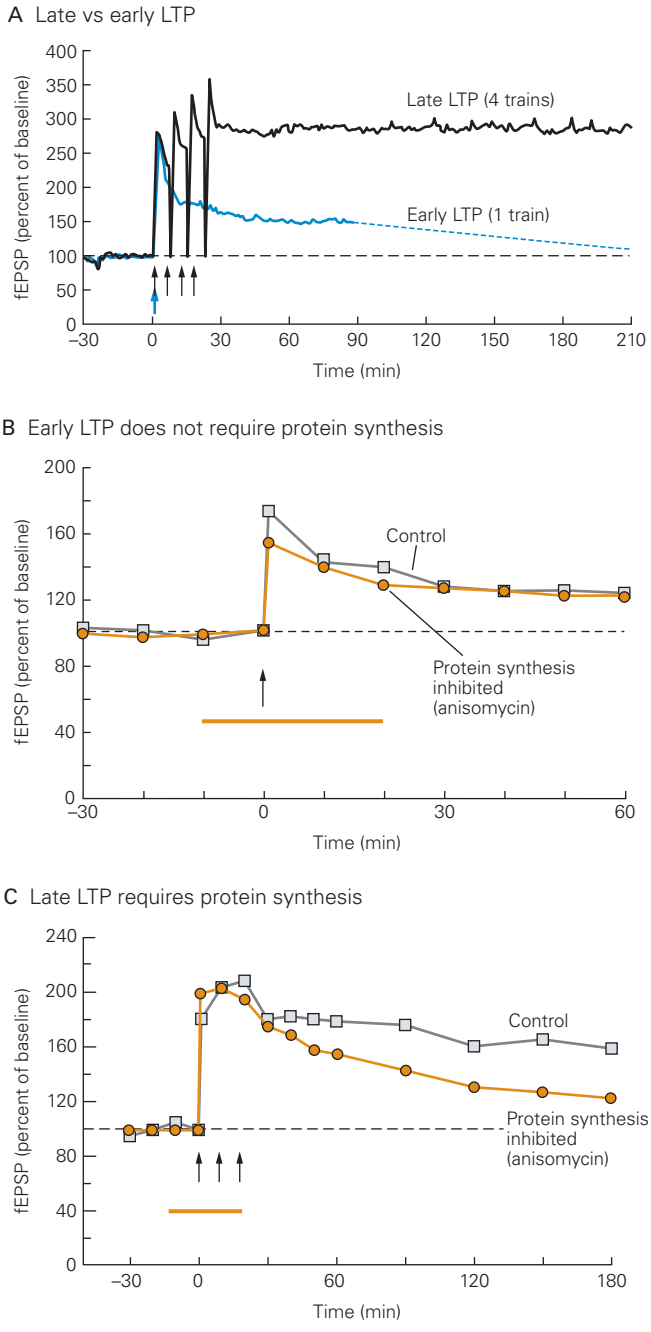

Figure 54–5 (Right) Long-term potentiation (LTP) in the CA1 region of the hippocampus has early and late phases.

A. Early LTP is induced by a single tetanus lasting 1 second at 100 Hz, whereas late LTP is induced by four tetani given 10 minutes apart. Early LTP of the field excitatory postsynaptic potential (**fEPSP**) lasts only 1 to 2 hours, whereas the late LTP lasts more than 8 hours (only the first 3.5 hours are shown).

B. Early LTP induced by one tetanus is not blocked by anisomycin (**bar**), an inhibitor of protein synthesis.

C. Late LTP, normally induced by three trains of stimulation, is blocked by anisomycin. (Three or four trains can be used to induce late LTP.) (Panels B and C reproduced, with permission, from Huang and Kandel 1994.)

Whereas the early phase of LTP is mediated by changes at existing synapses, late LTP is thought to result from the growth of new synaptic connections between pairs of co-activated neurons.

Although the mechanisms for early LTP in the Schaffer collateral and mossy fiber pathways are quite different, the mechanisms for late LTP in the two pathways appear similar (Figure 54–3). In both pathways, late LTP recruits the cAMP and PKA signaling pathway to activate by phosphorylation the cAMP response element binding protein (CREB) transcription factor, leading to the synthesis of new mRNAs and proteins. Like sensitization of the gill-withdrawal reflex in *Aplysia*, which also involves cAMP, PKA, and CREB (Chapter 53), late LTP in the Schaffer collateral pathway is synapse specific. When two independent sets of synapses in the same postsynaptic CA1 neuron are stimulated using two electrodes spaced some distance apart, the application of four trains of tetanic stimulation to one set of synapses induces late LTP only at the activated synapses; synaptic transmission is not altered at the second set of synapses that were not tetanized.

How can late LTP achieve synapse specificity given that transcription and most translation occurs in the cell body, such that newly synthesized proteins should be available to all synapses of a cell? To explain synapse specificity, Uwe Frey and Richard Morris proposed the synaptic capture hypothesis, in which synapses that are activated during the tetanus are tagged in some way, perhaps by protein phosphorylation, that enables them to make use of ("capture") the newly synthesized proteins. Frey and Morris tested this idea using the two-pathway protocol described above. They delivered four tetani to induce late LTP at one set of synapses with one electrode and delivered a single tetanus to a second set of synapses with the other electrode. Although a single tetanus on its own induces only early LTP, it is able to induce late LTP when delivered within 2–3 hours of the four tetani from the first electrode. This phenomenon is similar to the synapse-specific capture of long-term facilitation at the sensory-motor neuron synapses in *Aplysia* (Chapter 53).

According to Frey and Morris, the single train of tetanic stimulation, although not sufficient to induce new protein synthesis, is sufficient to tag the activated synapses, allowing them to capture the newly synthesized proteins produced in response to the prior delivery of the four trains of tetanic stimulation. The increased synaptic plasticity that this tagging mechanism affords, and its limitation to the period when newly synthesized proteins are around, may explain the recent finding that hippocampal cell assemblies that store memories of events closely spaced in time have a larger number of common neurons than do cell assemblies for events widely separated in time.

How can a few brief trains of synaptic stimulation produce such long-lasting increases in synaptic transmission? One mechanism proposed by John Lisman depends on the unique properties of CaMKII. After a brief exposure to Ca^{2+}, CaMKII can be converted to a calcium-independent state through its autophosphorylation at threonine-286 (Thr286). This ability to become persistently active in response to a transient Ca^{2+} stimulus has led to the suggestion that CaMKII may act as a simple molecular switch that can extend the duration of LTP following its initial activation.

Studies from Todd Sacktor have suggested that longer-lasting changes that maintain late LTP may depend on an atypical isoform of PKC termed PKMζ (PKM zeta). Most isoforms of PKC contain both a regulatory domain and a catalytic domain (Chapter 14). Binding of diacylglycerol, phospholipids, and Ca^{2+} to the regulatory domain relieves inhibitory domain binding to the catalytic domain, allowing PKC to phosphorylate its protein substrates. In contrast, PKMζ lacks a regulatory domain and so is constitutively active.

Levels of PKMζ in the hippocampus are normally low. Tetanic stimulation that induces LTP leads to an increase in synthesis of PKMζ through enhanced translation of its mRNA. Because this mRNA is present in the CA1 neuron dendrites, its translation can rapidly alter synaptic strength. Blockade of PKMζ with a peptide inhibitor during the tetanic stimulation blocks late LTP but not early LTP. If the blocker is applied several hours after LTP induction, the late LTP that had been established will be reversed. This result indicates that the maintenance of late LTP requires the ongoing activity of PKMζ to maintain the increase in AMPA receptors in the postsynaptic membrane (Figure 54–3). A second atypical PKC isoform may substitute for PKMζ under certain conditions, which may explain the surprising finding that genetic deletion of PKMζ has little effect on late LTP.

Constitutively active forms of protein kinases may not be the only mechanism for maintaining long-lasting synaptic changes in the hippocampus. Repeated stimulation may lead to the formation of new synaptic connections, just as long-term facilitation leads to the formation of new synapses during learning in *Aplysia*. In addition, long-lasting synaptic changes likely involve epigenetic changes in chromatin structure. During late LTP, phosphorylated CREB activates gene expression by recruiting the CREB binding protein (CBP), which acts as a histone acetylase, transferring an acetyl group to specific lysine residues on histone proteins, and thereby producing

long-lasting changes in gene expression. Mutations in CBP impair late LTP and learning and memory in mice. In humans, de novo mutations in the CBP gene underlie Rubinstein-Taybi syndrome, a developmental disorder associated with intellectual impairment. Other studies implicate a second epigenetic mechanism, DNA methylation, in long-lasting synaptic plasticity and learning and memory.

Spike-Timing-Dependent Plasticity Provides a More Natural Mechanism for Altering Synaptic Strength

Under most circumstances, hippocampal neurons do not produce the high-frequency trains of action potentials typically used to induce LTP experimentally. However, a form of LTP termed spike-timing-dependent plasticity (STDP) can be induced by a more natural pattern of activity in which a single presynaptic stimulus is paired with the firing of a single action potential in the postsynaptic cell at a relatively low frequency (eg, one pair per second over several seconds). However, the presynaptic cell must fire just before the postsynaptic cell. If instead the postsynaptic cell fires just before the EPSP, a long-lasting decrease in the size of the EPSP occurs. Such long-term depression of synaptic transmission represents a distinct form of synaptic plasticity from LTP and is described more fully below. If the postsynaptic action potential occurs more than a hundred milliseconds before or after the EPSP, the synaptic strength will not change.

The pairing rules of STDP thus follow Hebb's postulate and result in large part from the cooperative properties of the NMDA receptor-channel. If the postsynaptic spike occurs during the EPSP, it is able to relieve the Mg^{2+} blockade of the channel at a time when the NMDA receptor has been activated by the binding of glutamate. This leads to a large influx of Ca^{2+} through the receptor and the induction of STDP. However, if the postsynaptic action potential occurs prior to the presynaptic release of glutamate, any relief from the Mg^{2+} block will occur when the gate of the receptor-channel is closed (because of the absence of glutamate). As a result, there will be only a small influx of Ca^{2+} through the receptor that is insufficient to induce STDP.

Long-Term Potentiation in the Hippocampus Has Properties That Make It Useful as A Mechanism for Memory Storage

NMDA receptor–dependent LTP at the Schaffer collateral pathway and other hippocampal pathways has three properties with direct relevance to learning and memory (Figure 54–6). First, LTP in such pathways requires the near-simultaneous activation of a large number of afferent inputs, a feature called *cooperativity* (Figure 54–6). This requirement stems from the fact

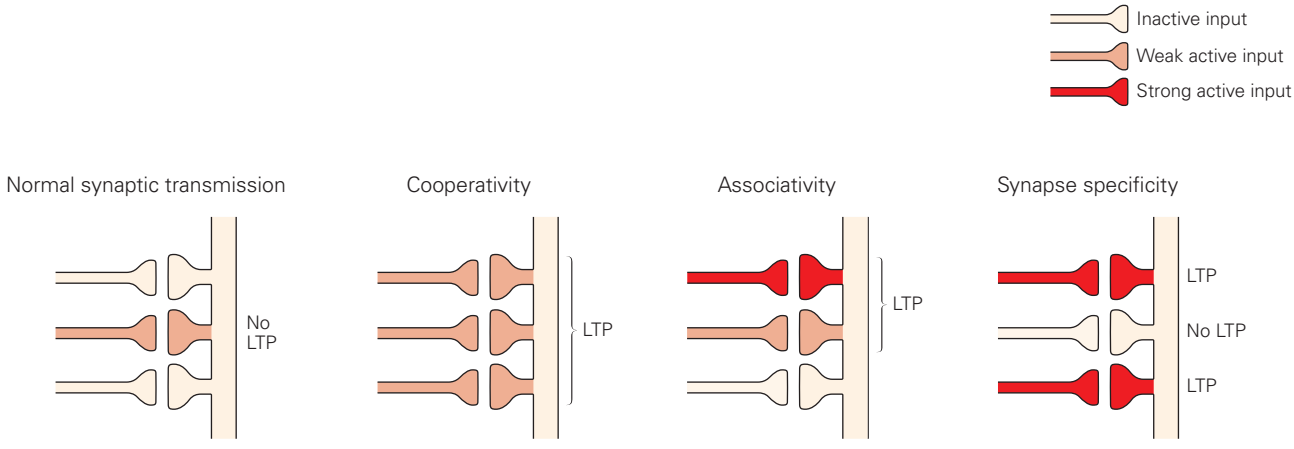

Figure 54–6 Long-term potentiation (LTP) in CA1 pyramidal neurons of the hippocampus shows cooperativity, associativity, and synapse specificity. With normal synaptic transmission, a single action potential in one or a few axons (weak input) leads to a small excitatory postsynaptic potential (EPSP) that is insufficient to expel Mg^{2+} from the *N*-methyl-D-aspartate (NMDA) receptor-channels and thus cannot induce LTP. This ensures that irrelevant stimuli are not remembered. The near-simultaneous activation of several weak inputs during strong activation (cooperativity) produces a suprathreshold EPSP that triggers an action potential, resulting in LTP in all pathways. Stimulation of strong and weak inputs together (associativity) causes LTP in both pathways. In this way, a weak input becomes significant when paired with a powerful one. An unstimulated synapse does not undergo LTP despite the strong stimulation of neighboring synapses. This ensures that memory is selectively stored at active synapses (synapse specificity).

that relief of Mg^{2+} block of the NMDA receptor-channel requires a large depolarization, which is achieved only when the postsynaptic cell receives input from a large number of presynaptic cells.

Second, LTP at synapses with NMDA receptor-channels is *associative.* A weak presynaptic input normally does not produce enough postsynaptic depolarization to induce LTP. However, if the weak input is paired with a strong input that produces a suprathreshold depolarization, the resulting large depolarization will propagate to the synapses with weak input, leading to relief of the Mg^{2+} blockade of the NMDA receptors and induction of LTP at those synapses.

Third, NMDA receptor-dependent LTP is *synapse specific.* If a particular synapse is not activated during a period of strong synaptic stimulation, the NMDA receptors at that site will not be able to bind glutamate and thus will not be activated despite the strong postsynaptic depolarization. As a result, that synapse will not undergo LTP.

Each of these three properties—cooperativity, associativity, and synapse specificity—underlies a key requirement of memory storage. Cooperativity ensures that only events of a high degree of significance, those that activate sufficient inputs, will result in memory storage. Associativity, like associative Pavlovian conditioning, allows an event (or conditioned stimulus) that has little significance in and of itself to be endowed with a higher degree of meaning if that event occurs just before or simultaneously with another more significant event (an unconditioned stimulus). In a network with strong recurrent connections, such as CA3, associative LTP enables a pattern of activity in one group of cells to become linked to a distinct pattern of activity in a separate, but partially overlapping, group of synaptically coupled cells. Such linkages of cell assemblies are thought to enable related events to become associated with one another and to be important for storing and recalling large varieties of experiences, as occurs with explicit memory. Finally, synapse specificity ensures that inputs that convey information not related to a particular event will not be strengthened. Synapse specificity is critical when large amounts of information must be stored in one network, because much more information can be stored in a cell through functional alterations at individual synapses than through blanket changes in a property of the cell, such as its excitability.

Spatial Memory Depends on Long-Term Potentiation

Long-term potentiation is an experimentally induced change in synaptic strength produced by strong direct stimulation of neural pathways. Does this or a related form of synaptic plasticity occur physiologically during explicit memory storage? If so, how important is it for explicit memory storage in the hippocampus?

To date, a large number of experimental approaches have shown that inhibiting LTP interferes with spatial memory. In one approach, a mouse is placed in a pool filled with an opaque fluid (the Morris water maze); to escape from the liquid, the mouse must swim to find a platform submerged in the fluid and completely hidden from view. The animal is released at random locations around the pool and initially encounters the platform by chance. However, in subsequent trials, the mouse quickly learns to locate the platform and then remembers its position based on spatial information—distal markings on the walls of the room in which the pool is located. This task requires the hippocampus. In a nonspatial, or cued, version of this test, the platform is raised above the water surface or marked with a flag so that it is visible, permitting the mouse to navigate directly to it using brain pathways that do not require the hippocampus.

When NMDA receptors are blocked by a pharmacological antagonist injected into the hippocampus immediately before an animal is trained to navigate the Morris water maze, the animal cannot remember the location of the hidden platform using spatial information but can find it in the version of the task with the visible marker. These experiments thus suggest that some mechanism involving NMDA receptors in the hippocampus, perhaps LTP, is involved in spatial learning. However, if the NMDA receptor blocker is injected into the hippocampus *after* an animal has learned a spatial memory task, it does not inhibit subsequent memory recall for that task. This is consistent with findings that NMDA receptors are required for the induction, but not the maintenance, of LTP.

More direct evidence correlating memory formation and LTP comes from experiments with mutant mice that have genetic lesions that interfere with LTP. One interesting mutation is produced by the genetic deletion of the NR1 subunit of the NMDA receptor. Neurons lacking this subunit fail to form functional NMDA receptors. Mice with a general deletion of the subunit die soon after birth, indicating the importance of these receptors for neural function. However, it is possible to generate lines of conditional mutant mice in which the NR1 deletion is restricted to CA1 pyramidal neurons and occurs only 1 or 2 weeks after birth (see Chapter 2, Figure 2–8, for a description of how this mouse line is generated). These mice survive into adulthood and show a loss of LTP in the Schaffer collateral pathway. Although this disruption is highly

localized, the mutant mice have a serious deficit in spatial memory (Figure 54–7).

In some cases, genetic changes can actually enhance both hippocampal LTP and spatial learning and memory. One of the first examples of such an enhancement comes from studies of a mutant mouse that overexpresses the NR2B subunit of the NMDA receptor. This subunit is normally present at hippocampal synapses in the early stages of development but is downregulated in adults. Receptors that include this subunit allow more Ca^{2+} influx than those without the subunit. In mutant mice that overexpress the NR2B subunit, LTP is enhanced, presumably because of an enhancement in Ca^{2+} influx. Importantly, learning and memory for several different tasks are also enhanced (Figure 54–8).

One concern with gene knockouts or transgene expression is that such mutations might lead to subtle developmental abnormalities. That is, changes in the size of LTP and spatial memory in the mutant animals could be the result of an early developmental alteration in the wiring of the hippocampal circuit rather than a change in the basic mechanisms of LTP. This possibility can be addressed by reversibly turning on and off a transgene that interferes with LTP.

Reversible gene expression has been used to explore the role of CaMKII, whose autophosphorylation properties and function in LTP were discussed earlier in this chapter (see also Chapter 2, Figure 2–9, for a description of the methodology). Mutation of the autophosphorylation Thr286 site to the negatively charged amino acid aspartate mimics the effect of autophosphorylation at Thr286 and converts the CaMKII to a calcium-independent form. Transgenic expression of this dominant mutation of CaMKII (CaMKII-Asp286) results in a systematic shift in the relation between the frequency of a tetanus and the resultant change in synaptic strength during long-term plasticity.

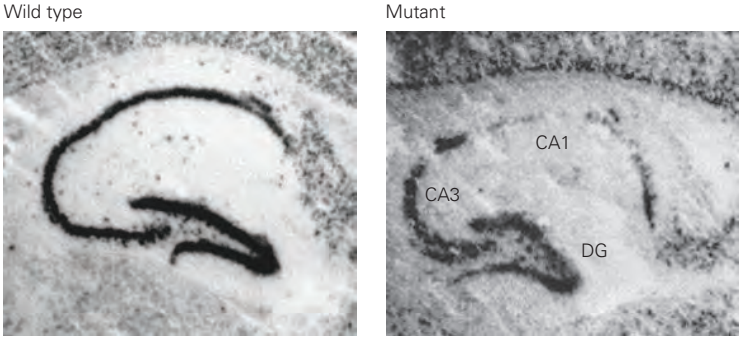
In the transgenic mice, tetanic stimulation at an intermediate frequency of 10 Hz, which normally induces a small amount of LTP, induces long-term depression of synaptic transmission in the Schaffer collateral pathway (Figure 54–9A). In contrast, the transgenic mice showed normal LTP to a 100-Hz tetanus. The defect in synaptic plasticity with 10-Hz stimulation is associated with an inability of the mutant mice to remember spatial tasks. However, the defects in the induction of LTP and in spatial memory can be fully extinguished when the mutant gene is switched off in the adult, showing that the memory defect is not due to a developmental abnormality (Figure 54–9).

These several experiments using restricted knockout and overexpression of the NMDA receptor and regulated overexpression of CaMKII-Asp286 make it clear that the molecular pathways important for LTP at Schaffer collateral synapses are also required for spatial memory. However, such results do not directly show that spatial learning and memory are actually associated with an enhancement in hippocampal synaptic transmission. Mark Bear and his colleagues addressed this question by monitoring the strength of synaptic transmission at the Schaffer collateral synapses in vivo in rats.

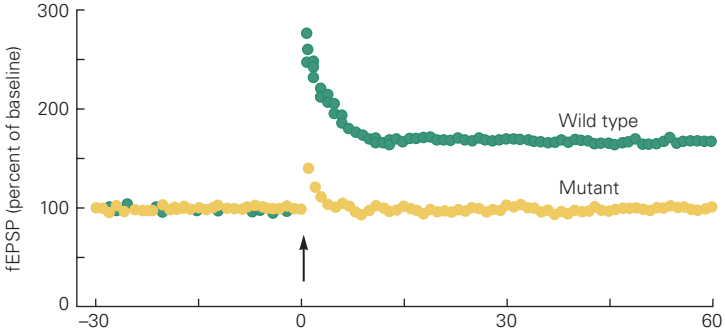
Recordings were made of synaptic strength using an array of extracellular electrodes to stimulate the Schaffer collateral inputs and another array to record the extracellular field EPSPs at various locations. Rats were then trained to avoid one side of a box through administration of a foot shock; the field EPSPs were remeasured after training, showing a small but significant increase in the amplitude of synaptic transmission at a subset of the recording electrodes. Does the increase in synaptic transmission during learning result from LTP or some other mechanism? Because the amount of LTP at a given synapse is finite, if learning does indeed recruit an LTP-like process, then the ability to induce LTP by tetanic stimulation after learning should be reduced. Indeed, Bear and his colleagues found that the magnitude of LTP is diminished at those recording sites where the behavioral training produced the greatest enhancement in the field EPSP. This result is similar to findings in the amygdala, where fear learning reduces the magnitude of LTP induced by subsequent tetanic stimulation.

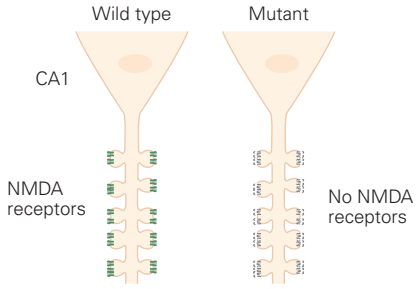
If LTP-like changes take place during memory formation in the hippocampus, such changes would be expected only in a small subset of synapses, namely those that participate in the storage of the particular memory. Different memories probably correspond to different assemblies of cells with strengthened synaptic interconnections. If this is true, however, hippocampal memories should be vulnerable to disruption by manipulations that indiscriminately alter synaptic strength within the network as a whole. To test this idea, investigators induced LTP throughout the dentate gyrus *after* hippocampal-dependent spatial training in the water maze task. This protocol indeed impairs the animal's memory of the goal location in the water maze. Control animals that are given NMDA receptor antagonists after learning but prior to high-frequency stimulation exhibit normal spatial memory. These results indicate that the memory impairment was generated specifically as a consequence of the generation of indiscriminate LTP, which likely disrupts the specific pattern of strong and weak synapses that encode memory of the goal location.

A Action of Cre recombinase is restricted to CA1 region

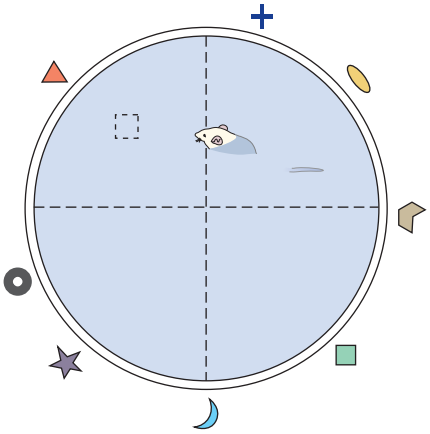


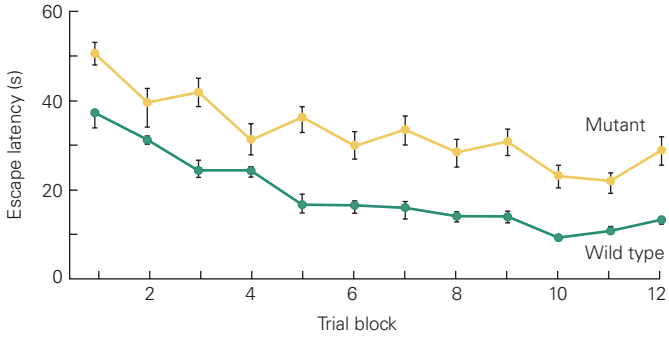
B Long-term potentiation



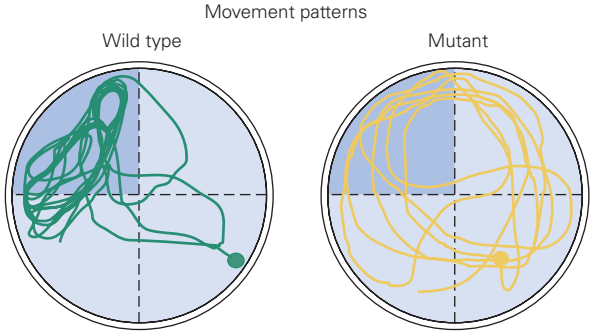


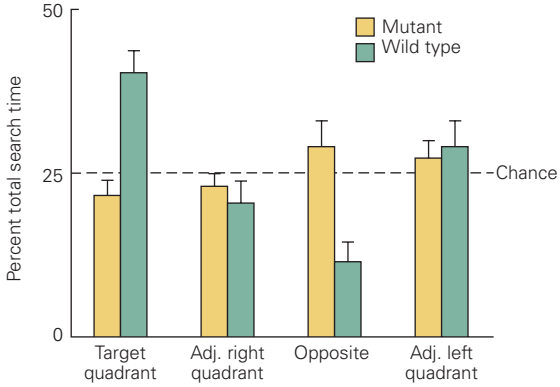
C Morris water maze learning





D Probe trial test of memory





Finally, although most behavioral tests of LTP have used spatial learning tasks to assess memory, studies have also shown that NMDA receptors, and by inference LTP, are necessary for a variety of hippocampal-dependent explicit memories. When NMDA receptors in the CA1 area are blocked, mice are not able to master a nonspatial object recognition task, learn complex odor discrimination, or undergo the social transmission of a food preference, in which an animal learns to accept a novel food by observing a conspecific (another animal of its species) consume that same food. Thus, NMDA receptor–dependent LTP is likely required for many, if not all, forms of explicit memory in the hippocampus (most of which include a spatial recognition element).

Explicit Memory Storage Also Depends on Long-Term Depression of Synaptic Transmission

If synaptic connections could only be enhanced and never attenuated, synaptic transmission might rapidly saturate—the strength of the synaptic connections might reach a point beyond which further enhancement is not possible. Moreover, uniform synaptic strengthening may lead to a loss of memory specificity, with one memory interfering with another. Yet individuals are able to learn, store, and recall new memories throughout a lifetime. This paradox led to the suggestion that neurons must have mechanisms to downregulate synaptic function to counteract LTP.

Such an inhibitory mechanism, termed *long-term depression* (LTD), was first discovered in the cerebellum, where it is important for motor learning. Since then, LTD has also been characterized at a number of synapses within the hippocampus. Whereas LTP is typically induced by a brief high-frequency tetanus, LTD is induced by prolonged low-frequency synaptic stimulation (Figure 54–10A). As mentioned above, it can also be induced by a spike pairing protocol in which an EPSP is evoked *after* an action potential in the postsynaptic cell. This suggests a corollary to Hebb's learning rule: Active synapses that do not contribute to the firing of a cell are weakened. Like LTP, a number of molecular and synaptic mechanisms are engaged during the induction and expression of LTD.

Surprisingly, many forms of LTD require activation of the same receptors involved in LTP, namely the NMDA receptors (Figure 54–10A). How can activation of a single type of receptor produce both potentiation and depression? A key difference lies in the experimental protocols used to induce LTP or LTD. Compared to the high-frequency stimulation used to induce LTP, the low-frequency tetanus used to induce LTD produces a relatively modest postsynaptic depolarization and thus is much less effective at relieving the Mg^{2+} block of the NMDA receptors. As a result, any increase in Ca^{2+} concentration in the postsynaptic cell is much smaller than the increase observed during induction of LTP and therefore insufficient to activate CaMKII, the enzyme implicated in LTP. Rather, LTD may result from activation of the calcium-dependent phosphatase calcineurin, an enzyme complex that has a higher affinity for Ca^{2+} compared to that of CaMKII (Chapter 14).

Figure 54–7 (Opposite) Long-term potentiation (LTP) and spatial learning and memory are impaired in mice that lack the *N*-methyl-D-aspartate (NMDA) receptor in the CA1 region of the hippocampus. (Reproduced, with permission, from Tsien, Huerta, and Tonegawa 1996.)

A. A line of mice is bred in which the gene encoding the NR1 subunit of the NMDA receptor is selectively deleted in CA1 pyramidal neurons. In situ hybridization is used to detect mRNA for the NR1 subunit in hippocampal slices from wild type and mutant mice that contain two floxed NR1 alleles and express Cre recombinase under the control of the *CaMKIIα* promoter. Note that NR1 mRNA expression (**dark staining**) is greatly reduced in the CA1 region of the hippocampus but not in CA3 and the dentate gyrus (**DG**).

B. LTP at the CA1 Schaffer collateral synapses is abolished in these mice. Field excitatory postsynaptic potentials (**fEPSPs**) were recorded in response to Schaffer collateral stimulation. Tetanic stimulation at 100 Hz for 1 second (**arrow**) caused a large potentiation in wild type mice but failed to induce LTP in the NMDA receptor knockout (mutant) mice.

C. Mice that lack the NMDA receptor in CA1 pyramidal neurons have impaired spatial memory. A platform (**dashed square**) is submerged in an opaque fluid in a circular tank (a Morris water maze). To avoid remaining in the water, the mice have to find the platform using spatial (contextual) cues on the walls surrounding the tank and then climb onto the platform. The graph shows escape latency or the time required by mice to find the hidden platform in successive trials. The mutant mice display a longer escape latency in every block of trials (four trials per day) than do the wild type mice. Also, mutant mice do not reach the optimal performance attained by the control mice after 12 training days, even though they show some improvement with training.

D. After the mice have been trained in the Morris maze, the platform is taken away. In this probe trial, the wild type mice spend a disproportionate amount of time in the quadrant that formerly contained the platform (the target quadrant), indicating that they remember the location of the platform. Mutant mice spend an equal amount of time (25%) in all quadrants; that is, they perform at chance level, indicating deficient memory.

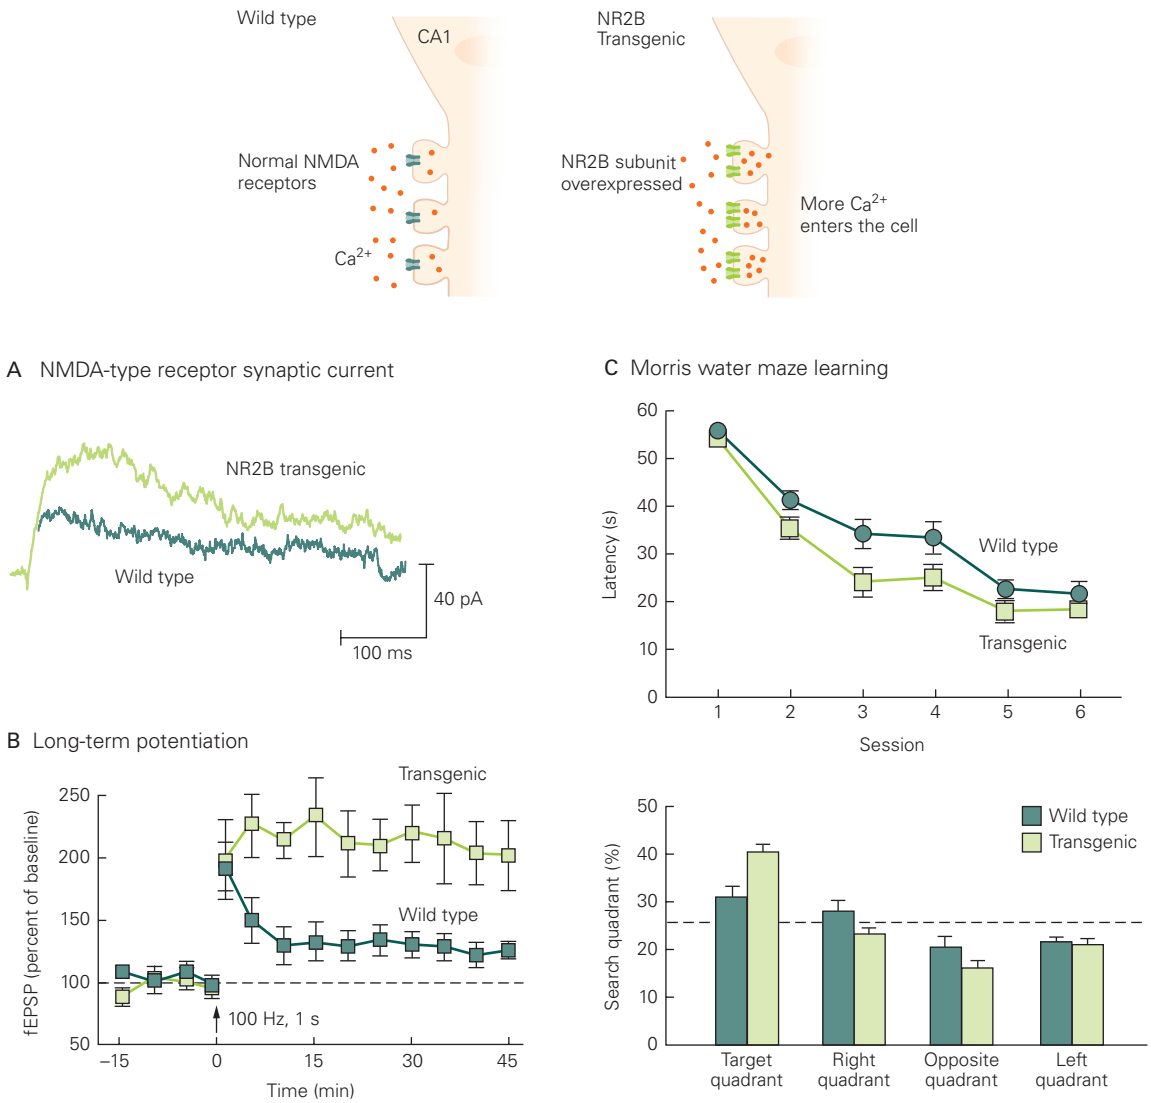


Figure 54–8 Learning and memory are enhanced in mice that overexpress a subunit of the *N*-methyl-D-aspartate (NMDA) glutamate receptor. (Reproduced, with permission, from Tang et al. 1999. Copyright © 1999 Springer Nature.)

A. The amplitude of the current generated by the NMDA receptors in response to a brief pulse of glutamate is enhanced and its time course prolonged in hippocampal neurons obtained from mice that contain a transgene that expresses higher levels of the receptor's NR2B subunit compared to wild type mice.

B. Long-term potentiation produced by tetanic stimulation of the Schaffer collateral synapses is greater in the transgenic mice than in wild type mice. (Abbreviation: **fEPSP**, field excitatory postsynaptic potential.)

C. Spatial learning is enhanced in the transgenic mice (**upper plot**). The rate of learning in a Morris water maze (the reduction in time to find the hidden platform, or escape latency) is faster in transgenic mice than in wild type mice. Spatial memory is also enhanced in the transgenic mice (**lower plot**). In the probe trial, the transgenic mice spend more time in the target quadrant, which previously contained the hidden platform, than do wild-type mice.

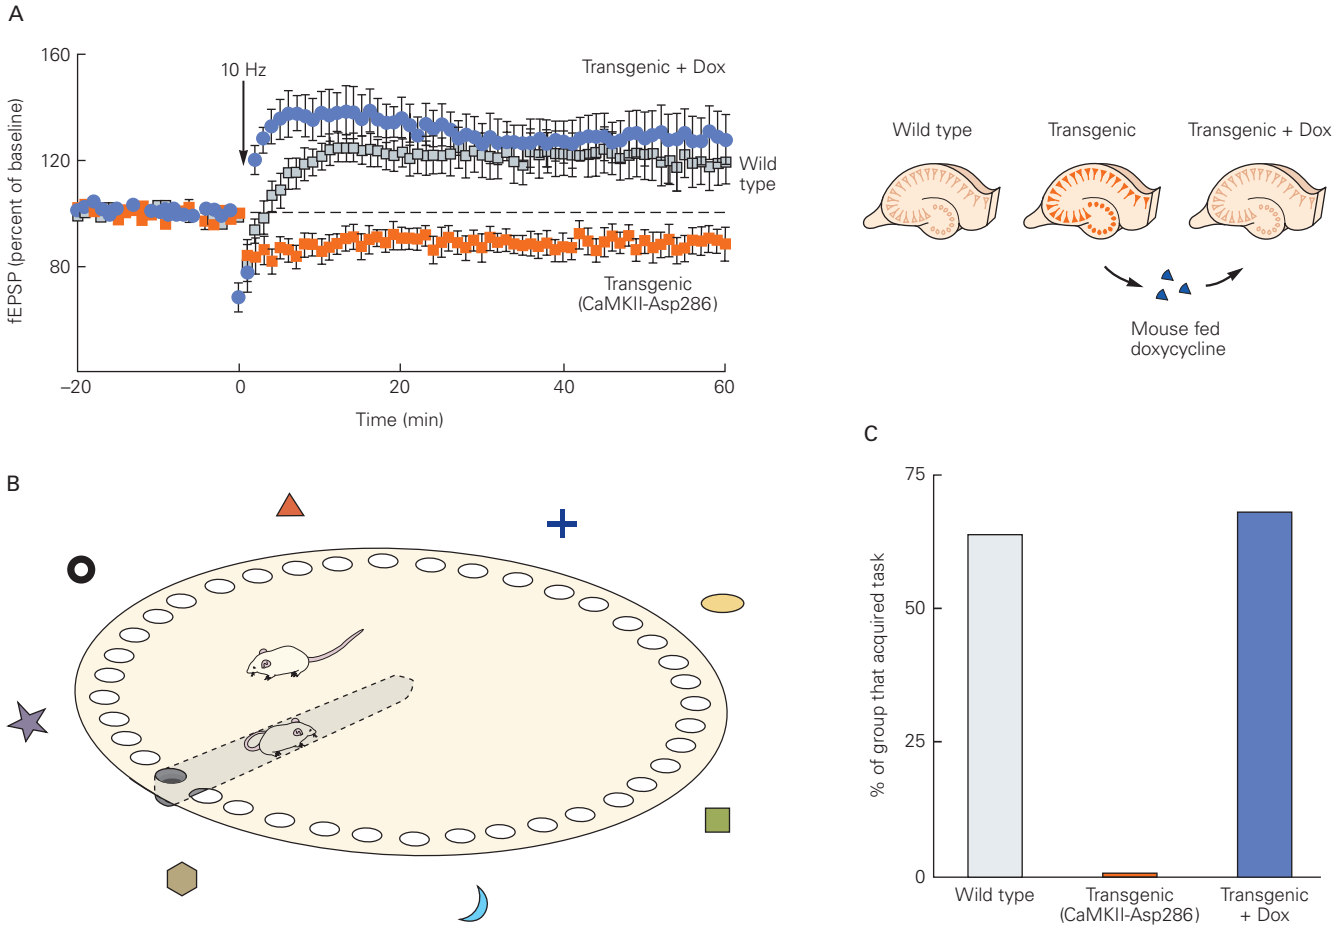

Figure 54–9 **Deficits in long-term potentiation (LTP) and spatial memory due to a transgene are reversible.** (Reproduced, with permission, from Mayford et al. 1996.)

A. An LTP deficit is seen in hippocampal slices from transgenic mice that overexpress CaMKII-Asp286 kinase, a constitutively active mutant form of CaMKII. Expression of this transgene is driven by a second transgene, the tTA bacterial transcription factor, which is inhibited by the antibiotic doxycycline (**Dox**) (see Chapter 2, Figure 2–9, for a complete description). Four groups of mice were tested: transgenic mice that were fed doxycycline, which blocks expression of the kinase; transgenic mice without doxycycline, in which the kinase is expressed; and wild type mice with and without doxycycline. In wild type mice, a 10-Hz tetanus induces LTP; doxycycline has no effect (data are not shown). In the transgenic mice, the tetanus fails to induce LTP but causes a small synaptic depression. In the transgenic mice that were fed doxycycline, the deficit in LTP is reversed. (Abbreviation: **fEPSP**, field excitatory postsynaptic potential.)

B. The effect of the kinase on spatial memory was tested in a Barnes maze. The maze consists of a platform with 40 holes, one of which leads to an escape tunnel that allows the mouse to exit the platform. The mouse is placed in the center of the platform. Mice do not like open, well-lit spaces and therefore try to escape from the platform by finding the hole that leads to the escape tunnel. The most efficient way of learning and remembering the location of the hole (and the only way of meeting the criteria set for the task by the experimenter) is for the mouse to use distinctive markings on the four walls as spatial cues, thus demonstrating hippocampal spatial memory.

C. Transgenic mice that receive doxycycline perform as well as wild type mice in learning the Barnes maze task (approximately 65% of animals learn the task), whereas transgenic mice without the doxycycline, which thus express CaMKII-Asp286, do not learn the task.

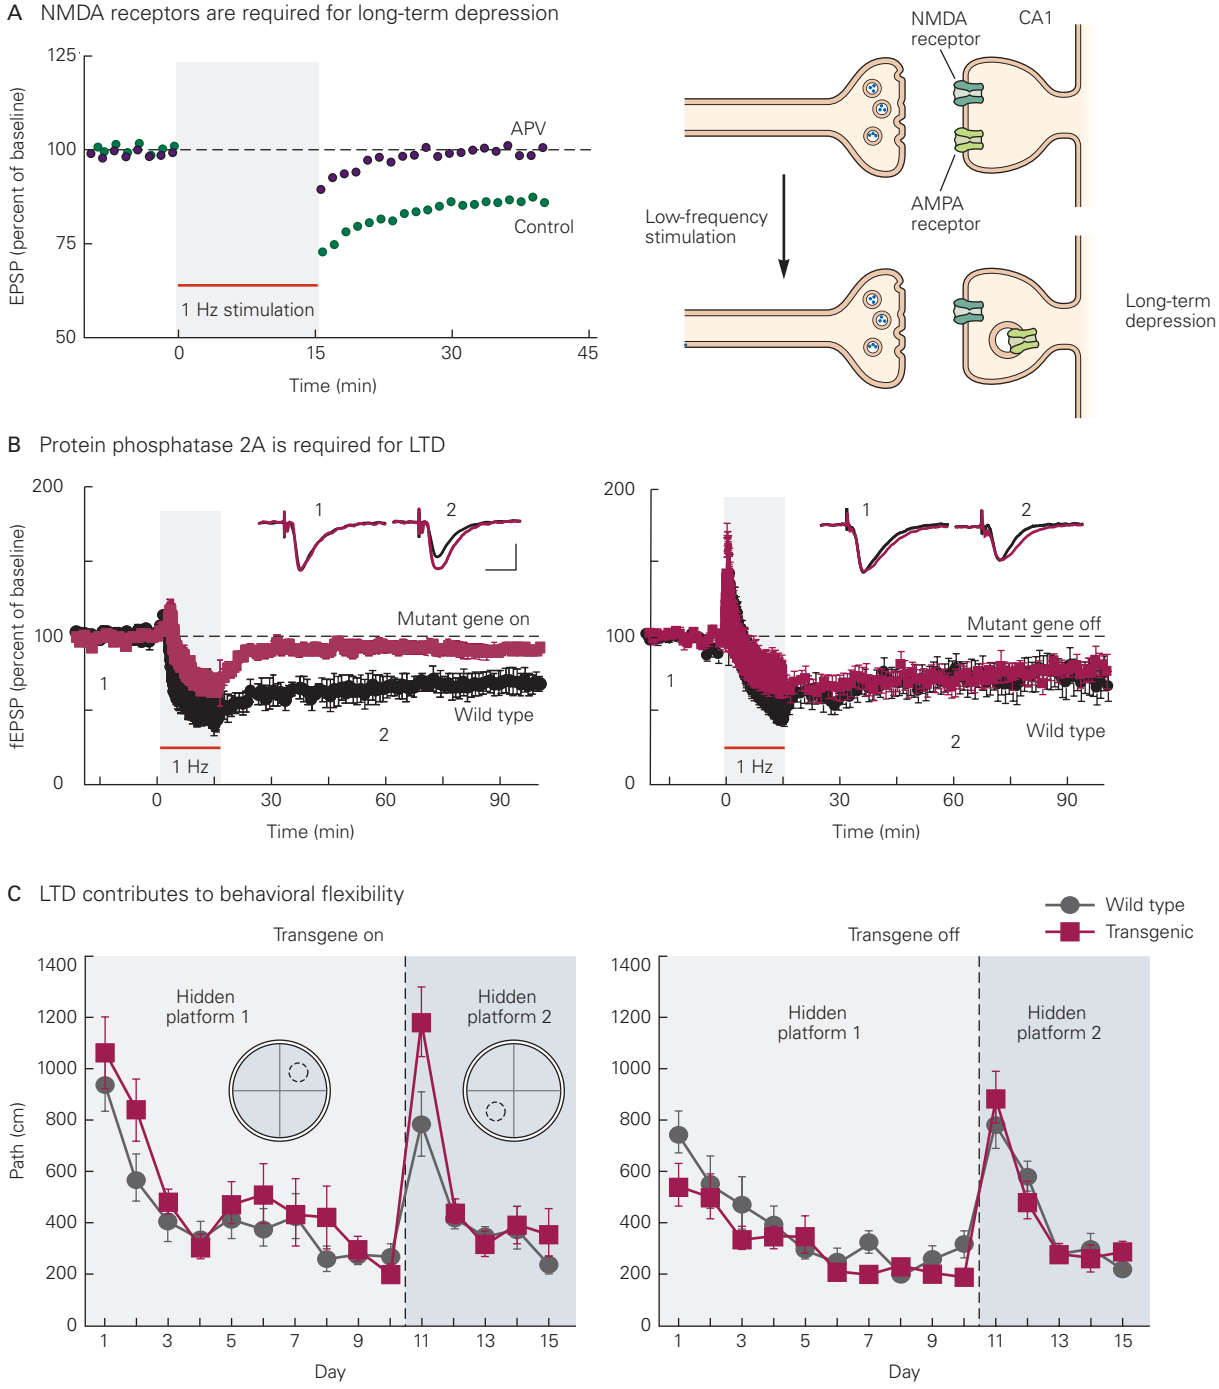

Figure 54–10 Long-term depression of synaptic transmission requires *N*-methyl-D-aspartate (NMDA) receptors and phosphatase activity.

A. Prolonged low-frequency stimulation (1 Hz for 15 minutes) of Schaffer collateral fibers produces a long-term decrease in the size of the field excitatory postsynaptic potential (**fEPSP**) in the hippocampal CA1 region, a decrease that outlasts the period of stimulation (control). Long-term depression (**LTD**) occurs when α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (**AMPA**) receptors are removed from the postsynaptic membrane by endocytosis; it is blocked when the NMDA receptors are blocked by the drug 2-amino-5-phosphonovaleric acid (**APV**). (Adapted from Dudek and Bear 1992.)

B. LTD requires protein dephosphorylation. The plots compare LTD in the hippocampal CA1 region of wild type mice and transgenic mice that express a protein that inhibits phosphoprotein phosphatase 2A. Transgene expression is under control of the tTA system. In the absence of doxycycline, the phosphatase inhibitor is expressed, and induction of LTD is inhibited (*left plot*). When expression of the phosphatase inhibitor is turned off by administering doxycycline, a normal-sized LTD is induced (*right plot*).

C. Inhibition of phosphatase 2A reduces behavioral flexibility. Transgenic mice expressing the phosphatase inhibitor learn the location of a submerged platform in the Morris maze at the same rate as wild-type mice (days 1–10). Thus, LTD is not necessary for learning the initial platform location. At the end of day 10, the platform is moved to a new hidden location and the mice are retested (days 11–15). Now the transgenic mice travel significantly longer paths to find the platform on the first day of retesting (day 11), indicating an impaired learning (reduced flexibility). When transgene expression is turned off with doxycycline, the transgenic mice display normal learning on all phases of the test. (Panels B and C reproduced, with permission, from Nicholls et al. 2008.)

Long-term depression may also depend on a surprising metabotropic action of the ionotropic NMDA receptor-channels. Glutamate binding, in addition to opening the receptor pore, is thought to trigger a conformational change in a cytoplasmic domain of the receptor that directly activates a downstream signaling cascade that increases the activity of phosphoprotein phosphatase 1 (PP1). Activation of PP1 or calcineurin eventually leads to changes in protein phosphorylation that promote endocytosis of AMPA receptors, resulting in a decrease in the size of an EPSP.

Distinctly different forms of LTD can be induced through the activation of G protein–coupled metabotropic glutamate receptors. Such forms of LTD depend on activation of mitogen-activated protein (MAP) kinase signaling pathways (Chapter 14) rather than activation of phosphatases. These types of LTD lead to a reduction in synaptic transmission through a decrease in glutamate release from presynaptic terminals as well as through alterations in the trafficking of AMPA receptors in the postsynaptic cells.

Much less is known about the behavioral role of LTD compared to that of LTP, but some insight has come from studies with mice using a transgene that expresses an inhibitor of protein phosphatase. LTD that depends on NMDA receptors is inhibited when the transgene is expressed but is normal when transgene expression is suppressed (Figure 54–10B). Transgene expression does not affect LTP or forms of LTD that involve metabotropic glutamate receptors. Mice that express the transgene show normal learning the first time they are tested in the Morris maze. However, when the same mice are retested after the hidden platform has been moved to a new location, they show a decreased ability to learn the new location and tend to persevere in searching for the platform near the previously learned location (Figure 54–10C). Thus, LTD may be necessary not only to prevent LTP saturation but also to enhance flexibility in memory storage and specificity in memory recall. Studies on fear conditioning suggest that LTD in the amygdala may be important for reversing learned fear.

Memory Is Stored in Cell Assemblies

While the cumulative evidence for a relationship between long-term synaptic plasticity and memory formation is strong, we know less about how specific cellular processes such as LTP enable memory formation. This reflects limitations in our knowledge of how neural circuits operate and how memories might be embedded in them. Theoretical models for memory storage in neural circuits can be traced to Hebb's concept of a cell assembly—a network of neurons that is activated whenever a function is executed; for example, each time a memory is recalled. Cells within an assembly are bound together by excitatory synaptic connections strengthened at the time the memory was formed.

Today, more than half a century later, Hebb's thoughts still form the framework for how the hippocampus mediates the storage and recall of memory, although experimental proof has been difficult to obtain. A proper test requires recording the activity of thousands of neurons simultaneously, in combination with the experimental excitation or inactivation of selected cell groups. Technological advances are now enabling such experiments. By and large, the results obtained so far confirm Hebb's cell assembly model and implicitly point to LTP as the mechanism for their formation.

In a telling study with mice, Susumu Tonegawa and his colleagues tested whether reactivation of neurons that participated in the storage of a specific memory is sufficient to trigger recall of that memory. The researchers first applied an electric shock to an animal as it explored a novel environment. Reexposure of the animal to the same environment a day or more later elicited a freezing response, indicating that the animal associated the environment or context (the conditioned stimulus) with the shock (the unconditioned stimulus). Using a genetic strategy, Tonegawa caused a subset of dentate gyrus granule neurons that were active during the fear conditioning to express the light-activated cation channel channelrhodopsin-2 (Figure 54–11). The conditioned animals were subsequently placed in a novel environment that did not resemble the conditioned environment and so did not elicit a fear response. However, light activation of the subset of granule cells that were active during fear conditioning was able to elicit a strong freezing response, even though the animals were in a nonthreatening environment. This supports the idea that memories are stored in cell assemblies and, more importantly, demonstrates that reactivation of these assemblies is sufficient to induce recall of an experience.

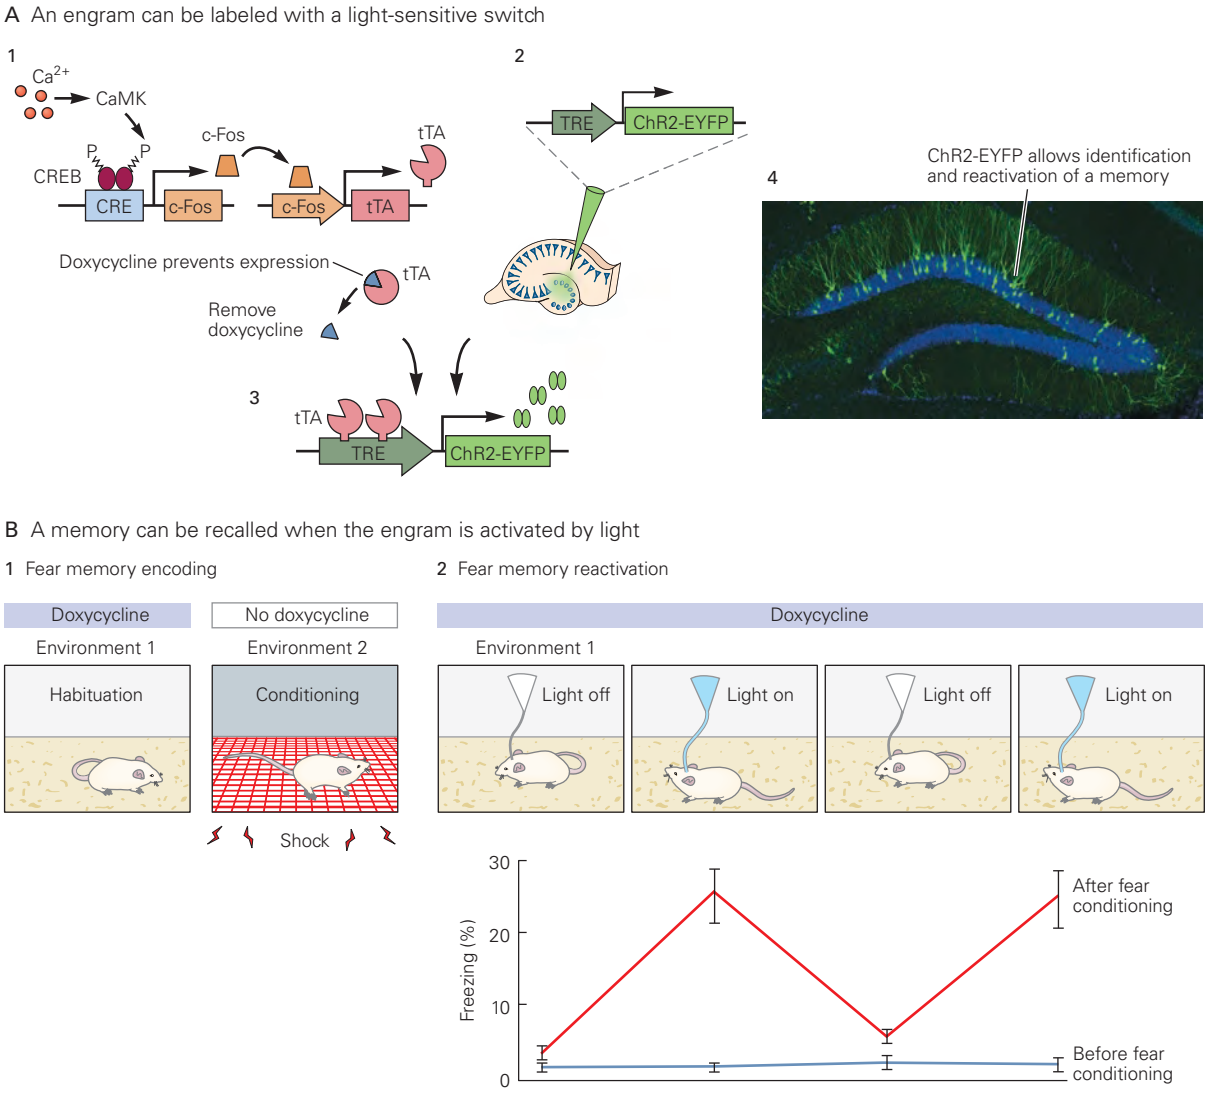
In a complementary experimental approach, a light-activated inhibitory Cl^- transporter was expressed in CA1 cells active at the time of fear conditioning. Later, the labeled cells were inactivated and the animals were placed again in the environment in which they received the shock. Under these conditions, the normal freezing behavior (ie, recall of the memory of fear conditioning) was blocked, suggesting that activity in the labeled CA1 cell population was necessary for memory retrieval. Taken together, these findings

suggest that reactivation of the specific cell assembly pattern that occurred during encoding is both necessary and sufficient for memory retrieval.

Perhaps the most direct test of the ensemble model is the creation of a false memory. Tonegawa and colleagues expressed channelrhodopsin in cells that were active during exploration of a novel environment (context A), except that no shock was delivered this time. At a later time, the labeled cells were reactivated using light stimulation as the mice explored a second novel environment (context B), this time in combination with an electric shock. When the animals were returned to the neutral context A, they froze, although they had never been shocked in this environment. This result indicates that the reactivation of the original engram of context A when paired with an aversive experience in context B is able to create a false memory, causing the animals to fear context A. Thus, it is possible to modify the behavioral significance of a neural representation (a pattern of neural firing in response to a given stimulus) by pairing the assembly with a new experience unrelated to the original experience.

Different Aspects of Explicit Memory Are Processed in Different Subregions of the Hippocampus

Explicit memory stores knowledge of facts (semantic memory), places (spatial memory), other individuals (social memory), and events (episodic memory). As discussed above, successful storage and recall of explicit



memory requires that patterns of activity be formed within local cell assemblies to avoid mix-up between memories. At the same time, an important psychological feature of hippocampal-dependent memory is that a few cues are usually enough to trigger the recall of a complex memory. How does the hippocampus perform all of these diverse functions? Do its subregions have specialized roles, or is memory a unitary function of the hippocampus? In at least some instances, it has been possible to assign key functions to specific areas of the hippocampus.

The Dentate Gyrus Is Important for Pattern Separation

How does the hippocampus store a different pattern of neural activity in response to every experience that needs to be remembered, including patterns that distinguish between two closely related environments? Contemporary ideas about how neural circuits accomplish this task, often referred to as *pattern separation*, dates to the theoretical work of David Marr in the late 1960s and early 1970s. In a landmark paper on the cerebellum, Marr suggested that the extensive divergence of mossy-fiber inputs onto an extraordinarily large number of cerebellar granule cells might allow for pattern separation in this system.

This idea of "expansion recoding," in which distinct firing patterns are formed through the projection of a limited number of inputs onto a larger population of synaptic target cells, was later applied by others to the hippocampus. They proposed that hippocampal pattern separation results from the divergence of entorhinal inputs onto a larger number of granule cells in the dentate gyrus. The findings of subsequent experimental studies are broadly in line with these theoretical suggestions: Neural activity patterns recorded in different environments differ more extensively in the dentate gyrus and CA3 than they do one synapse upstream in the entorhinal cortex. The dentate gyrus is also implicated in pattern separation by the fact that lesions or genetic manipulations targeted to this area impair the ability of rats and mice to discriminate between similar locations and contexts.

The dentate gyrus is the site of one of the most unexpected findings in neuroscience, the discovery that the birth of new neurons, or neurogenesis, is not limited to early stages of development. New neurons

Figure 54–11 (Opposite) Stimulating a neuronal assembly associated with a stored memory of fear conditioning elicits fear behavior. (Panels reproduced or redrawn, with permission, from Liu et al. 2012. Copyright © 2012 Springer Nature.)

A. *Experimental protocol*. 1. Exposure of a mouse to a new environment increases activity in a group of hippocampal neurons (cell assembly) that codes for the environment. The activity increases intracellular Ca^{2+}, which activates a CaM kinase signaling cascade, resulting in phosphorylation of the transcription factor CREB. Phosphorylated CREB increases expression of immediate early genes, including the c-Fos transcription factor. In the *c-fos-tTA* transgenic mouse line, c-Fos binds to the *c-fos* promoter of the transgene and thereby initiates expression of the transcription factor tTA. The antibiotic doxycycline is fed to mice, which binds to and inhibits tTA, until the day of the experiment. 2. The dentate gyrus of the same transgenic mice was previously injected with an adeno-associated virus that contains a DNA sequence encoding ChR2 fused to the fluorescent marker protein EYFP (ChR2-EYFP). The transcription of this sequence is under control of the TRE promoter, which requires tTA (without doxycycline) for expression. 3. Exposure of the mice to a novel environment (after removing doxycycline from the feed) leads to expression of tTA and subsequent expression of ChR2-EYFP in a subset of active dentate gyrus neurons. 4. The ChR2-EYFP remains expressed for several days in the neurons, as seen by the EYFP fluorescence signal in dentate gyrus granule cells in a hippocampal slice. (ChR2-EYPF in **green**, dentate gyrus cell body layer in **blue**.)

B. *Recall of a fear memory*. An optical fiber is implanted above the dentate gyrus. 1. During fear memory encoding, mice were first habituated in one environment while being fed doxycycline (which prevents expression of ChR2-EYFP). The mice were then taken off doxycycline and exposed to a new environment for a few minutes. This turns on gene transcription in the assembly of neurons that are active in the new environment, leading to prolonged expression of ChR2-EYFP in these cells. The mice were then given a series of footshocks while in the new environment to induce fear conditioning: The mice learn to associate the new environment with a fearful stimulus. The mice were then returned to their cage and put back on doxycycline. 2. During fear memory reactivation 5 days after conditioning, mice show a normal defensive freezing behavior when reintroduced to the environment where they received footshocks (not shown). However, when mice are exposed to the environment to which they were initially habituated (no associated foot shock), they normally recognize this as a neutral environment and do not exhibit defensive freezing. However, as the mice explore the neutral environment, delivery of blue light to activate ChR2-expressing neurons in the dentate gyrus causes the mice to freeze. This indicates that activation of the ensemble of ChR2-expressing neurons initially activated in the conditioning environment is sufficient to recall the fear memory associated with that environment. The experimental data show the freezing response in the neutral environment is much greater when light pulses are turned on compared to when the light is off (**red plot**; light delivery indicated in cartoon on top). Delivery of light pulses to an animal that had not undergone fear conditioning does not elicit freezing (**blue plot**).

continue to be born from precursor stem cells throughout adulthood and become incorporated into neural circuits. Nevertheless, adult neurogenesis is limited to granule neurons in two brain regions: inhibitory granule cells in the olfactory bulb and the excitatory granule neurons of the dentate gyrus. Recent experimental findings raise the possibility that newly born granule neurons in the adult are particularly important for pattern separation, even though they represent only a minor fraction of the total number of granule cells. Procedures that stimulate neurogenesis enhance the ability of a mouse to discriminate between closely related environments. Experimental silencing of all dentate gyrus granule neurons except those newly born in the adult does not seem to impair pattern separation, implying that it is the newborn neurons that are most essential to pattern separation. Although some uncertainties remain on the role of neurogenesis in pattern separation and memory encoding, methods that enhance neurogenesis are currently being explored as a means of treating different types of age-related memory loss.

The CA3 Region Is Important for Pattern Completion

A key feature of explicit memory is that a few cues are often sufficient to retrieve a complex stored memory. Marr suggested in a second landmark paper in 1971 that the recurrent excitatory connections of CA3 pyramidal cells might underlie this phenomenon. He proposed that when a memory is encoded, neuronal activity patterns are stored as changes in connections between active CA3 cells. During subsequent retrieval of the memory, the reactivation of a subset of this stored cell assembly would be sufficient to activate the entire original neural ensemble that encodes the memory because of the strong recurrent connections between the cells of the ensemble. This restoration is referred to as *pattern completion*.

The importance of LTP for pattern completion in the CA3 network is seen in studies with mice in which the NMDA glutamate receptor is selectively deleted from the CA3 neurons. These mice experience a selective loss of LTP at the recurrent synapses between CA3 neurons, with no change in LTP at the synapses between mossy fibers and CA3 neurons or at the Schaffer collateral synapses between CA3 and CA1 neurons. Despite this deficit, the mice show normal learning and memory for finding a submerged platform in a water maze using a complete set of spatial cues. However, when the mice are asked to find the platform with fewer spatial cues, their performance is impaired, indicating that LTP at the recurrent synapses between CA3 neurons is important for pattern completion.

The CA2 Region Encodes Social Memory

Studies comparing neuronal representations in the dentate gyrus and CA3 and CA1 areas have indicated that each region has a unique function in the storage and retrieval of hippocampal memory. Recent evidence suggests that the CA2 region plays a crucial role in social memory, the ability of an individual to recognize and remember other members of its own species (conspecifics). Genetic silencing of CA2 disrupts the ability of a mouse to remember encounters with other mice, but does not impair other forms of hippocampal-dependent memory, including memory of objects and places.

The CA2 region is also unique among hippocampal regions in having very high levels of receptors for the hormones oxytocin and vasopressin, important regulators of social behaviors. Selective stimulation of the vasopressin inputs to CA2 neurons can greatly prolong the duration of a social memory. Social memory also depends on CA1 neurons in the ventral region of the hippocampus, an area linked to emotional behavior, which receives important input from CA2.

A Spatial Map of the External World Is Formed in the Hippocampus

How do hippocampal neurons encode features of the external environment to form a memory of spatial locale, enabling an animal to navigate to a remembered goal? At the end of the 1940s, the cognitive psychologist Edward Tolman proposed that somewhere in the brain there must be representations of one's environment. He referred to these neural representations as cognitive maps. They were thought to form not only an internal map of space but also a mental database in which information is stored in relation to an animal's position in the environment, similar to the GPS coordinates of a photograph.

Tolman did not have the opportunity to determine whether a cognitive map actually existed in the brain, but in 1971, John O'Keefe and John Dostrovsky discovered that many cells in the CA1 and CA3 areas of the rat hippocampus fire selectively when an animal is located at a specific position in a specific environment. They called these cells "place cells" and the spatial location in the environment where the cells preferentially fired "place fields" (Figure 54–12A,B). When the animal enters a new environment, new place fields are formed within minutes and are stable for weeks to months.

Different place cells have different place fields, and collectively, they provide a map of the environment, in the sense that the combination of currently active cells is sufficient to read out precisely where the animal is in the environment. A place-cell map is not egocentric in its organization, like the neural maps for touch or vision on the surface of the cerebral cortex. Rather, it is allocentric (or geocentric); it is fixed with respect to a point in the outside world. Based on these properties, John O'Keefe and Lynn Nadel suggested in 1978 that place cells are part of the cognitive map that Tolman had in mind. The discovery of place cells provided the first evidence for an internal representation of the environment that allows an animal to navigate purposefully around the world.

Entorhinal Cortex Neurons Provide a Distinct Representation of Space

How is the hippocampal spatial map formed? What type of spatial information is carried by afferent connections from the entorhinal cortex to the hippocampal place cells? In 2005, a surprising discovery was made about the spatial representation formed by certain neurons in the medial entorhinal cortex, whose axons provide a major part of the perforant pathway input to the hippocampus. These neurons represent space in a manner very different from the hippocampal place cells. Instead of firing when the animal is in a unique location, like the place cells, these entorhinal neurons, termed *grid cells*, fire whenever the animal is at any of several regularly spaced positions forming a hexagonal grid-like array (Figure 54–12C). When the animal moves about in the environment, different grid cells become activated, such that the activity in the entire population of grid cells always represents the animal's current position.

The grid allows the animal to locate itself within a Cartesian-like external coordinate system that is independent of context, landmarks, or specific markings. A grid cell's firing pattern is expressed in all environments that an animal visits, including during complete darkness. The independence of grid-cell firing from visual input implies that intrinsic networks, as well as self-motion cues, may serve as sources of information to ensure that grid cells are activated systematically throughout the environment. The gridded spatial information conveyed by the entorhinal inputs is then transformed within the hippocampus into unique spatial locations represented by the firing of ensembles of place cells, but how this transformation occurs remains to be determined. Since grid cells were discovered in the medial entorhinal cortex of rats in 2005, they have been identified in mice, bats, monkeys, and humans. Recordings from flying bats have shown that grid cells and place cells represent locations in three-dimensional space, suggesting the generality of the cortico-hippocampal spatial navigation system. Finally, it has been proposed that grid cells in primates may encode positions in multiple sensory coordinate systems, including eye fixation coordinates.

Grid cells display a characteristic relation between their firing fields and anatomical organization (Figure 54–13). The x,y coordinates of a cell's grid fields—often called the phase of the grid—differ among cells at the same location of the medial entorhinal cortex. The x,y coordinates of two neighboring cells are often as different as those of widely separated grid cells. In contrast, the size of the individual grid fields and the spacing between them generally increase topographically from the dorsal to the ventral part of the medial entorhinal cortex, expanding from a typical grid spacing of 30 to 40 cm at the dorsal pole to several meters in some cells at the ventral pole (Figure 54–13A). The expansion is not linear but step-like, suggesting that the grid-cell network is modular.

Interestingly, a gradual expansion is seen also in the size of the place fields of hippocampal place cells along the dorsal to ventral axis of the hippocampus (Figure 54–13B). This is consistent with the known pattern of synaptic connectivity: Dorsal entorhinal cortex innervates dorsal hippocampus, whereas ventral entorhinal cortex innervates ventral hippocampus. The finding that place fields are larger in the ventral hippocampus is in accord with results suggesting that the dorsal hippocampus is more important for spatial memory, whereas the ventral hippocampus is more important for nonspatial memory, including social memory and emotional behavior.

Grid cells are not the only medial entorhinal cells with projections to the hippocampus. Others include *head direction cells*, which respond primarily to the direction that the animal is facing (Figure 54–14A). Such cells were originally discovered in the presubiculum, another region of the parahippocampal cortex, but they exist also in the medial entorhinal cortex. Many entorhinal head direction cells also have grid-like firing properties. Like grid cells, such head direction cells are active when an animal traverses the vertices of a triangular grid in a two-dimensional environment. However, within each grid field, these cells fire only if the animal is facing a certain direction. Head direction cells and conjunctive grid and head direction cells are thought to provide directional information to the entorhinal spatial map.

Intermingled among grid cells and head direction cells is yet another type of spatially modulated cell, the *border cell* (Figure 54–14B). The firing rate of a border

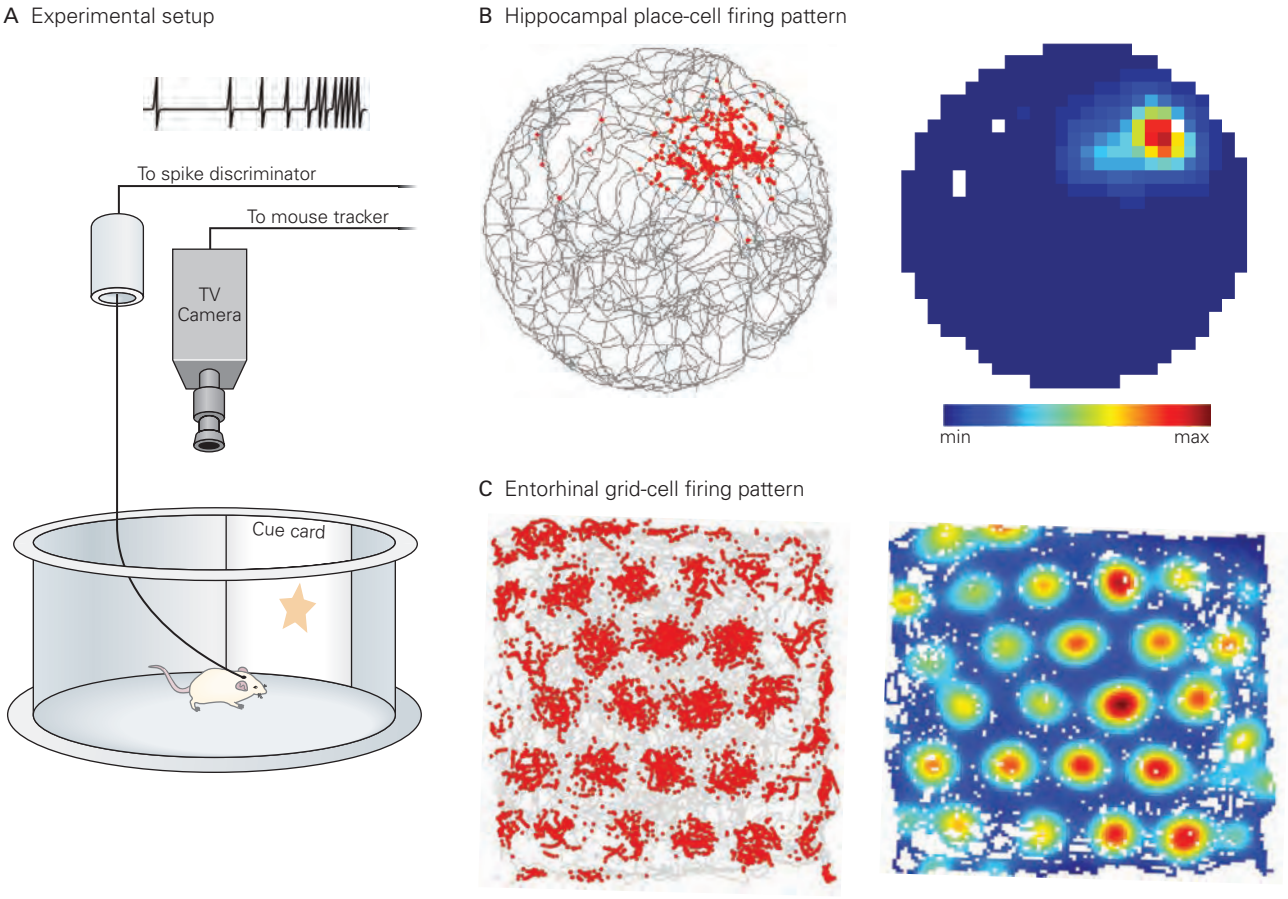


Figure 54–12 The firing patterns of cells in the hippocampus and medial entorhinal cortex signal the animal's location in its surroundings.

A. Electrodes implanted in the hippocampus of a mouse are attached to a recording cable, which is connected to an amplifier attached to a computer-based spike-discrimination program. The mouse is placed in an enclosure with an overhead TV camera that transmits to a device that detects the position of the mouse. The enclosure also contains a visual cue to orient the animal. Spikes in individual hippocampal pyramidal neurons ("place cells") are detected by a spike discrimination program. The firing rate of each cell is then plotted as a function of the animal's location in the cylinder. This information is visualized as a two-dimensional activity map for the cell, from which the cell's firing fields can be determined (shown in part **B**). (Adapted, with permission, from Muller, Kubie, and Ranck 1987. Copyright © 1987 Society for Neuroscience.)

B. Location-specific firing of a hippocampal place cell. A rat is running in a cylindrical enclosure similar to the one shown in part **A**. *Left*: The animal's path in the enclosure is shown in **gray**; firing locations of individual spikes are shown for a single place cell as **red dots**. *Right*: The firing rate of the same cell is color-coded (**blue** = low rate, **red** = high rate). In larger environments, place cells usually have more than one firing field but the fields have no apparent spatial relationship.

C. Spatial pattern of firing of an entorhinal grid cell in a rat during 30 minutes of foraging in a square enclosure 220 cm wide. The pattern shows typical periodic grid firing fields. *Left*: The trajectory of the rat is shown in **gray**; individual spike locations are shown as **red dots**. *Right*: Color-coded firing rate map for the grid cell to the left. Color coding as for the place cell in part **B**. (Adapted, with permission, from Stensola et al. 2012.)

cell increases whenever the animal approaches a local border of the environment, such as an edge or a wall. Border cells may help align the phase and orientation of grid cell firing to the local geometry of the environment. A similar role may be played by recently discovered object-vector cells—cells in medial entorhinal cortex that encode the animal's distance and direction relative to salient landmarks. A final entorhinal cell type is the *speed cell*. Speed cells fire proportionally to the running speed of the animal, irrespective of the animal's location or direction (Figure 54–14C). Together with head direction cells, speed cells can provide grid cells with information about the animal's instantaneous velocity, allowing the ensemble of active grid cells to be updated dynamically in accordance with a moving animal's changing location.

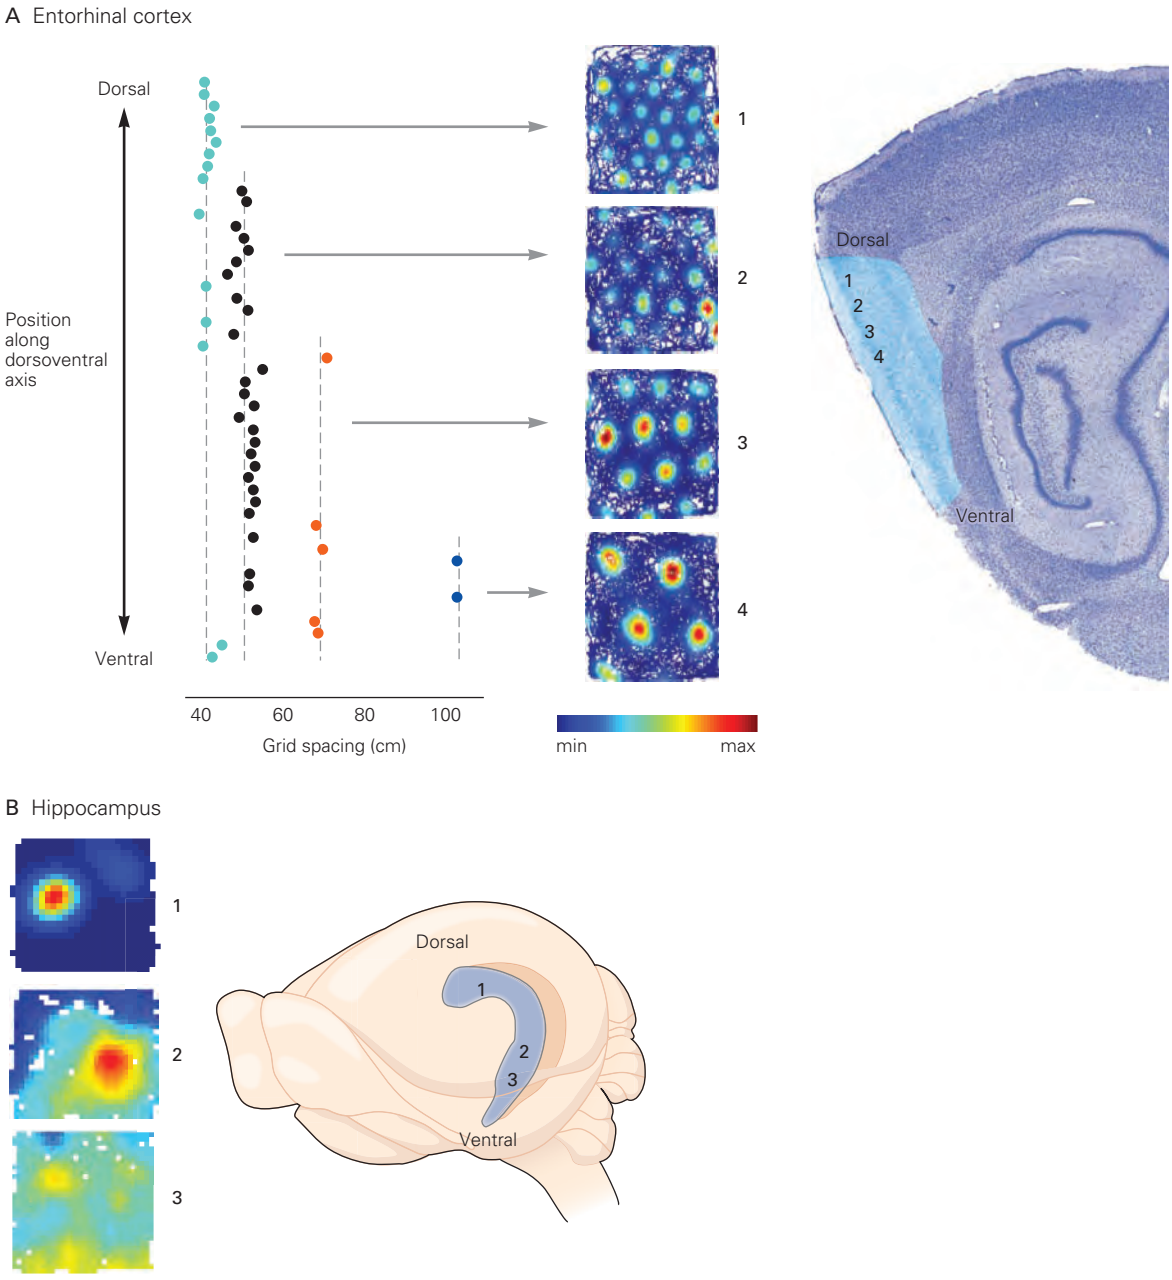

Figure 54–13 Grid fields and place fields expand in size as a function of neuronal location along the dorsoventral axis of the entorhinal cortex and hippocampus.

A. Topographical organization of grid scale in the entorhinal cortex. Grid spacing (distance between grid fields) was determined for 49 grid cells (colored dots) recorded in the same rat at successive dorsal to ventral levels in the medial entorhinal cortex (**green** area in the sagittal brain section on the right). **Dashed lines** indicate mean grid-spacing values, indicating that grid-spacing falls in one of four discrete modules, with points colored according to module. Firing rate maps for four of the cells are shown in the middle (similar to those of Figure 54–12C). Recording locations for these cells are indicated by numbers 1 to 4 to the right. (Adapted, with permission, from Stensola et al. 2012.)

B. Place fields from three different locations along the dorsoventral axis of the hippocampus. *Right*: Recording positions (numbers) in the hippocampal formation are shown at right. *Left*: Color-coded maps show the firing fields of each place cell at the recording locations. The field size expands in cells along the dorsoventral axis of the hippocampus. (Reproduced, with permission, from Kjelstrup et al. 2008.)

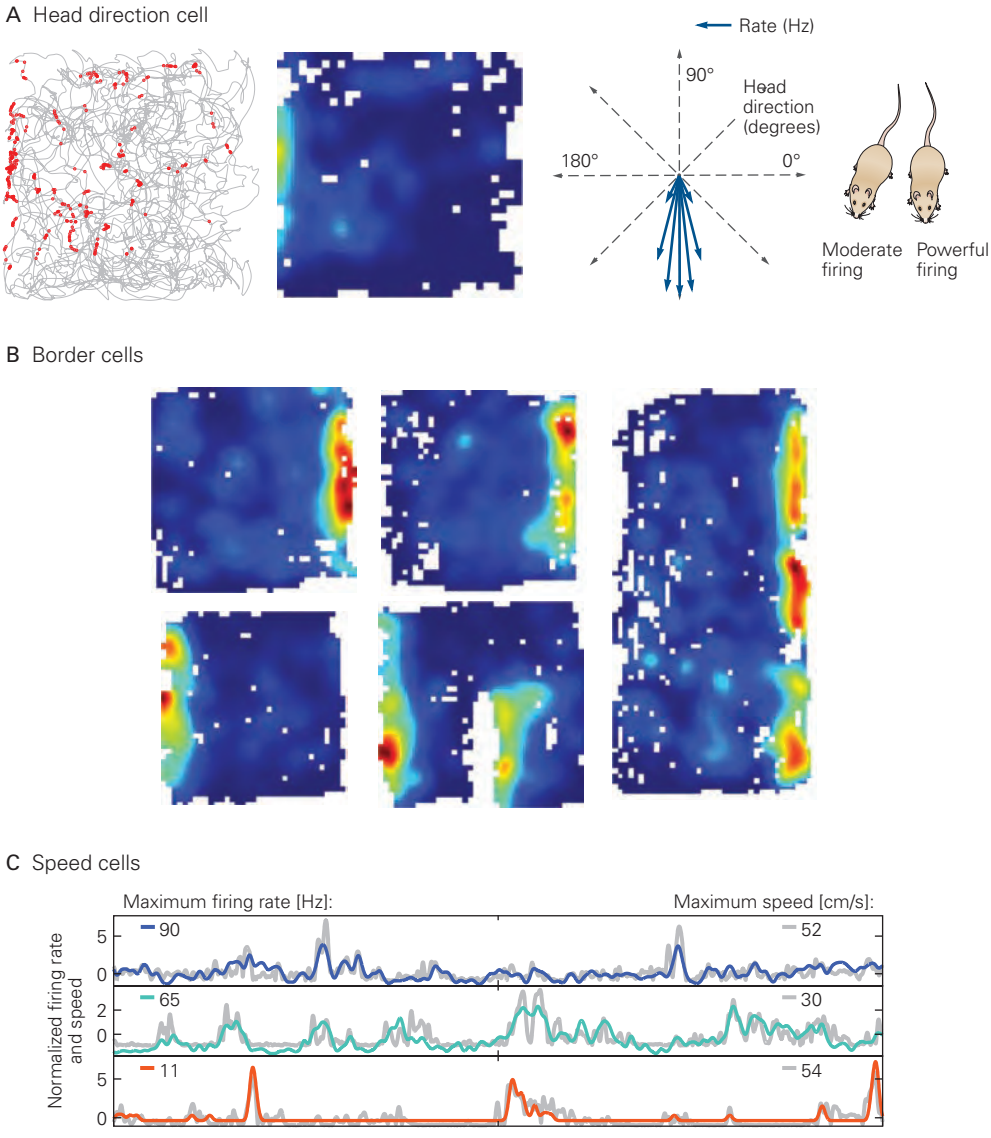

Figure 54–14 The medial entorhinal cortex contains several functional cell types tuned to distinct representations of an animal's navigation.

A. On the left is the trajectory of a rat exploring a 100-cm-wide square enclosure (**red dots** indicate firing locations). A color-coded firing rate map is also shown (color scale as in previous figures). Note that the cell's firing is scattered across the enclosure. The plot on the right shows the same cell's firing rate as a function of head direction, in polar coordinates. The cell fires selectively when the rat faces south, anywhere in the box. (Adapted, with permission, from Sargolini et al. 2006.)

B. Firing rate maps for a representative border cell in enclosures with different geometric shapes (**red** = high rate; **blue** = low rate). **Top row:** The firing field map follows the walls when the enclosure is stretched from a square (left and middle maps) to a rectangle (right map). **Bottom row:** The firing field of the same border cell in another environment. Introduction of a discrete wall (**white pixels**, right map) inside the square enclosure causes a new border field to appear to the right of the wall. (Reproduced, with permission, from Solstad et al. 2008.)

C. Speed cells. Traces show normalized firing rate (**colored traces**) and speed (**gray**) for seven representative entorhinal speed cells during 2 minutes of free foraging. Maximum values of firing rate and speed are indicated (left and right, respectively). Note high correspondence between speed and firing rate in these cells. (Reproduced, with permission, from Kropff et al. 2015.)

Taken together, these discoveries point to a network of functionally dedicated cells in the medial entorhinal cortex reminiscent of the feature detectors of the sensory cortices. The functional specificity of each cell type stems from the cell's representation of a specific feature of behavior. In this sense, the entorhinal cell types differ from cells in most other association cortices, which integrate information from many sources in ways that are not straightforward to decode.

What are the key differences between space-coding cells in the hippocampus and the medial entorhinal cortex? A striking property of all entorhinal cell types is the rigidity of their firing patterns. Ensembles of colocalized grid cells maintain the same intrinsic firing pattern regardless of context or environment. When a pair of grid cells has overlapping grid fields in one environment, their grid fields overlap also in other environments. If their grid fields are opposite, or "out of phase," they will be opposite in other environments as well. A similar rigidity is seen in head direction cells and border cells: Cells with similar orientation in one environment have similar orientations in other environments. Speed cells also maintain their unique tuning to running speed across environments. These findings suggest that the medial entorhinal cortex, or modules of this cortical circuit, may operate like a universal map of space that disregards the details of the environment. By doing so, the entorhinal map differs strongly from the place-cell map of the hippocampus.

The firing pattern of a hippocampal place cell is very sensitive to changes in the environment. The place fields of a given place cell in the hippocampus often switch to encode a completely different spatial locale when an animal's environment undergoes a major change, a process referred to as "remapping." Sometimes even minor changes in sensory or motivational inputs are sufficient to elicit remapping. The lack of correlation of hippocampal place maps for different environments (Figure 54–15) is thought to facilitate storage of discrete memories and minimize the risk that one memory will be confused with another, a process termed interference. For an explicit memory system like the hippocampus, with millions of events to be stored, this may be a huge advantage. For accurate and fast representation of an animal's position in space, as occurs in the medial entorhinal cortex, it may instead be beneficial to use a more stereotyped code that is less sensitive to environmental context or nonspatial sensory stimuli.

Place Cells Are Part of the Substrate for Spatial Memory

In addition to representing the animal's current location, place cells are thought to also store the memory of a location in position-related firing patterns that are evoked in the absence of the sensory inputs that originally elicited the firing. For example, as an animal sleeps after running repeated laps along a linear maze,

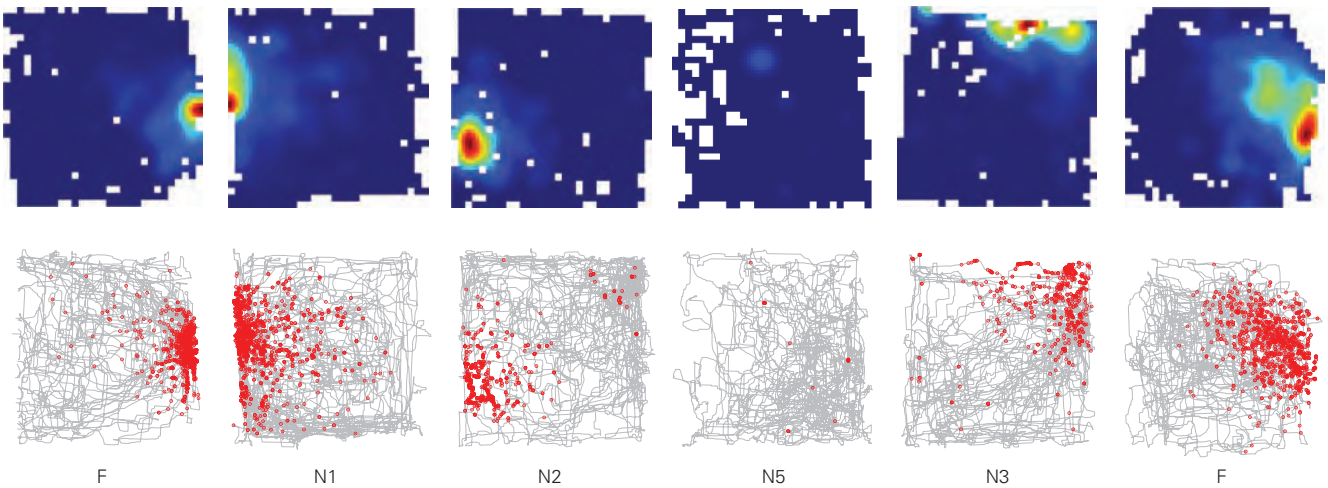

Figure 54–15 Place cells form independent maps for different environments. Rate maps showing firing patterns of a single hippocampal place cell in different square enclosures, each located in a different room. The rat was tested in one familiar (**F**) and 11 novel (**N**) rooms (recordings only shown for four of the novel rooms). The top row shows firing rate maps, whereas the bottom row shows trajectories of the animal's movement with firing locations in **red**. The cell was active only in some of the rooms (F, N1, N2, N3), where the firing locations were different. When the rat was returned to the familiar room at the end of the experiment, the cell's firing field had a similar location to the initial recording in the familiar room, indicating that a given cell's spatial firing pattern in the same environment is stable. (Adapted, with permission, from Alme et al. 2014.)

place cells spontaneously fire in the same order that they did in the maze, a phenomenon called "replay." Similarly, past trajectories and experiences may influence firing rates at particular locations in the environment. The ability of place cells to represent events and locations experienced in the past likely underlies the ability of the hippocampus to encode complex memories of events.

Once the firing pattern of a population of hippocampal neurons is formed for a given environment, how is it maintained? Because the place cells are the same hippocampal pyramidal neurons that undergo experimental LTP, a natural question is whether LTP is important. This question was addressed in experiments in mice in which LTP was disrupted.

In mice lacking the NR1 subunit of the NMDA receptor, hippocampal pyramidal neurons still fire in place fields despite the fact that LTP is blocked. Thus, this form of LTP is not required for the transformation of spatial sensory information into place fields. However, the place fields of the mutant mice are larger and fuzzier in outline than those in normal animals. In a second experiment with mutant mice, late LTP and long-term spatial memory were selectively disrupted by expression of a transgene that encodes a protein inhibitor of PKA. In these mice, place fields also form, but the firing patterns of individual cells are stable only for an hour or so (Figure 54–16). Thus, late LTP is required for long-term stabilization of place fields but not their formation.

To what degree do these maps of an animal's surroundings mediate explicit memory? In humans, explicit memory is defined as the conscious recall of facts about people, places, and objects. Although consciousness cannot be studied empirically in the mouse, selective attention, which is required for conscious recall, can be examined.

When mice are presented with different behavioral tasks, the long-term stability of place fields correlates strongly with the degree of attention required to

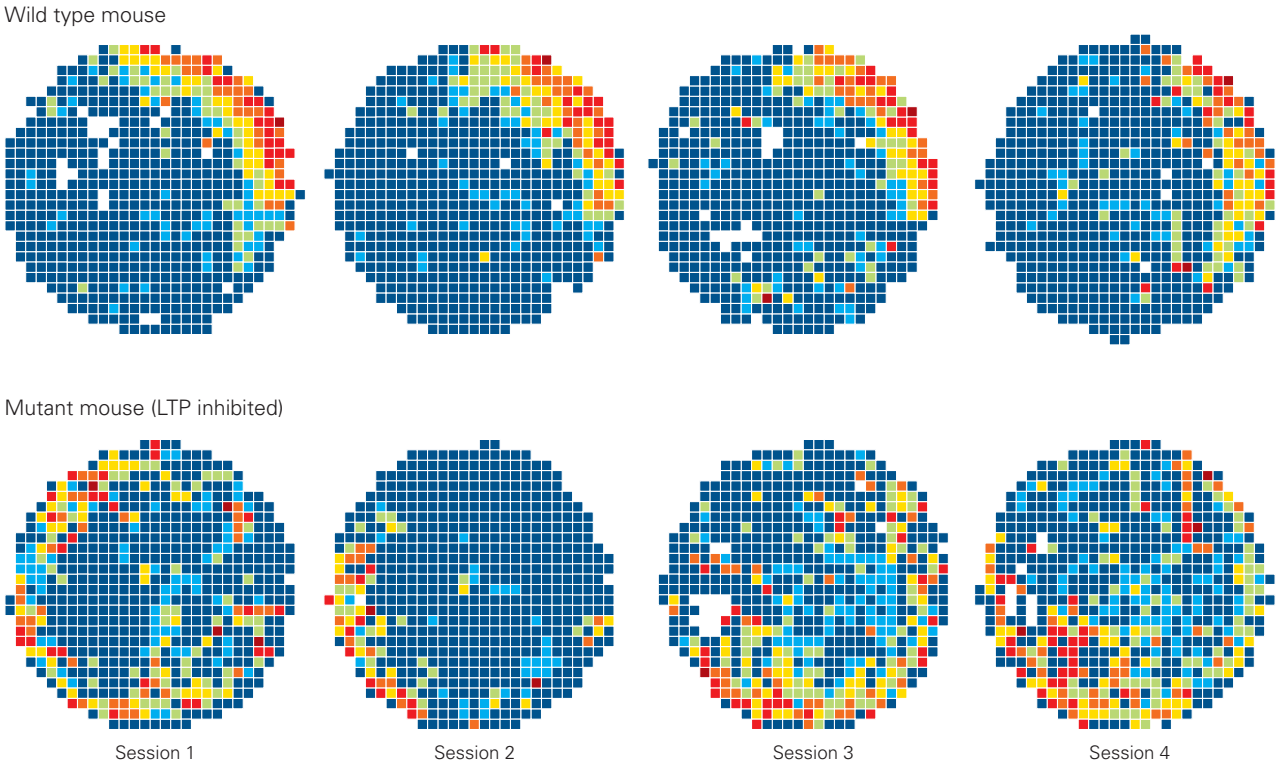

Figure 54–16 Disruption of long-term potentiation (LTP) degrades the stability of place field formation in the hippocampus. Color-coded firing rate maps (see Figure 54–12) show place fields recorded in four successive sessions from a single hippocampal pyramidal neuron in a wild type mouse and from a neuron in a mutant mouse that expresses the persistently active CaMKII (which inhibits the induction of LTP). Before each recording session, the animal is taken out of the enclosure and sometime later reintroduced into it. In each of the four sessions, the place field for the cell in the wild type animal is stable; the cell fires whenever the animal is in the upper right region of the enclosure. By contrast, the place field for the cell in the mutant mouse is unstable across the four sessions. (Reproduced, with permission, from Rotenberg et al. 1996.)

perform the task. When a mouse does not attend to the space it walks through, place fields form but are unstable after 3 to 6 hours. Animals with unstable place fields are unable to learn a spatial task. However, when a mouse is forced to attend to the space, for example, when trained to run to a specific location, the place fields are stable for days.

How does this attentional mechanism work? Studies in primates have shown the importance of the prefrontal cortex and the modulatory dopaminergic system during attention. Indeed, the formation of stable place fields in mice requires the activation of the dopamine D_1/D_5 type of receptor, which has been shown to enhance the formation of late LTP through production of cAMP and activation of PKA. These results suggest that long-term memory of a place field, rather than being a form of implicit memory that is stored and recalled without conscious effort, requires the animal to attend to its environment, as is the case for explicit memory in humans.

Disorders of Autobiographical Memory Result From Functional Perturbations in the Hippocampus

Our sense of identity is greatly dependent on our store of explicit autobiographical memories and our ability to recognize and navigate through familiar spatial environments. Neurological and psychiatric disorders that disrupt these abilities often occur as a result of changes in neural circuitry and plasticity mechanisms within the hippocampus and related regions in the temporal lobe.

There is now substantial evidence that the devastating memory loss associated with Alzheimer disease is associated with an accumulation of extracellular plaques of the protein fragment β-amyloid (Aβ) and intracellular neurofibrillary tangles of tau, a microtubule associated protein (Chapter 64). However, even before plaques and tangles are apparent, elevated levels of soluble Aβ and tau are thought to disrupt a number of cellular processes, particularly by reducing the magnitude of both early and late LTP at certain synapses. Mouse models of Alzheimer disease also show alterations in hippocampal place cell stability and population-level synchrony, which may contribute to memory loss and spatial disorientation. Changes in grid-cell function have also been observed in electrophysiological recordings in mouse disease models and in humans through functional magnetic resonance imaging studies. Although a number of preclinical studies have shown that agents that decrease levels of Aβ can rescue synaptic function and memory in rodents, so far these treatments have been less successful in treating patients with Alzheimer disease, perhaps because treatment must be initiated at early stages prior to irreversible synaptic changes.

Altered hippocampal function may also contribute to cognitive problems experienced by individuals with schizophrenia, including disturbances in working memory (Chapter 60). Recent studies using a genetic mouse model of schizophrenia report reduced synchrony between the hippocampus and prefrontal cortex associated with working memory. Furthermore, the place fields of place cells in the hippocampus CA1 region may be overly rigid in this mouse, suggesting that the ability of the hippocampus to distinguish different contexts may be impaired. Finally, a deficit in social memory in these mice has been linked to a reduction of parvalbumin-positive inhibitory neurons in the CA2 region; a similar loss of inhibitory neurons has been observed in postmortem brain tissue from individuals with schizophrenia and bipolar disorder.

Thus, studies of the hippocampus and related temporal lobe structures offer the great promise of providing fundamental insight into how explicit memories are stored and recalled and how functional alterations in these structures may contribute to neuropsychiatric disease. In turn, such insight may aid in the discovery of new treatments for these devastating disorders.

Highlights

1. Explicit memory has both a short-term component, termed working memory, and a long-term component. Both forms depend on the prefrontal cortex and hippocampus.
2. Long-term memory is thought to depend on activity-dependent long-term synaptic plasticity at synapses within the cortico-hippocampal circuit. A brief high-frequency train of tetanic stimulation leads to long-term potentiation (LTP) of excitatory synaptic transmission at each stage of the cortico-hippocampal circuit.
3. LTP at many synapses depends on calcium influx into the postsynaptic cell mediated by the *N*-methyl-D-aspartate (NMDA) type of glutamate receptor. This receptor acts as a coincidence detector: It requires both glutamate release and strong postsynaptic depolarization to conduct calcium.
4. The expression of LTP depends on either the insertion of the α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) type of

glutamate receptors in the postsynaptic membrane or an increase in presynaptic glutamate release, depending on the type of synapse and intensity of tetanic stimulation.

5. LTP has both early and late phases. Early LTP depends on covalent modifications, whereas late LTP depends on new protein synthesis, gene transcription, and growth of new synaptic connections.
6. Pharmacological and genetic manipulations that disrupt LTP often lead to an impairment of long-term memory, indicating that LTP may provide an important cellular mechanism for memory storage.
7. Memories are stored by cell assemblies. LTP may be required for forming event-specific assemblies. Recall of memory may reflect reactivation of the same assemblies that were active during the original event.
8. The hippocampus encodes both spatial and nonspatial signals. Many hippocampal neurons act as place cells, firing action potentials when an animal visits a particular location in its environment.
9. The entorhinal cortex, the area of the cortex that provides most of the input to hippocampus, also encodes both nonspatial and spatial information. The medial portion of entorhinal cortex contains neurons, called grid cells, that fire when an animal crosses the vertices of a hexagonal grid-like lattice of spatial locales. Grid cells are organized into semi-independent semi-topographically organized modules with distinct grid frequencies. The entorhinal map also contains border cells, object-vector cells, head direction cells, and speed cells.
10. Within a grid-cell module, pairs of grid cells maintain firing relationships rigidly across environments and experiences, suggesting that grid cells form a universal map that is expressed similarly in all environments. In contrast, place cells in the hippocampus form maps that are plastic as they are completely uncorrelated between environments.
11. Neuropsychiatric disorders such as Alzheimer disease and schizophrenia have been associated with deficits in hippocampal and entorhinal synaptic function, place-cell properties, and learning and memory. Treatments aimed at restoring such function may yield new therapeutic approaches to disease.
12. Despite their clear differences, implicit (Chapter 53) and explicit memory storage rely on a common logic. Both activity-dependent presynaptic facilitation for storing implicit memory and associative long-term potentiation for storing explicit memory rely on the associative properties of specific proteins: Adenylyl cyclase activation in implicit memory requires neurotransmitter plus intracellular Ca^{2+}, whereas NMDA receptor activation in explicit memory requires glutamate plus postsynaptic depolarization. Such similarities indicate the fundamental importance of associative learning rules for memory storage.

Language

Language is uniquely human and arguably our greatest skill and our highest achievement. Despite its complexity, all typically developing children master it by the age of 3. What causes this universal developmental phenomenon, and why are children so much better at acquiring a new language than adults? What brain systems are involved in mature language processing, and are these systems present at birth? How does brain damage produce the various disorders of language known as the aphasias?

For centuries, these questions about language and the brain have prompted vigorous debate among theorists. In the last decade, however, an explosion of information regarding language has taken us beyond the nature–nurture debates and beyond the standard view that a few specialized brain areas are responsible for language. Two factors have brought about this change.

First, functional brain imaging techniques such as positron emission tomography (PET), functional magnetic resonance imaging (fMRI), electroencephalography (EEG), and magnetoencephalography (MEG) have allowed us to examine activation patterns in the brain while a person carries out language tasks—naming objects or actions, listening to sounds or words, and detecting grammatical anomalies. The results of these studies reveal a far more complex picture than the one first proposed by Carl Wernicke in 1874. Moreover, structural

brain imaging techniques, such as diffusion tensor imaging (DTI), tractography, and quantitative magnetic resonance imaging (qMRI), have revealed a network of connections that link specialized language areas in the brain. These discoveries are taking us beyond previous, simpler views of the neural underpinnings of language processing and production that assumed involvement of only a few specific brain areas and connections.

Second, behavioral and brain studies of language acquisition show that infants begin to learn language earlier than previously thought, and in ways that had not been previously envisioned. Well before children produce their first words, they learn the sound patterns underlying the phonetic units, words, and phrase structure of the language they hear. Listening to language alters the infant brain early in development, and early language learning affects the brain for life.

Taken together, these advances are shaping a new view of the functional anatomy of language in the brain as a complex and dynamic network in the adult brain, one in which multiple, spatially distributed brain systems cooperate functionally via long-distance neural fascicles (axon fiber bundles). This mature network arises from the considerable brain structure and function in place at birth and develops in conjunction with powerful innate learning mechanisms responsive to linguistic experience. This new view of language encompasses not only its development and mature state, but also its dissolution when brain damage leads to aphasia.

Humans are not the only species to communicate. Passerine birds attract mates with songs, bees code the distance and direction to nectar by dancing, and monkeys signal a desire for sexual contact or fear at the approach of an enemy with coos and grunts. With language, we accomplish all of the above and more. We use language to provide information and express our emotions, to comment on the past and future, and to create fiction and poetry. Using sounds that have only an arbitrary association with the meanings they convey, we talk about anything and everything. No animal has a communication system that parallels human language either in form or in function. Language is the defining characteristic of humans, and living without it creates a totally different world, as patients with aphasia following a stroke experience so heartbreakingly.

Language Has Many Structural Levels: Phonemes, Morphemes, Words, and Sentences

What distinguishes language from other forms of communication? The key feature is a finite set of distinctive speech sounds or phonemes that can be combined with infinite possibilities. Phonemes are the building blocks of units of significance called morphemes. Each language has a distinctive set of phonemes and rules for combining them into morphemes and words. Words can be combined according to the rules of syntax into an infinite number of sentences.

Understanding language presents an interesting set of puzzles, ones that challenge supercomputers. The advent of virtual personal assistants such as Siri and Alexa, based on machine-learning algorithms, has allowed electronic devices to respond to select kinds of human utterances. However, we are still not conversing with computers. Fundamental advances will need to be made before humans can expect to have a conversation with a machine that resembles a conversation you can have with any 3-year-old. Machine-learning solutions do not accomplish their limited responses by mimicking human brain systems used for language, nor do they learn in the ways that human infants learn. Comparing machine-learning approaches (artificial intelligence) and human approaches is of theoretical and practical interest (Chapter 39) and is a hot topic for future research.

Language presents such a complex puzzle because it involves many functionally interconnected levels, starting at the most basic level with the sounds that distinguish words. For example, in English, the sounds /r/ and /1/ differentiate the words *rock* and *lock*. In Japanese, however, this sound change does not distinguish words because the /r/ and /l/ sounds are used interchangeably. Similarly, Spanish speakers distinguish between the words *pano* and *bano*, whereas English speakers treat the /p/ and /b/ sounds at the beginning of these words as the same sounds. Given that many languages use identical sounds but group them differently, children must discover how sounds are grouped to make meaningful distinctions in their language.

Phonetic units are subphonemic. As we have illustrated above with /r/ and /l/, these two sounds are both phonetic units, but their phonemic status differs in English and Japanese. In English, the two are phonemically distinct, meaning that they change the meaning of a word. In Japanese, /r/ and /l/ belong to the same phonemic category and are not distinct. Phonetic units are distinguished by subtle acoustic variations caused by the shape of the vocal tract called *formant frequencies* (Figure 55–1). The patterns and timing of formant frequencies distinguish words that differ in only one phonetic unit, such as the words *pat* and *bat*. In normal speech, formant changes occur very rapidly, on the order of milliseconds. The auditory system has to track these rapid changes in order for an individual

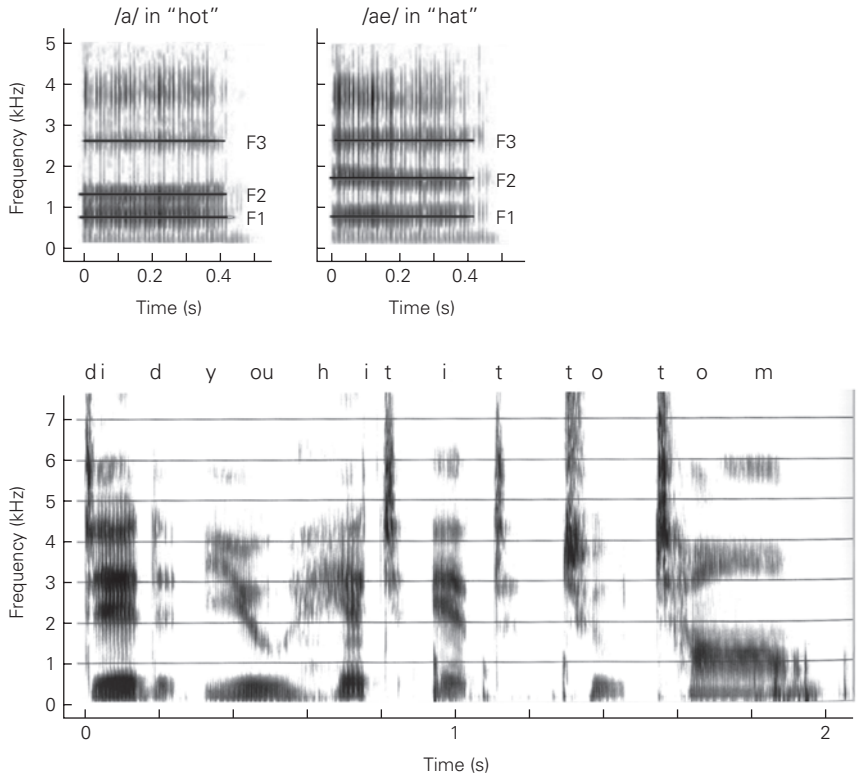

Figure 55–1 Formant frequencies. Formants are systematic variations in the concentration of energy at various sound frequencies and represent resonances of the vocal tract. They are shown here as a function of time in a spectrographic analysis of speech. The formant patterns for two simple vowels (/a/ and /ae/) spoken in isolation are distinguished by differences in formant 2 (F2). Formant patterns for the sentence "Did you hit it to Tom?" spoken slowly and clearly illustrate the rapid changes that underlie normal speech. (Data from Patricia Kuhl.)

to distinguish semantically different sounds and thus understand speech. Whereas in written language, spaces are customarily inserted between words, in speech, there are no acoustic breaks between words. Thus, speech requires a process that can detect words on the basis of something other than sounds bracketed by silence. Computers have a great deal of trouble recognizing words in the normal flow of speech.

Phonotactic rules specify how phonemes can be combined to form words. Both English and Polish use the phonemes /z/ and /b/, for example, but the combination /zb/ is not allowed in English, whereas in Polish, it is common (as in the name *Zbigniew*).

Morphemes are the smallest structural units of a language, best illustrated by prefixes and suffixes. In English, for example, the prefix *un* (meaning *not*) can be added to many adjectives to convey the opposite meaning (eg, *unimportant*). Suffixes often signal the tense or number of a word. For example, in English, we add *s* or *es* to indicate more than one of something (*pot* becomes *pots*, *bug* becomes *bugs*, or box becomes *boxes*). To indicate the tense of a regular verb, we add an ending to the word (eg, *play* can become *plays*, *playing*, and *played*). Irregular verbs do not follow the rule (eg, *go* becomes *went* rather than *goed* and *break* becomes *broke* rather than *breaked*). Every language has a different set of rules for altering the tense and number of a word.

Finally, to create language, words have to be strung together. *Syntax* specifies word and phrase order for a given language. In English, for example, sentences typically conform to a subject-verb-object order (eg, *He eats cake*), whereas in Japanese, it is typically subject-object-verb (eg, *Karewa keeki o tabenzasu*, literally *He cake eats*). Languages have systematic differences in the order of larger elements (noun phrases and verb phrases) of a sentence, and in the order of words within phrases, as illustrated by the difference between English and French noun phrases. In English, adjectives precede the noun (eg, *a very intelligent man*), whereas in French, most follow the noun (eg, *un homme tres intelligent*).

Language Acquisition in Children Follows a Universal Pattern

Regardless of culture, all children initially exhibit universal patterns of speech perception and production that do not depend on the specific language children hear (Figure 55–2). By the end of the first year, infants have learned through exposure to a specific language which phonetic units convey meaning in that language and to recognize likely words, even though they do not yet understand those words. By 12 months of age,

infants understand approximately 50 words and have begun to produce speech that resembles the native language. By the age of 3 years, children know approximately 1,000 words (by adulthood 70,000), create long adult-like sentences, and can carry on a conversation. Between 36 and 48 months, children respond to the differences between grammatical and ungrammatical sentences in an adult-like way, although tests using the most complex sentences indicate that the intricacies of grammar are not mastered until late childhood, between 7 and 10 years of age.

In the last half of the 20th century, debate on the nature and acquisition of language was ignited by a highly publicized exchange between a strong learning theorist and a strong nativist. In 1957, the behavioral psychologist B. F. Skinner proposed that language was acquired through learning. In his book *Verbal Behavior*, Skinner argued that language, like all animal behavior, was a learned behavior that developed in children as a function of external reinforcement and careful parental shaping. By Skinner's account, infants learn language as a rat learns to press a bar—through monitoring and management of reward contingencies. The nativist Noam Chomsky, writing a review of *Verbal Behavior*, took a very different position. Chomsky argued that traditional reinforcement learning has little to do with the ability of humans to acquire language. Instead, he proposed that every individual has an innate "language faculty" that includes a universal grammar and a universal phonetics; exposure to a specific language triggers a "selection" process for one language.

More recent studies of language acquisition in infants and children have clearly demonstrated that the kind of learning going on in infancy does not resemble that described by Skinner with its reliance on external shaping and reinforcement. At the same time, a nativist account such as Chomsky's, in which the language the infant hears triggers selection of one of several innate options, also does not capture the process.

The "Universalist" Infant Becomes Linguistically Specialized by Age 1

In the early 1970s, psychologist Peter Eimas showed that infants were especially good at hearing the acoustic changes that distinguish phonetic units in the world's languages. When speech sounds were acoustically varied in small equal steps to form a series ranging from one phonetic unit to another, say from /ba/ to /pa/, Eimas showed that infants could discern very slight acoustic changes at the locations in the series (the "boundary") where adults heard an abrupt change between the two phonetic categories, a phenomenon called *categorical perception.* Eimas demonstrated that infants could detect these slight acoustic changes at the phonetic boundary between two categories for phonetic units in languages they had never experienced, whereas adults have this ability only for phonetic units in languages in which they are fluent. Japanese people, for example, find it very difficult to hear the acoustic differences between the American English /r/ and /l/ sounds. Both are perceived as Japanese /r/, and as we have seen, Japanese speakers use the two sounds interchangeably when producing words.

Categorical perception was originally thought to occur only in humans, but in 1975, cognitive neuroscientists showed that it exists in nonhuman mammals such as chinchillas and monkeys. Since then, many studies have confirmed this result (as well as identifying species differences between mammals and birds). These studies suggest that the evolution of phonetic units was strongly influenced by preexisting auditory structures and capacities. Infants' ability to hear all possible differences in speech prepares them to learn any language; at birth, they are linguistic "universalists."

Speech production develops simultaneously with speech perception (Figure 55–2). All infants, regardless of culture, produce sounds that are universal. Infants "coo" with vowel-like sounds at 3 months of age and "babble" using consonant–vowel combinations at about 7 months of age. Toward the end of the first year, language-specific patterns of speech production begin to emerge in infants' spontaneous utterances. As children approach the age of 2 years, they begin to mimic the sound patterns of their native language. Chinese toddlers' utterances reflect the pitch, rhythm, and phonetic structure of Mandarin, and the utterances of British toddlers sound distinctly British. Infants develop an ability to imitate the sounds they hear others produce as early as 20 weeks of age. Very early in development, infants begin to master the subtle motor patterns required to produce their "mother tongue." Speech-motor patterns acquired in the earliest stages of language learning persist throughout life and influence the sounds, tempo, and rhythm of a second language learned later.

Right before the onset of first words, infants' abilities to discriminate native and nonnative phonetic units show a dramatic shift. At 6 months of age, infants can discriminate all phonetic units used in all languages, but by the end of the first year, they fail to discriminate phonetic changes that they successfully recognized 6 months earlier. At the same time, infants become significantly more adept at hearing native-language phonetic differences. For example, when American

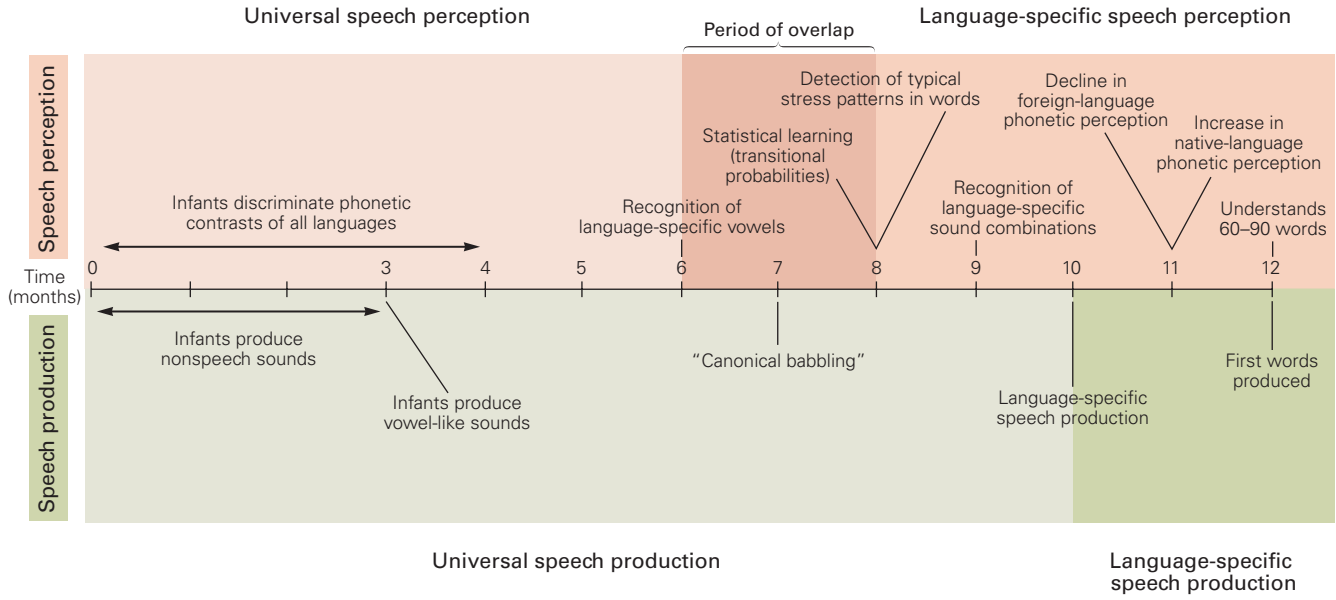

Figure 55–2 Language development progresses through a standard sequence in all children. Speech perception and production in children in various cultures initially follow a language-universal pattern. By the end of the first year of life, language-specific patterns emerge. Speech perception becomes language-specific before speech production. (Adapted, with permission, from Doupe and Kuhl 1999.)

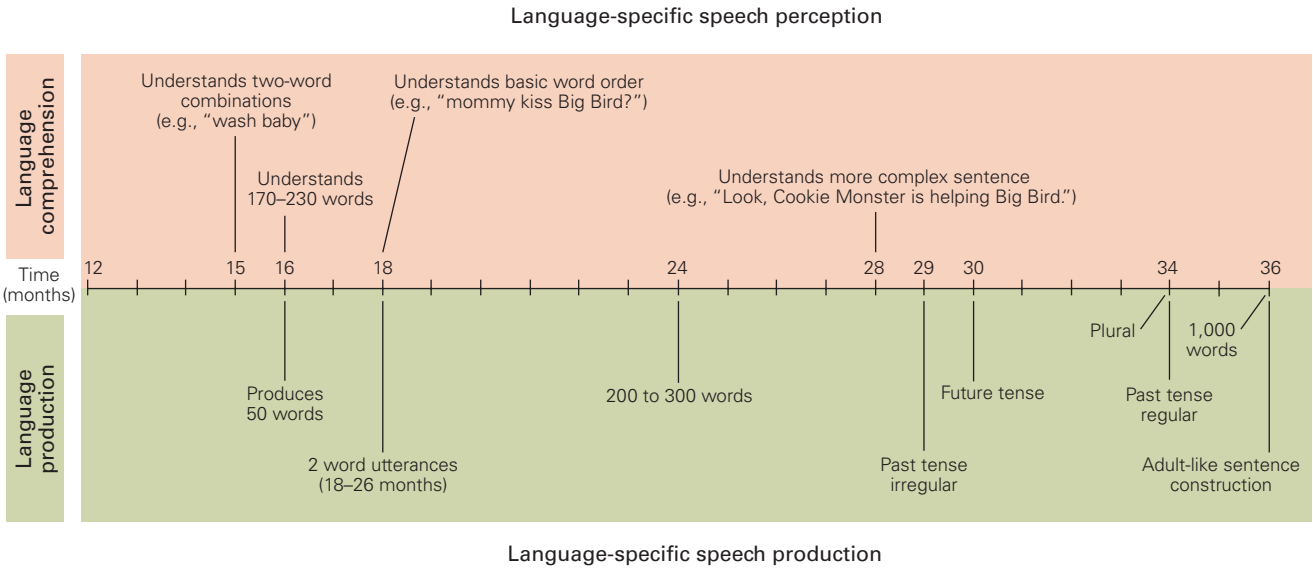
and Japanese infants were tested between 6 and 12 months of age on the discrimination of the American English /r/ and /l/, American infants improved significantly between 8 and 10 months, whereas Japanese infants declined, suggesting that this is a sensitive period for phonetic learning. Moreover, infants' native-language discrimination ability at 7.5 months of age predicts the rate at which known words, sentence complexity, and mean length of utterance grow between 14 and 30 months.

If the second half of the first year is a sensitive period for speech learning, what happens when infants are exposed to a new language during this time? Do they learn? When American infants were exposed to Mandarin Chinese in the laboratory between 9 and 10 months of age, the infants learned if exposure occurred through interaction with a human being; infants exposed to the exact same material through television or audiotape with no live human interaction do not learn (Figure 55–3). When tested, the performance of the group exposed to live speakers was statistically indistinguishable from that of infants raised in Taiwan who had listened to Mandarin for 10 months. These results established that, at 9 months of age, the right kind of exposure to a foreign language permits phonetic learning, supporting the view that this is a sensitive period for such learning. The study also demonstrated, however, that social interaction plays a more significant role in learning than previously thought.

Further work showed that the degree to which infants track the eye movements of the tutor—watching what she is looking at as she names objects in the foreign language—correlates strongly with neural measures of phonetic and word learning after exposure to the new language, again implicating social brain areas in language learning.

An infant's ability to pick up social cues is essential to language learning, but what other skills promote learning during this critical period? Studies suggest that early exposure to speech induces an implicit learning process that increases native-language discrimination and reduces the infant's innate ability to hear distinctions between the phonetic units of all other languages. Infants are sensitive to the statistical properties of the language they hear. Distributional frequency patterns of sounds affect infants' speech learning by 6 months of age. Infants begin to organize speech sounds into categories based on *phonetic prototypes*, the most frequently occurring phonetic units in their language.

Six-month-old infants in the United States and Sweden were tested with prototypical English and Swedish vowels to examine whether infants discriminated acoustic variations in the vowels, like those that occur when different talkers produce them. By 6 months of age, the American and Swedish infants ignored



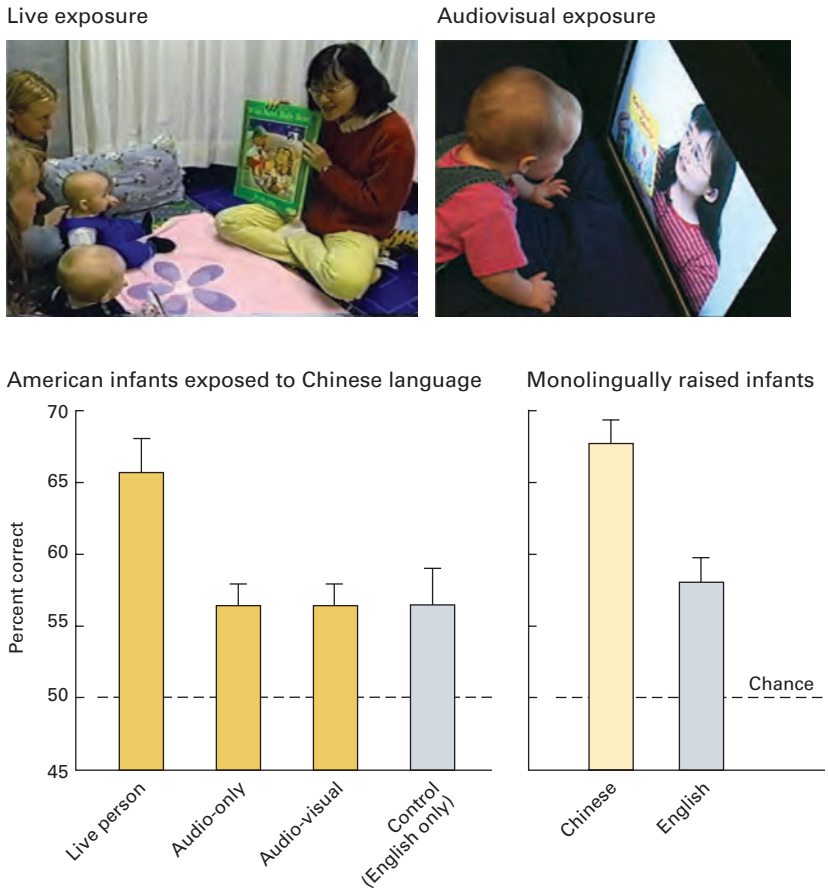


Figure 55–3 Infants can learn the phonemes of a nonnative language at 9 months of age. Three groups of American infants were exposed for the first time to a new language (Mandarin Chinese) in 12 25-minute sessions between the ages of 9 and 10.5 months. One group interacted with live native speakers of Mandarin; a second group was exposed to the identical material through television; and a third group heard tape recordings only. A control group had similar language sessions but heard only English. Performance on discrimination of Mandarin phonemes was tested in all groups after exposure (age 11 months). (Reproduced, with permission, from Kuhl, Tsao, and Liu 2003.)

Left. Only infants exposed to live Mandarin speakers discriminated the Mandarin phonemes. Infants exposed through TV or tapes showed no learning, and their performance was indistinguishable from that of control infants (who heard only English).

Right. The performance of American infants exposed to live Mandarin speakers was equivalent to that of monolingual Taiwanese infants of the same age who had experienced Mandarin from birth.

acoustic variations around native language prototypes but not with nonnative prototypes. Paul Iverson has shown that language experience alters the acoustic features to which speakers of different languages attend and distorts perception around category prototypes. This makes stimuli perceptually more similar to the prototype, which helps explain why 11-month-old Japanese infants fail to discriminate English /r/ and /1/ after experience with Japanese.

The Visual System Is Engaged in Language Production and Perception

Language is ordinarily communicated through an auditory-vocal channel, but deaf individuals communicate through a visual-manual channel. Natural signed languages, such as American Sign Language (Ameslan or ASL), are those invented by the deaf and vary across countries. Deaf infants "babble" with their hands at approximately the same time in development as hearing infants babble orally. Other developmental milestones, such as first words and two-word combinations, also occur on the developmental timetable of hearing infants.

Additional studies indicate that visual information of another kind, the face of the talker, is not only very helpful for communication but also affects the everyday perception of speech. We all experience the benefits of "lip reading" at noisy parties—watching speakers' mouths move helps us understand speech in a noisy environment. The most compelling laboratory demonstration that vision plays a role in everyday speech perception is the illusion that results when discrepant speech information is sent to the visual and auditory modalities. When subjects hear the syllable "ba" while watching a person pronounce "ga" they report hearing an intermediate articulation "da." Such demonstrations support the idea that speech categories are defined both auditorily and visually and that perception is governed by both sight and sound.

Prosodic Cues Are Learned as Early as In Utero

Long before infants recognize that things and events in the world have names, they memorize the global sound patterns typical in their language. Infants learn such prosodic cues as pitch, duration, and loudness changes. In English, for example, a strong/weak pattern of stress is typical—as in the words "BAby," "MOMmy," "TAble," and "BASEball"—whereas in some languages, a weak/strong pattern predominates. Six- and 9-month-old infants given a listening choice between words in English or Dutch show a listening preference for native-language words at the age of 9 months (but not at 6 months).

Prosodic cues can convey both linguistic information (differences in intonation and tone in languages such as Chinese) and paralinguistic information, such as the emotional state of the speaker. Even in utero fetuses learn prosodic cues by listening to their mother's speech. Certain sounds are transmitted through bone conduction to the womb; these are typically intense (above 80 dB), low-frequency sounds (particularly below 300 Hz, but as high as 1,000 Hz with some attenuation). Thus, the prosodic patterns of speech, including voice pitch and the stress and intonation patterns characteristic of a particular language and speaker, are transmitted to the fetus, while the sound patterns that convey phonetic units and words are greatly attenuated. At birth, infants demonstrate having learned this prosodic information by their preference for (1) the language spoken by their mothers during pregnancy, (2) their mother's voice over that of another female, and (3) stories with a distinct tempo and rhythm read out loud by the mother during the last 10 weeks of pregnancy.

Transitional Probabilities Help Distinguish Words in Continuous Speech

Seven- to 8-month-old infants learn to recognize words using the probability that one syllable will follow another. Such transitional probabilities between syllables within a word are high because the sequential order remains fixed. In the word *potato*, for example, the syllable "ta" always follows the syllable "po" (probability of 1.0). Between words, on the other hand, as between "hot" and "po" in the string *hot potato*, are much lower transitional probabilities.

Psychologist Jenny Saffran showed that infants treat phonetic units and syllables with high transitional probabilities as word-like units. In one experiment, infants heard 2-minute strings of pseudo-words, such as *tibudo*, *pabiku*, *golatu*, and *daropi*, without any acoustic breaks between them. They were then tested for recognition of these pseudo-words as well as new ones formed by combining the last syllable of one word with the two initial syllables of another word (such as *tudaro* formed from *golatu* and *daropi*). Infants recognized the original pseudo-words but not the new combinations they had not been previously exposed to, indicating that they used transitional probabilities to identify words.

These forms of learning clearly do not involve Skinnerian reinforcement. Caretakers do not manage the contingencies and gradually shape through reinforcement the statistical analyses performed by infants. Conversely, language learning by infants also

does not appear to reflect a process in which innately provided options are chosen based on language experience. Rather, infants learn language implicitly through detailed analysis of the patterns of statistical variation in the natural speech they hear and sophisticated analysis of information provided through social interaction (eg, eye gaze). The learning of these patterns in turn alters perception to favor the native language. In summary, both the statistical properties of language and the social cues provided during language interactions help infants learn. Language evolved to capitalize on the kinds of cues that infants are innately able to recognize. This mirrors the argument that the development of phonetic units was significantly influenced by the features of mammalian hearing, ensuring that infants would find it easy to discriminate phonemes, the fundamental units of meaning in language.

There Is a Critical Period for Language Learning

Children learn language more naturally and efficiently than adults, a paradox given that the cognitive skills of adults are superior. Why should this be the case?

Many consider language acquisition to be an example of a skill that is learned best during a critical period in development. Eric Lenneberg proposed that maturational factors at puberty cause a change in the neural mechanisms that control language acquisition. Evidence supporting this view comes from classic studies of Chinese and Korean immigrants to the United States who had been immersed in English at ages ranging from 3 to 39 years. When asked to identify errors in sentences containing grammatical mistakes, an easy task for native speakers, the responses of second-language learners declined with the age of arrival in the United States. A similar trend emerges when one compares individuals exposed to ASL from birth to those exposed between 5 and 12 years of age. Those exposed from birth were best at identifying errors in ASL, those exposed at age 5 were slightly poorer, and those exposed after the age of 12 years were substantially poorer.

What restricts our ability to learn a new language after puberty? Developmental studies suggest that prior learning plays a role. Learning a native language produces a neural commitment to detection of the acoustic patterns of that language, and this commitment interferes with later learning of a second language. Early exposure to language results in neural circuitry that is "tuned" to detect the phonetic units and prosodic patterns of that language. Neural commitment to native language enhances the ability to detect patterns based on those already learned (eg, phonetic learning supports word learning) but reduces the ability to detect patterns that do not conform. Learning the motor patterns required to speak a language also results in neural commitment. The motor patterns learned for one language (eg, lip rounding in French) can interfere with those required for pronunciation of a second language (eg, English) and thus can hinder efforts to pronounce the second language without an accent. Early in life, two or more languages can be easily learned because interference effects are minimal until neural patterns are well established.

Neurobiologist Takao Hensch has been working on identifying the chemical switches that open and close neurodevelopmental critical periods in learning, including those in animals and humans. Hensch has found that the neurotransmitter γ-aminobutyric acid (GABA) opens the critical period by inhibiting the firing of excitatory neurons, bringing them into balance with the firing of inhibitory neurons so as to create an excitatory–inhibitory (EI) balance. Studies testing this hypothesis in humans are difficult to conduct, but investigations on the infants of mothers who altered the EI balance of the fetus during pregnancy by taking psychotropic medications (serotonin reuptake inhibitors [SRIs]) for depression support the EI hypothesis. One of fluoxetine's off-target effects is to increase the sensitivity of some GABA receptors to GABA. When compared to infants of depressed mothers who were not exposed prenatally to SRIs and control mothers without depression or SRIs, infants exposed prenatally to SRIs showed an accelerated phonetic learning process, indicating that the well-established timing of the early transition in infants' phonetic perception can be altered.

We do not completely lose the ability later in life to learn a new language, but it is far more difficult. Regardless of the age at which learning begins, second-language learning is improved by a training regimen that mimics critical components of early learning—long periods of listening in a social context (immersion), the use of both auditory and visual information, and exposure to simplified and exaggerated speech resembling "parentese."

The "Parentese" Speaking Style Enhances Language Learning

Everyone agrees that when adults talk to their children they sound unusual. Discovered by linguists and anthropologists in the early 1960s as they listened to languages spoken around the world, "motherese" (or "parentese," as fathers produce it as well) is a special speaking style used when addressing infants and

young children. Parentese has a higher pitch, slower tempo, and exaggerated intonation contours, and is easily recognized. Compared to adult-directed speech, the pitch of the voice is increased on average by an octave both in males and in females. Phonetic units are spoken more clearly and are acoustically exaggerated, thus increasing the acoustic distinctiveness of phonetic units. Adults speaking to infants exaggerate just those features of speech that are critical to their native language. For example, when talking to their infants, Chinese mothers exaggerate the four tones in Mandarin that are critical to word meaning.

When given a choice, infants prefer listening to infant-directed rather than adult-directed speech. When infants are allowed to activate recordings of infant-directed or adult-directed speech by turning their head left or right, they will turn in whatever direction is required to turn on infant-directed speech.

Recent research by psychologists Nairan Ramirez-Esparza and Adrian Garcia-Sierra shows that the degree to which parentese is used in language spoken to infants at 11 and 14 months of age at home is strongly correlated with a child's language development by the age of 24 months and remains strongly correlated at the age of 36 months. This relationship holds for both monolingual and bilingual children. However, in bilingual children, early advances in the two languages differ depending on the language spoken in parentese. For example, Spanish-language parentese enhances a child's behavioral and neural responses to Spanish, but not English, and vice versa. Children raised in families in which the amount of language exposure and the use of parentese are low often show deficits in language and literacy by the time they enter school, and these deficits correlate with decreased functional activation in brain areas related to language.

Successful Bilingual Learning Depends on the Age at Which the Second Language Is Learned

How does the brain handle two languages? Behavioral data show that if exposure to two languages begins at birth, children reach the milestones of language at the same age as their monolingual peers—they coo, babble, and produce words at the benchmark ages seen in monolinguals. The idea that bilingual experience produces "confusion" has been debunked by studies that measure "conceptual" vocabulary, that is, word knowledge regardless of the language the child uses to express that knowledge. Older studies measured words in only one of the infants' two languages, and such word counts often showed decreased vocabulary when compared to monolinguals. Conceptual vocabulary scores show that bilingual children's vocabulary counts meet or exceed those of their monolingual peers.

Exposure to a second language after puberty shows limitations in the degree to which the new language can be learned. Whether subjects are tested on phonological rules, morphological endings, or syntax, the ability to learn a new language appears to decline every 2 years after the age of 7 years, indicating that acquisition of a second language after puberty is quite difficult.

Brain measures on bilingual infants reflect these behavioral data. Psychologist Naja Ferjan Ramirez used MEG to show that activation of the superior temporal area in 11-month-old infants exposed to two languages (English and Spanish) from birth is the same for the sounds of both languages and that brain responses to English sounds are equivalent to those of age-matched monolingual infants for English. Bilingual infants listening to speech also exhibit greater activation in the prefrontal cortex, a region mediating attention, when compared to monolingual infants; this finding is consistent with the fact that bilingual children (adults as well) demonstrate superior cognitive skills related to attention. Arguably, listening to two languages requires multiple shifts in attention to activate one language over another.

If a second language is acquired later in development, the age at which exposure occurs and the degree of eventual proficiency affect how the brain processes both languages. In "late" bilinguals (those who learned a second language after puberty), the second language and native language are processed in spatially separated areas in the language-sensitive left frontal region. In "early" bilinguals (those who acquired both languages as children), the two languages are processed in the same left frontal area.

A New Model for the Neural Basis of Language Has Emerged

Numerous Specialized Cortical Regions Contribute to Language Processing

The classical Wernicke-Geschwind neural model of language was based on the works of Broca (1861), Wernicke (1874), Lichtheim (1885), and Geschwind (1970). In the Wernicke-Geschwind model, acoustic cues contained in spoken words were processed in auditory pathways and relayed to Wernicke's area, where the meaning of a word was conveyed to higher brain structures. The arcuate fasciculus was assumed to

Table 55–1 Differential Diagnosis of the Main Types of Aphasia

Type of aphasia	Speech	Comprehension	Capacity for repetition	Other signs	Region affected
Broca	Nonfluent, effortful	Largely preserved for single words and grammatically simple sentences	Impaired	Right hemiparesis (arm > leg); patient aware of defect and can be depressed	Left posterior frontal cortex and underlying structures
Wernicke	Fluent, abundant, well articulated, melodic	Impaired	Impaired	No motor signs; patient can be anxious, agitated, euphoric, or paranoid	Left posterior superior and middle temporal cortex
Conduction	Fluent with some articulatory defects	Intact or largely preserved	Impaired	Often none; patient can have cortical sensory loss or weakness in right arm	Left superior temporal and supramarginal gyri
Global	Scant, nonfluent	Impaired	Impaired	Right hemiplegia	Massive left perisylvian lesion
Transcortical motor	Nonfluent, explosive	Intact or largely preserved	Intact or largely preserved	Sometimes right-sided weakness	Anterior or superior to Broca's area
Transcortical sensory	Fluent, scant	Impaired	Intact or largely preserved	No motor signs	Posterior or inferior to Wernicke's area

be a unidirectional pathway that brought information from Wernicke's area to Broca's area to enable speech production. Both Wernicke's and Broca's areas interacted with association areas. The Wernicke-Geschwind model formed the basis for a practical classification of the aphasias that clinical neurologists still use today (Table 55–1).

Advancements in basic and clinical neuroscience, the advent of more sophisticated functional brain imaging tools, advanced methods for structural brain imaging, and an increasing number of studies that combine brain and behavioral measures have resulted in the development of a new "dual-stream" model. In the dual-stream model, the processing of language is thought to involve large-scale networks that are composed of different brain areas, each with a specialized function, and the white matter tracts that connect them.

This dual-stream model of language processing is similar to the well-established "what" and "where" dual-stream model of the visual system. The existence of two cortical streams of auditory information processing was first postulated by Josef Rauschecker. Gregory Hickok and David Poeppel further elaborated the dual-stream model, and it has since been even further expanded upon by Angela Friederici as well as others studying the neurobiology of language. Figure 55–4 shows the basic components of the dual-stream model.

Compared to the classic Wernicke-Geschwind model, the dual-stream model comprises a larger number of cortical areas that are more widely distributed in the brain and adds critical connecting bidirectional pathways between specialized brain regions. These improvements in the model for language processing are due to advances in structural brain imaging techniques, such as DTI and diffusion-weighted imaging, which provide quantitative measures on a microscopic scale of the white matter in fascicles that connect various cortical areas and allow for the detailed delineation of neural tracts throughout the brain (tractography).

In the dual-stream model, initial spectrotemporal processing of auditory speech sounds is performed bilaterally in the auditory cortex. This information is then communicated to the posterior superior temporal gyrus bilaterally, where phonological-level processing occurs. Language processing then diverges into a dorsal "sensorimotor stream," which maps sound to articulation, and a ventral "sensory-conceptual" stream, which maps sound to meaning.

The bidirectional dorsal stream connects auditory speech information with motor plans that produce speech. The dorsal stream passes above the lateral ventricles and maps sounds onto articulatory representations, connecting regions of the inferior frontal lobe, premotor cortex, and insula (all involved in speech articulation) to the region that is classically recognized as Wernicke's area. It is considered to comprise two pathways: Dorsal pathway 1 connects the posterior

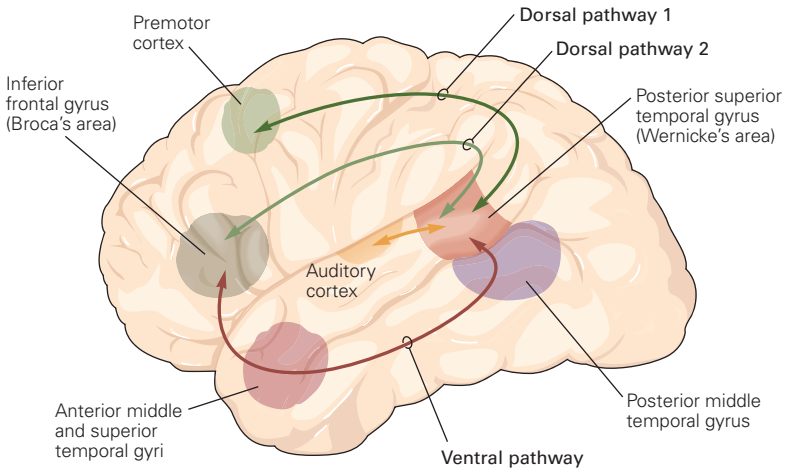

Figure 55–4 Dual-stream model of language processing. Temporal and spectral analyses of speech signals occur bilaterally in the auditory cortex followed by phonological analysis in the posterior superior temporal gyri (**yellow arrow**). Processing then diverges into two separate pathways: a dorsal stream that maps speech sounds to motor programs and a ventral stream that maps speech sounds to meaning. The dorsal pathway is strongly left hemisphere dominant and has segments that extend to the premotor cortex (dorsal pathway 1) and to the posterior inferior frontal cortex (dorsal pathway 2). The ventral pathway occurs bilaterally and extends to the anterior temporal lobe and the posterior inferior frontal cortex. (Adapted, with permission, from Hickok and Poeppel 2007, and Skeide and Friederici 2016.)

superior temporal gyrus to the premotor cortex, and dorsal pathway 2 connects the posterior superior temporal gyrus to Broca's area. Pathway 2 is involved in higher-order analysis of speech, such as discriminating subtle differences in meaning based on grammar and interpreting language using more complex concepts. The dorsal stream is strongly left hemisphere dominant. The arcuate fasciculus and the superior longitudinal fasciculus are white matter fiber tracts that mediate communication along the dorsal stream.

The ventral stream passes below the Sylvian fissure and is composed of regions of the superior and middle temporal lobes as well as regions of the posterior inferior frontal lobe. This stream conveys information for auditory comprehension, which requires transformation of the auditory signal to representations in a mental lexicon, a "brain-based dictionary" that links individual word forms to their semantic meaning. This stream comprises the inferior fronto-occipital fasciculus, the uncinate fasciculus, and the extreme fiber capsule system and is largely bilaterally represented.

The cortical brain regions included in the dual-stream model also interact with spatially distributed regions throughout both hemispheres of the brain that provide additional information crucial for language processing. These regions include the prefrontal cortex and cingulate cortices, which exert executive control and mediate attentional processes, respectively, as well as regions in the medial temporal, frontal, and parietal areas involved in memory retrieval.

The Neural Architecture for Language Develops Rapidly During Infancy

The study of language development in infancy requires a methodology that documents significant changes in behavior and links those changes to changes in brain function and morphology over time. Neuroimaging methods for the infant brain have improved substantially over the past decade, allowing for a detailed assessment of the progression of development of the specialized regions and structural connections required by the language network. For example, developmental neuroscientists have created models of the average infant brain and brain atlases for the infant brain at 3 and 6 months of age. These models indicate that brain structures essential to language processing in adulthood, such as the inferior frontal cortex, premotor cortex, and superior temporal gyrus, support speech processing in early infancy. Studies using DTI and tractography indicate that the arcuate fasciculus and the uncinate fasciculus connect language regions by 3 months of age.

The development of the neural substrates for language in 1- to 3-day-old infants has been studied in depth by Daniela Perani using fMRI and DTI. Perani's fMRI work reveals that listening to speech activates the infant superior temporal gyrus bilaterally and that in the left hemisphere this activation extends to the planum temporale, inferior frontal gyrus, and inferior parietal lobe. Perani's DTI studies of the same newborn infants demonstrate weak intrahemispheric connections, but strong connections between the hemispheres. Nevertheless, the ventral fiber tract connecting the ventral portion of the inferior frontal gyrus via the extreme fiber capsule system to the temporal cortex is evident in newborns and in both hemispheres. The dorsal pathway connecting the temporal cortex to the premotor cortex is also present in the newborns, although the dorsal tract that connects the temporal cortex to Broca's area in adults is not detectable in newborns. These early connections between sensory areas

and the premotor cortex are important because they may allow the sensory-to-motor mapping essential for the development of early imitation of the sounds and words of the language.

Jens Brauer and colleagues replicated these findings on the development of ventral and dorsal pathways in newborns, revealing the maturational primacy of the ventral connection linking temporal areas to the inferior frontal gyrus. Brauer also verified that the dorsal pathway connects the temporal and premotor cortex at birth and showed that the dorsal pathway to the inferior frontal gyrus develops later. Brauer used the same protocol with children 7 years of age and adults. In 7-year-olds, the dorsal pathway fully connects auditory areas and the inferior frontal gyrus, but in adults, it has more extensive and far-reaching connections.

EEG and MEG functional brain imaging studies on young infants as early as 2 months of age show that the inferior frontal and temporal cortices, implicated in both the classical and contemporary models of language processing, are activated bilaterally by speech—syllables, words, and sentences. This finding supports the hypothesis that left hemisphere specialization increases over time, with syllables showing dominant left hemisphere specialization at the end of the first year, words by the age of 2, and sentences in middle childhood.

EEG and MEG studies of young infants in which infants listen passively to native and nonnative syllables have produced results consistent with the behavioral transitions described earlier in this chapter. Several infant laboratories have shown that brain activity in response to speech, measured early in development, provides sensitive markers that predict language skills several years later. These studies hold promise for the eventual identification of brain measures in infants that indicate risk for developmental disabilities involving language, such as autism spectrum disorder, dyslexia, and specific language impairment. Early identification would allow earlier and more effective interventions for these impairments, improving outcomes for these children and their families.

Studies using functional MEG brain imaging of infants show that at 7 months of age, native and nonnative speech syllables activate not only superior temporal regions of the infant brain but also inferior frontal regions and the cerebellum, forging an association between speech patterns they hear and the motor plans they use to babble and imitate. By 12 months of age, language experience alters the patterns of activation in both sensory and motor brain regions.

Auditory activation becomes stronger for *native* sounds, indicating that brain areas have begun to become specialized for native language phonology. In contrast, motor activation in both Broca's area and the cerebellum is increased in response to *nonnative* sounds, because by 12 months infants have sufficient sensorimotor knowledge to imitate native sounds and some words and have linked stored auditory patterns (words like "cup" and "ball") to the motor plans necessary to produce them. But they cannot make the sensorimotor associations for foreign-language sounds and words because the necessary motor plans cannot be generated. Therefore, we see longer and more diffuse activation as infants struggle to create the motor plans for a sound or word they have never experienced. The importance of motor learning in language development is also shown by longitudinal whole-brain voxel-based morphometry studies of 7-month-old infants showing that gray matter concentrations in the cerebellum correlate with the number of words those infants can produce at 1 year of age.

Over the next 5 years, there is likely to be an explosive increase in brain studies focused on development of the language network. In a number of laboratories, these brain measures will be linked to behavioral measures, enabling the creation of models that delineate how language experience alters the infant brain to increase its specialization for the language or languages to which the child is exposed. The finding that the classic brain regions known to be part of the language network in adults—in particular, the left and right temporal cortices and the left inferior frontal cortex—are already activated by speech at birth recalls Chomsky's view of innate language capabilities.

The Left Hemisphere Is Dominant for Language

Current views of language processing agree that while the neural circuitry necessary for transforming speech sounds to meaning may be present in both hemispheres, the left hemisphere is more highly specialized for language processing. This left hemisphere dominance develops with maturation and learning.

Evidence from a variety of sources suggests that left hemisphere specialization for language develops rapidly in infancy. Word learning represents a case in point. Deborah Mills and her colleagues used event-related potentials to track development of the neural signals generated in response to words that children knew. Her studies showed that both age and language proficiency produce changes in the strength of the neural responses to known words, as well as a change in hemisphere dominance between 13 and 20 months of age. At the earliest age studied, known words activate a broad and bilaterally distributed

pattern across the brain. As infants approach 20 months and vocabulary grows, the activation pattern shifts to become left hemisphere dominant in the temporal and parietal regions. In late talkers, this shift is delayed to nearly 30 months. In 24-month-old children with autism, the degree to which this left hemisphere dominance is evident predicts children's linguistic, cognitive, and adaptive abilities at age 6.

Several studies show that immersion in a second language in adulthood produces growth in the superior longitudinal fasciculus, a white matter fiber tract that is important for language. Neuroscientist Ping Mamiya, collaborating with geneticist Evan Eichler, demonstrated, using DTI, that white matter integrity of the superior longitudinal fasciculus in the right hemisphere increased in Chinese college students in proportion to the number of days they spent in an English immersion class and decreased after immersion ended. Moreover, analysis of polymorphisms in the catechol-*O*-methyltransferase (*COMT*) gene showed an effect on this relationship—students with two of the variants demonstrated these changes, while students with the third variant showed no change in white matter properties with language experience.

There is great interest in brain studies investigating the selectivity of the brain mechanisms underlying language. Studies in the visual system by neuroscientist Nancy Kanwisher led to the suggestion that certain visual areas (the fusiform face area) are highly selective for particular stimuli, such as faces. Similar claims have been advanced for brain areas underlying speech analysis. For example, Kanwisher's group has proposed that Broca's area contains many subregions, each highly selective for particular levels of language. Additional studies on selectivity, particularly during development, will be the focus of future studies.

Helen Neville and Laura-Anne Pettito have shown that the left hemisphere is activated not only by auditory stimuli but also by visual stimuli that have linguistic significance. Deaf individuals process sign language in left hemisphere speech-processing regions. Such studies show that the language network processes linguistic information regardless of modality.

Prosody Engages Both Right and Left Hemispheres Depending on the Information Conveyed

Prosodic cues in language can be linguistic, conveying semantic meaning as tones do in Mandarin Chinese or Thai, as well as paralinguistic, expressing our attitudes and emotions. The pitch of the voice carries both kinds of information, and the brain's processing of each kind of information differs.

Emotional changes in pitch engage the right hemisphere, primarily the right frontal and temporal regions. Emotional information helps convey a speaker's mood and intentions, and this helps interpret sentence meaning. Patients with right hemisphere lesions often produce speech with inappropriate stress, timing, and intonation, and their speech sounds emotionally flat; they also frequently fail to interpret the emotional cues in others' speech.

Semantic changes in pitch involve a different pattern of brain activity, as demonstrated by neuroimaging studies. Jackson Grandour used a novel experimental design using Chinese syllables that carried either their native Chinese tone or the nonnative Thai tone. fMRI results for both Chinese and Thai speakers show higher activation in the left planum temporale for syllables carrying the native tone as opposed to nonnative tone (Figure 55–5). The right hemisphere did not show this double dissociation, supporting the view that language processing occurs in the left hemisphere even for auditory signals typically processed on the right.

Studies of the Aphasias Have Provided Insights into Language Processing

According to recent estimates, there are more than 795,000 strokes per year in the United States. Aphasia occurs in 21% to 38% of acute strokes and increases the probability of mortality and morbidity. In the past decade, the number of individuals with aphasia grew by more than 100,000 per year. Broca's aphasia, Wernicke's aphasia, and conduction aphasia compose the three classical models of clinical aphasia syndromes. Hickok and Poeppel describe each of these subtypes in the context of the dual-stream model. Accordingly, Broca's aphasia and conduction aphasia are due to sensorimotor integration problems related to damage to the dorsal stream of language processing, whereas Wernicke's aphasia, word deafness, and transcortical sensory aphasia are produced by damage to the ventral stream.

Broca's Aphasia Results From a Large Lesion in the Left Frontal Lobe

Broca's aphasia is a disorder of speech production, including impairments in grammatical processing, caused by lesions of the dorsal stream. When we speak, we rely on auditory patterns stored in the brain. Naming a cup when presented with coffee requires a

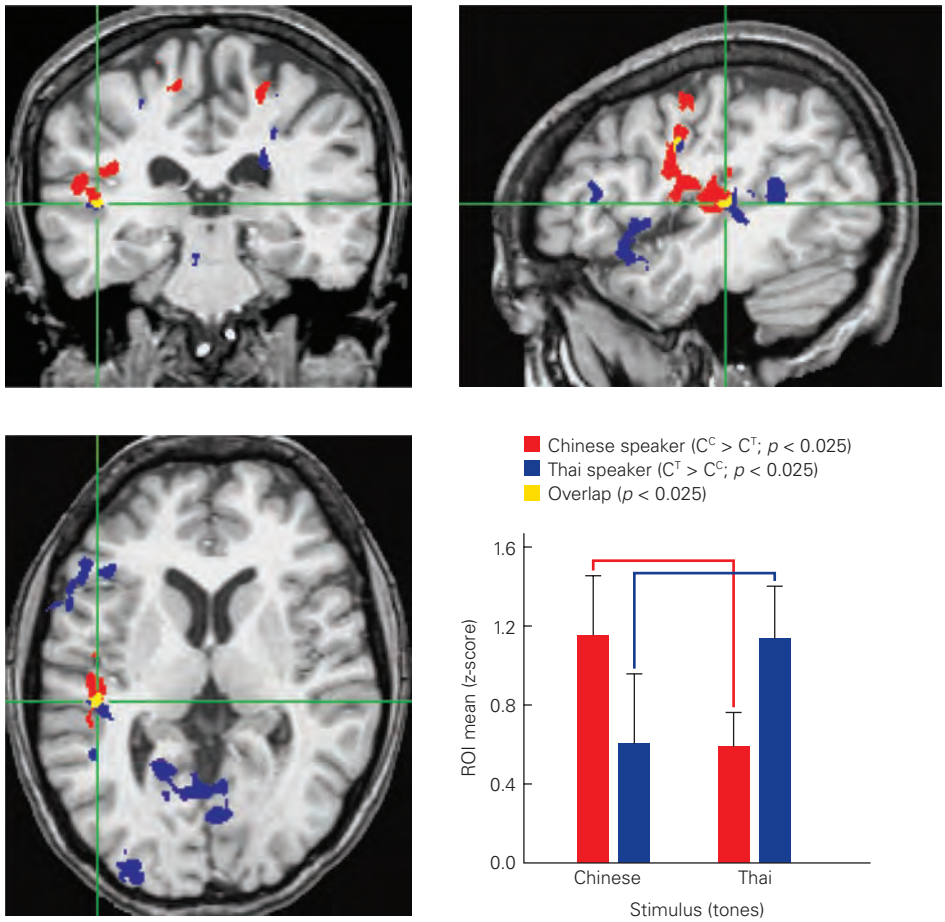

Figure 55–5 Brain activation for Chinese and Thai lexical tones revealed by functional magnetic resonance imaging. Language stimuli were composed of Chinese syllables superimposed with either Thai tones (C^T) or Chinese tones (C^C). Both native Chinese and native Thai speakers demonstrated a left hemisphere (**LH**) dominance when listening to their native tones. In the Chinese speakers, activation of the left hemisphere was stronger for Chinese tones, whereas in the Thai speakers, activation was stronger for Thai tones. Overlap for the two groups occurs in the left planum temporale and the ventral precentral gyrus. In the left planum temporale (**green crosshairs**), a double dissociation was found between tonal processing and language experience (bar charts). The right hemisphere (**RH**) did not show these effects. (*Top left*, coronal section; *top right*, sagittal section; *bottom left*, axial section.) (Abbreviation: **ROI**, region of interest.) patient to connect the stored sensory pattern associated with the word "cup" to the motor plans required to hit that auditory target. With Broca's aphasia, the sensorymotor integration necessary for fluent speech production is damaged. Thus, speech is labored and slow, articulation is impaired, and the melodic intonation of normal speech is lacking (Table 55–2). Yet patients sometimes have considerable success at verbal communication because their selection of certain types of words, especially nouns, is often correct. By contrast, verbs and grammatical words such as prepositions and conjunctions are poorly selected or can be missing altogether. Another major sign of Broca's aphasia is a defect in the ability to repeat complex sentences.

Because most patients with Broca's aphasia give the impression of understanding conversational speech, the condition was initially thought to be a deficit of production only. But Broca's aphasics have difficulty comprehending sentences with meanings that depend mostly on grammar. Broca's aphasics can understand *The apple that the girl ate was green*, but have trouble understanding *The girl that the boy is chasing is tall*. This is because they can understand the first sentence without recourse to grammatical rules—girls eat apples but apples do not eat girls; apples can be green but girls cannot. However, they have difficulty with the second sentence because both girls and boys can be tall, and either can chase the other. To understand

Table 55–2 Examples of Spontaneous Speech Production and Repetition for the Primary Types of Aphasia

Type of aphasia	Spontaneous speech	Repetition
	Stimulus (Western Aphasia Battery picnic picture): What do you see in this picture?	Stimulus: "The pastry cook was elated."
Broca	"O, yea. Det's a boy an' a girl . . . an' . . . a . . . car . . . house . . . light po' (pole). Dog an' a . . . boat. 'N det's a . . . mm . . . a coffee, an' reading. Det's a mm . . . a . . . det's a boy . . . fishin'." (Elapsed time: 1 min 30 s)	"Elated."
Wernicke	"Ah, yes, it's, ah . . . several things. It's a girl . . . uncurl . . . on a boat. A dog . . . 'S is another dog . . . Uh-oh . . . long's . . . on a boat. The lady, it's a young lady. An' a man a They were eatin'. 'S be place there. This . . . a tree! A boat. No, this is a . . . It's a house. Over in here . . . a cake. An' it's, it's a lot of water. Ah, all right. I think I mentioned about that boat. I noticed a boat being there. I did mention that before. . . . Several things down, different things down . . . a bat . . . a cake . . . you have a . . ." (Elapsed time: 1 min 20 s)	"/I/ . . . no . . . In a fog."
Conduction	"Kay. I see a guy readin' a book. See a women /ka . . . he . . . /pourin' drink or something. An' they're sittin' under a tree. An' there's a . . . car behind that an' then there's a house behind th' car. An' on the other side, the guy's flyn' a /fait . . . fait/(kite). See a dog there an' a guy down on the bank. See a flag blowin' in the wind. Bunch of /hi . . . a . . . /trees in behind. An a sailboat on th' river, river . . . lake. 'N guess that's about all. . . . 'Basket there." (Elapsed time: 1 min 5 s)	"The baker was . . . What was that last word?" ("Let me repeat it: The pastry cook was elated.") "The baker-er was / vaskerin/ . . . uh . . ."
Global	(Grunt)	(No response)

the second sentence, it is necessary to analyze its grammatical structure, something that Broca's aphasics have difficulty doing.

Broca's aphasia results from damage to Broca's area (the left inferior frontal gyrus); the surrounding frontal fields; the underlying white matter, insula, and basal ganglia; and a small portion of the anterior superior temporal gyrus (Figure 55–6). A small sector of the insula, an island of cortex buried deep inside the cerebral hemisphere, can also be included among the neural correlates of Broca's aphasia. Broca's aphasics typically have no difficulty perceiving speech sounds or recognizing their own errors and no trouble in coming up with words. When damage is restricted to Broca's area alone or to its subjacent white matter, the result is the condition of Broca's area aphasia, a milder version of true Broca's aphasia, from which many patients are able to recover.

Wernicke's Aphasia Results From Damage to Left Posterior Temporal Lobe Structures

Wernicke's aphasics have difficulty comprehending the sentences uttered by others, and damage occurs in areas of the brain that subserve grammar, attention, and word meaning. Wernicke's aphasia can be caused by damage to different levels of the ventral stream, where auditory information is linked to word knowledge. It is usually caused by damage to the posterior section of the left auditory association cortex, although in severe cases, the middle temporal gyrus and white matter are involved (Figure 55–7).

Patients with Wernicke's aphasia can produce speech at a normal rate that sounds effortless, melodic, and quite unlike that of patients with Broca's aphasia. But speech can be unintelligible as well because Wernicke's aphasics often shift the order of individual sounds and sound clusters. These errors are called *phonemic paraphasias* (a paraphasia is substitution of an erroneous phoneme for the correct one). Even when individual sounds are normally produced, Wernicke's aphasics have great difficulty selecting words that accurately represent their intended meaning (known as a *verbal* or *semantic paraphasia*). For example, a patient might say *headman* when they mean president.

Conduction Aphasia Results From Damage to a Sector of Posterior Language Areas

Conduction aphasia, like Broca's aphasia, is thought to involve the dorsal stream. Speech production and auditory comprehension are less compromised than

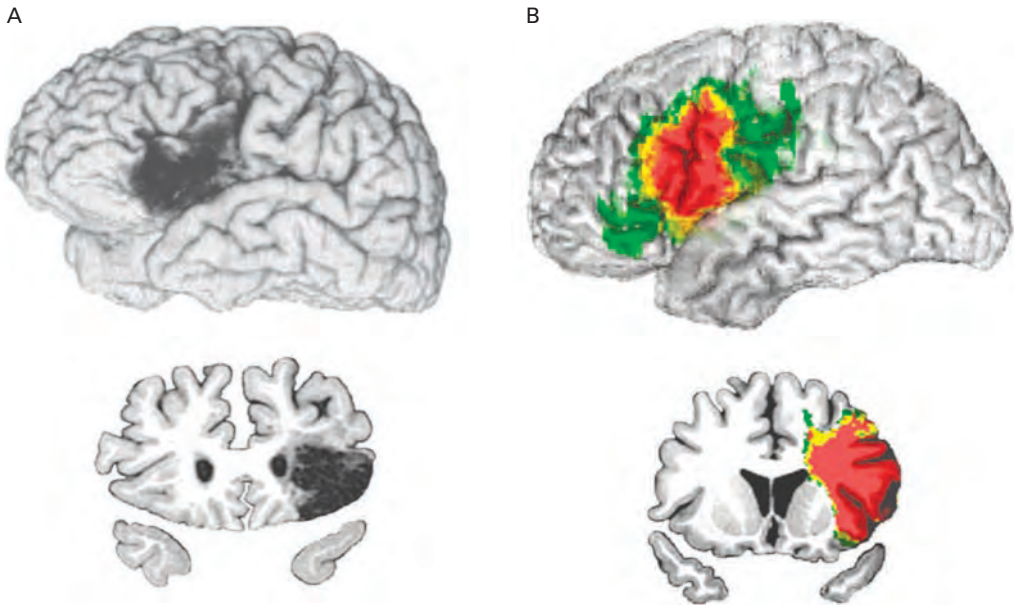

Figure 55–6 Sites of lesions in Broca's aphasia. (Images used with permission of Hanna and Antonio Damasio.)

A. Top: A three-dimensional magnetic resonance imaging (MRI) reconstruction of a lesion (infarction) in the left frontal operculum (**dark gray**) in a patient with Broca's aphasia. **Bottom:** A coronal MRI section of the same brain through the damaged area.

B. Top: A three-dimensional MRI overlap of lesions in 13 patients with Broca's aphasia (**red** indicates that lesions in five or more patients share the same pixels). **Bottom:** A coronal MRI section of the same composite brain image through the damaged area.

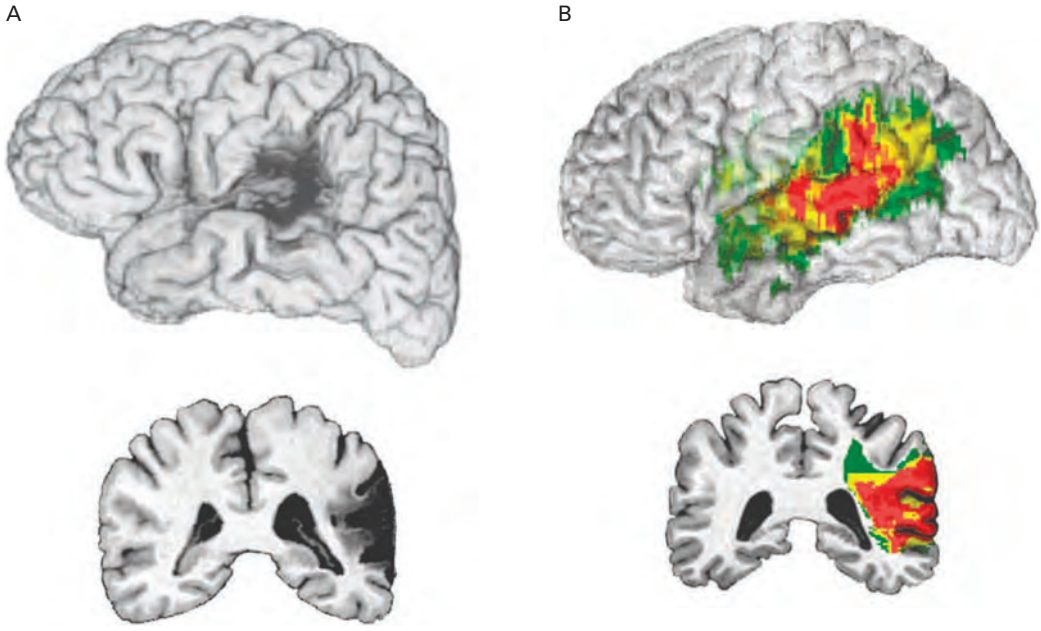

Figure 55–7 Sites of lesions in Wernicke's aphasia. (Images reproduced, with permission, from Hanna and Antonio Damasio.)

A. Top: Three-dimensional magnetic resonance imaging (MRI) reconstruction of a lesion (an infarction) in the left posterior and superior temporal cortex (**dark gray**) in a patient with Wernicke's aphasia. **Bottom:** Coronal MRI section of the same brain through the damaged area.

B. Top: Three-dimensional MRI overlap of lesions in 13 patients with Wernicke's aphasia obtained with the MAP-3 technique (**red** indicates that five or more lesions share the same pixels). **Bottom:** Coronal MRI section of the same composite brain image through the damaged area.

in the two other major aphasias, but patients cannot repeat sentences verbatim, cannot assemble phonemes effectively (and thus produce many phonemic paraphasias), and cannot easily name pictures and objects (Table 55–2).

Conduction aphasia is caused by damage to the left superior temporal gyrus and the inferior parietal lobe. The damage can extend to the left primary auditory cortex, the insula, and the underlying white matter. Large lesions in the Sylvian parietal temporal area, situated in the middle of the network of auditory and motor regions, are consistent with the idea that the damage occurs in the dorsal stream. Damage to left hemisphere auditory regions often produces speech production deficits, supporting the idea that sensory systems participate in speech production. Such lesions interrupt the interfaces linking auditory representations of words and the motor actions used to produce them. The damage compromises white matter (dorsal stream) and affects feedforward and feedback projections that interconnect areas of temporal, parietal, insular, and frontal cortex.

Global Aphasia Results From Widespread Damage to Several Language Centers

Patients with global aphasia are almost completely unable to comprehend language or formulate and repeat sentences, thus combining features of Broca's, Wernicke's, and conduction aphasias. Speech is reduced to a few words at best. The same word might be used repeatedly, appropriately or not, in a vain attempt to communicate an idea. Nondeliberate ("automatic") speech may be preserved, however. This includes stock expletives (which are used appropriately and with normal phonemic, phonetic, and inflectional structures), routines such as counting or reciting the days of the week, and the ability to sing previously learned melodies and their lyrics. Auditory comprehension is limited to a small number of words and idiomatic expressions.

Classic global aphasia involves damage to the inferior frontal and parietal cortices (as seen in Broca's aphasia), the auditory cortex and the insula (as seen in conduction aphasia), and the posterior superior temporal cortex (as seen in Wernicke's aphasia). Subcortical regions, such as the basal ganglia, are often affected as well. Such widespread damage is typically caused by a stroke in the region supplied by the middle cerebral artery. Weakness in the right side of the face and paralysis of the right limbs accompany classic global aphasia.

Transcortical Aphasias Result From Damage to Areas Near Broca's and Wernicke's Areas

Aphasias can be caused by damage not only to speech centers of the cortex but also to pathways that connect those components to the rest of the brain. Transcortical aphasia can be either motor or sensory. Patients with transcortical motor aphasia speak nonfluently, but they can repeat sentences, even very long sentences. Transcortical motor aphasia has been linked to damage to the left dorsolateral frontal area, a patch of association cortex anterior and superior to Broca's area, although there can be substantial damage to Broca's area itself. The left dorsolateral frontal cortex is involved in the allocation of attention and the maintenance of higher executive abilities, including the selection of words.

Transcortical motor aphasia can also be caused by damage to the left supplementary motor area, located high in the frontal lobe, directly in front of the primary motor cortex and buried mesially between the hemispheres. Electrical stimulation of the area in nonaphasic surgery patients causes the patients to make involuntary vocalizations or to be unable to speak, and functional neuroimaging studies have shown it to be activated during speech production. Thus, the supplementary motor area appears to contribute to the initiation of speech, whereas the dorsolateral frontal regions contribute to ongoing control of speech, particularly when the task is difficult.

Transcortical sensory aphasics have fluent speech, impaired comprehension, and great trouble naming things. These patients have deficits in semantic retrieval, without significant disruption of syntactic and phonological abilities.

Transcortical motor and sensory aphasias are caused by damage that spares the arcuate fasciculus and the dorsal stream. Transcortical aphasias are thus the complement of conduction aphasia, behaviorally and anatomically. Transcortical sensory aphasia appears to be caused by damage to the ventral stream, affecting parts of the junction of the temporal, parietal, and occipital lobes, which connect the perisylvian language areas with the parts of the brain responsible for word meaning.

Less Common Aphasias Implicate Additional Brain Areas Important for Language

Several other language-related regions in the cerebral cortex and subcortical structures, for example, the anterior temporal and inferotemporal cortex, have only recently become associated with language. Damage to the left temporal cortex causes severe and pure

naming defects—impairments of word retrieval without any accompanying grammatical, phonemic, or phonetic difficulty.

When the damage is confined to the left temporal pole, the patient has difficulty recalling the names of unique places and persons but not the names of common things. When the lesions involve the mid-temporal sector, the patient has difficulty recalling both unique and common names. Finally, damage to the left posterior inferotemporal sector causes a deficit in recalling words for particular types of items—tools and utensils—but not words for natural or unique things. Recall of words for actions or spatial relationships is not compromised (Figure 55–8).

The left temporal cortex contains neural systems that hold the key to retrieving words denoting various categories of things ("tools," "eating utensils"), but not words denoting actions ("walking," "riding a bicycle"). These findings were obtained not only from studies of patients with brain lesions resulting from

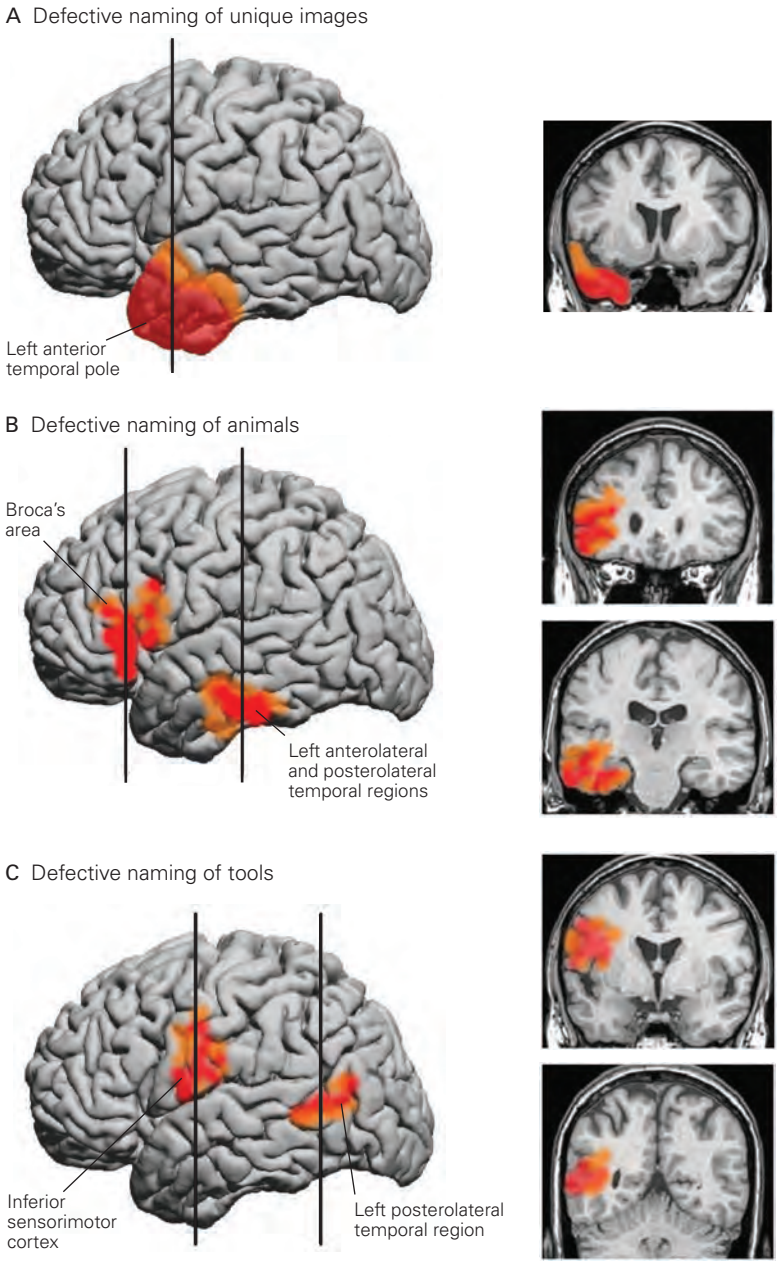

Figure 55–8 Regions of the brain other than Broca's and Wernicke's areas involved in language processing. Functional magnetic resonance imaging was used to study patients with selected brain lesions. (Images reproduced, with permission, from Hanna and Antonio Damasio.)

A. The region of maximal overlap of lesions associated with impaired naming of unique images, such as the face of a person, is the left anterior temporal pole.

B. The sites of maximal overlap of lesions associated with impaired naming of nonunique animals are the left anterolateral and posterolateral temporal regions as well as Broca's region.

C. The sites of maximal overlap of lesions associated with deficits in naming of tools are the left sensorimotor cortex and left posterolateral temporal cortex.

stroke, head injury, herpes encephalitis, and degenerative processes such as Alzheimer disease, but also from functional imaging studies of typical individuals and from electrical stimulation of these same areas of temporal cortex during surgery.

Areas of frontal cortex in the mesial surface of the left hemisphere, which include the supplementary motor area and the anterior cingulate region, play an important role in the initiation and continuation of speech. Damage in these areas impairs the initiation of movement (akinesia) and causes mutism, a complete absence of speech. In aphasic patients, the complete absence of speech is a rarity and is only seen during the very early stages of the condition. Patients with akinesia and mutism fail to communicate by words, gestures, or facial expression because the drive to communicate is impaired, not because the neural machinery of expression is damaged as in aphasia.

Damage to the left subcortical gray nuclei impairs grammatical processing in both speech and comprehension. The basal ganglia are closely interconnected with the frontal and parietal cortex and may have a role in assembling morphemes into words and words into sentences, just as they serve to assemble the components of a complex movement into a smooth action.

Highlights

1. Language exists at many levels, each of which has to be mastered during childhood—the elemental phonetic units (vowels and consonants) used to change the meaning of a word, the words themselves, word endings (morphemes) that change tense and pluralization, and the grammatical rules that allow words to be strung together to create sentences with meaning. By the age of 3, young children, regardless of the language(s) they are learning, have mastered all levels and can carry on a conversation with an adult. No artificially intelligent machine can yet duplicate this feat.
2. The learning strategies used by children to master language under 1 year of age are surprising. Language learning proceeds as infants (1) exploit the statistical properties of speech (distributional frequency patterns of sounds to detect relevant phonetic units and transitional probabilities between adjacent syllables to detect likely words), and (2) exploit the social context in which language occurs by following the eye movements of adults as they refer to objects and actions to learn word–object and word–action correspondences. At early ages, natural language learning requires a social context and social interaction. Infants' strategies are not well described by Skinnerian operant conditioning or by Chomsky's innate representation and selection based on experience. Instead, powerful implicit learning mechanisms that operate in social contexts vault infants forward from the very earliest months of life.
3. Infants' speech production and speech perception skills are "universal" at birth. In speech perception, infants discriminate all sounds used to distinguish words across all languages until the age of 6 months. By 12 months, discrimination for native-language sounds has dramatically increased, whereas discrimination of foreign-language sounds decreases. Production is initially universal as well and becomes language specific by the end of the first year. By the age of 3, infants know 1,000 words. Mastery of grammatical structure in complex sentences continues until the age of 10. Future work will advance the field by linking the detailed behavioral milestones that now exist to functional and structural brain measures to show how the brain's network for language is shaped as a function of language experience.
4. A new "dual-stream" model of language has emerged based on advances in functional neural imaging and structural brain imaging over the past decade. The new model bears similarities to the dual-stream model for the visual system. The dual-stream model for language goes beyond the classic Wernicke-Geschwind model by showing that numerous brain regions and the neural pathways that connect them support sound-to-meaning (ventral) and sound-to-articulation (dorsal) pathways. Refinement in the model will continue as additional studies show relationships between behavioral and brain measures. Future studies will integrate structural and functional brain measures, genetic measures, and behavioral assessments of language processing and of learning, including second language learning in adulthood.
5. Studies on the infant brain reveal a remarkably well-developed set of brain structures and pathways by 3 to 6 months of age. Structural DTI reveals a fully formed ventral pathway at birth and a dorsal pathway that links auditory areas to premotor, but not Broca's, area at birth. EEG and MEG brain imaging studies mirror the transition in phonetic perception between 6 and 12 months of age, a "critical period" for sound learning. MEG

brain scans at this period reveal the co-activation of auditory and motor centers when infants hear speech and show changes in both sensory and motor brain areas as a function of experience. The data indicate that dorsal pathways are sufficiently well formed in the first year to support sensory-to-motor connections and imitation learning during this period.

6. Hemispheric specialization generally increases with age and language experience, with initial representation of the areas and pathways represented bilaterally and dominance emerging with language experience. There are differences in the degree of lateralization, however, for various levels of language. The dorsal stream, which mediates auditory-motor representations of speech, is more left lateralized than the ventral stream, which mediates auditory-conceptual representations of words.
7. The classical aphasias—Broca's, Wernicke's, and conduction aphasia—are well described within the context of the dual-stream model of language. Broca's aphasia, with its emphasis on the inability to produce speech but relatively good speech understanding, is seen as a dorsal stream deficit, whereas Wernicke's aphasia, with its emphasis on speech comprehension deficits, is seen as a ventral stream deficit. Conduction aphasia, like Broca's, is viewed as caused by a dorsal stream deficit, with damage that encompasses auditory and motor regions. Future research on aphasia will benefit from additional studies of functional and structural damage that can be combined with detailed behavioral protocols.
8. Future studies will allow detailed comparisons between human and nonhuman brains to reveal the structures and pathways that are uniquely human and subserve language. Future work will also focus on the degree to which language structures in humans are selectively activated by speech as opposed to other complex auditory sounds and whether adult-level selectivity is present early in development.
9. Human language represents a unique aspect of human cognitive achievement. Understanding the brain systems that allow this cognitive feat in nearly all children, and especially the discovery of biomarkers that identify children who are at risk for developmental disorders of language, will advance brain science and be beneficial for society. Behavioral studies now allow us to connect the dots with regard to how early language experience is linked to advanced language development by the time children enter school. This may lead to language interventions that improve outcomes for all children.

Decision-Making and Consciousness

In the earlier chapters, we have seen how sensory input is transformed into neural activity that is then processed by the brain to give rise to immediate percepts and how those percepts can be stored as short- and long-term memories (Chapters 52–54). We have also examined in detail how movement is controlled by the spinal cord and brain. Here, we begin to consider one of the most challenging aspects of neuroscience: the transformation of sensory input to motor output through the higher-order cognitive process of decision-making. In doing so, we are afforded a glimpse of the building blocks of higher thought and consciousness.

Outside neuroscience, the term *cognitive* typically connotes some distinction from reflexes and dedicated routines, and yet as we shall see, neuroscience recognizes the rudiments of cognition in simple behaviors that display two types of flexibility—contingency and freedom from immediacy. Contingency means that a stimulus does not command or initiate an action in the way it does for a reflex. A stimulus might motivate a particular behavior, but the action may be delayed, pending additional information, or it may never occur. This freedom from immediacy of action means there are operations that transpire over time scales that are not immediately beholden to changes in the environment or the real-time demands of control of the body.

Both types of flexibility—contingency and time—are on display when we make decisions. Of course, not all decisions invoke cognition. Many behavioral routines—swimming, walking, feeding, and grooming—have branch points that may be called decisions, but they proceed in an orderly manner without much flexibility or control of tempo. They are governed mainly by the time steps of nervous transmission and are dedicated for the most part to particular input–output relationships. The point of drawing these distinctions is not to establish sharp boundaries around decision-making, but to help us focus on aspects of decisions that make them a model for cognition.

For present purposes, we will use the following definition: A decision is a commitment to a proposition, action, or plan based on evidence (sensory input),

prior knowledge (memory), and expected outcomes. The commitment is provisional. It does not necessitate behavior, and it can be modified. We can change our mind. The critical component is that some consideration of evidence leads to a change in the state of the organism that we liken to a provisional implementation of an action, strategy, or new mental process.

Such propositions can be represented as a plan of action: I decide to turn to the right, to leave safe shelter, to look for water, to choose a path least likely to encounter a predator, to approach a stranger, or to seek information in a book. The concept of a plan emphasizes freedom from immediacy. Moreover, not all plans come to fruition. Not all thought leads to action, but it is useful to conceive of thought as a type of plan of action. This view invites us to consider knowing as the result of directed—mostly nonconscious—interrogation, rather than an emergent property of neural representations.

Decision-making has been studied in simple organisms, notably worms, flies, bees, and leeches, as well as in mammals from mice to primates. Simpler organisms are appealing because they have smaller nervous systems, but they lack the behavioral repertory required to study decisions that entail forms of cognition. The hope is that the biological insights from these species will inform our understanding of the processes characterized in mammals, especially primates. This is a laudable goal because, to paraphrase Plato, decision-making offers our best shot at carving cognitive function at its joints—to identify the common principles that support its normal function and to elucidate their mechanisms so they may be repaired in disease.

In this chapter, we focus primarily on perceptual decisions made by primates in contrived settings. The principles extend naturally to reasoning from evidence and to value-based decisions concerning preference. In the last part of the chapter, we derive insights about broader aspects of cognition. Viewed through the lens of decision-making, brain states associated with knowing and being consciously aware may be closer to a neurobiological explanation than is commonly thought.

Perceptual Discriminations Require a Decision Rule

Until recently, decision-making was studied primarily by economists and political scientists. However, psychologists and neuroscientists working in the field of perception have been long concerned with decisions. Indeed, the simplest type of decision involves the detection of a weak stimulus, such as a dim light or a faint sound, odor, or touch. The decision a subject must make is whether or not the stimulus is present—yes or no. In the laboratory, there is no uncertainty about where and when the stimulus is likely to be present. Such experiments were therefore used to infer the fundamental sensitivities of a sensory system from behavior, a subfield of psychology known as psychophysics. Detection experiments played a role in inferring signal-to-noise properties of sensory neurons that transduce light touch, faint sounds, and dim lights. In the last case, such experiments provided evidence that the visual system is capable of detecting the dimmest of light, a single photon, subject to background noise of photoreceptors. In other words, it is as efficient as possible, given the laws of physics.

The psychophysical investigation of perception began with Ernst Weber and Gustav Fechner in the 19th century. They were interested in measuring the smallest detectable difference in intensity between two sensory stimuli. Such measurements can reveal fundamental principles of sensory processing without ever recording from a neuron. It turns out they also lay the foundation for the neuroscience of decision-making, because every yes/no answer is a choice based on the sensory evidence.

In Chapter 17, we learned how psychophysicists conceptualize the detection problem (Box 17–1). On any one trial, the state of the world is either stimulus present or stimulus absent. The decision is based on a sample of noisy evidence. If the stimulus is present, the evidence is a random sample drawn from the probability distribution of signal + noise. If the stimulus is absent, the evidence is a sample from the noise-only distribution (Figure 56–1A). The brain does not directly perceive a stimulus but receives a neural representation of the sample. As a result, some of the noise arises from the neural activity involved in forming this representation. It is the job of the brain to decide from which distribution the sample came, using information encoded in neural firing rates. However, the brain does not have access to the distributions, just the one sample involved in each given decision. It is the separation of these distributions—the degree that they do not overlap—that determines the discriminability of a stimulus from noise. The decision rule is to say "yes" if the evidence exceeds some criterion or threshold.

A Simple Decision Rule Is the Application of a Threshold to a Representation of the Evidence

The criterion instantiates the decision-maker's policy or strategy. If the criterion is lax—that is, the threshold

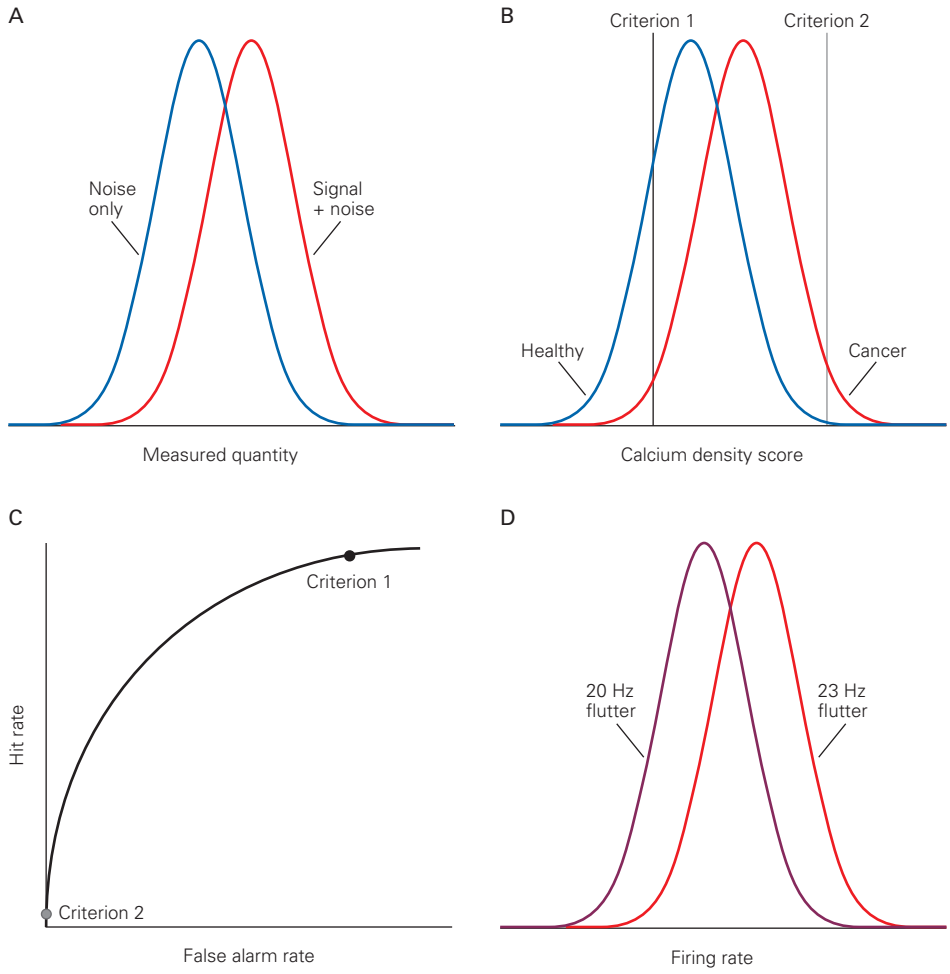

Figure 56–1 The framework of signal detection theory formalizes the relationship between evidence and decisions. In panels **A** through **C**, we consider simple yes–no decisions in which a decision-maker receives just one measurement.

A. The height of the curves represents the probability of observing a measurement on the x-axis (be it number of spikes per second, radioactive counts, or blood pressure) under two conditions: signal present or absent. In both cases, the measurement is variable, giving rise to the spread of possible values associated with the two conditions. If the signal is present, the decision-maker receives a random sample from the **Signal + noise** probability distribution (**red**). If the signal is absent, the decision-maker receives a sample from the **Noise only** probability distribution (**blue**). The decision arises by comparing the measure to a criterion, or threshold, and answering *yes* or *no*, signal is present or absent, if the value is greater or less than the criterion.

B. The criterion is an expression of policy, as illustrated in medical decision-making. Suppose the measure is derived from calcifications detected in a screening mammogram—a score combining number, density, and shape. The criterion 1 (**left line**) for interpreting the test as a positive or negative (breast cancer or not) is liberal. It leads to many false positives (83%), but very few women with cancer receive a negative result. Criterion 2 (**right line**) is conservative. It would miss many cases of cancer, but it would rarely render a positive result to a healthy person. That would make sense if a positive decision were rationale for a dangerous (or painful) procedure.

C. The receiver operating characteristic shows the combination of proportions of "yes" decisions that are correct (hit rate) and incorrect (false alarm rate) for all possible criteria. The liberal and conservative criteria are shown by the **black** and **gray** symbols, respectively.

D. The framework also applies to decisions between two alternatives. Here, the decision is whether a vibration applied to the index finger has a higher frequency than a vibration applied a few seconds before. The same depiction of overlapping distributions might conform to neural responses from some part of the brain that represents a sensory stimulus. For example, a neuron in the somatosensory cortex might respond over many individual trials with a higher average spike rate to vibratory stimulation of the finger at 23 Hz than stimulation at 20 Hz. However, the distributions overlap so that on any given presentation we cannot say with 100% certainty whether the vibration was at 20 Hz or 23 Hz based on the neuron's response.

is low—the decision-maker will rarely fail to detect the stimulus, but they will often respond "yes" on the trials when there was no stimulus because the background noise exceeds the threshold. This type of error is called a *false alarm*. If the criterion is more conservative—that is, the threshold is high—the decision-maker will rarely say "yes" when the stimulus is absent but will often say "no" when the stimulus is present. This type of error is called a *miss*. The appropriate criterion depends on the relative cost of the two types of errors and also on the design of the experiment. For example, if the stimulus is present on 90% of trials, then a lax criterion might be warranted since false alarms will be rare.

The policy ought to be influenced by a value or cost associated with making correct and incorrect decisions. For example, in medical diagnosis, it is often the case that a disease affects only a small fraction of the population, but a diagnostic test does not discriminate perfectly between people with and without the disease. We can illustrate this using the distribution of mammogram calcification scores. The scores are larger in women with breast cancer than in healthy women, but the range of values overlaps to an extent, implying that the test is not perfect (Figure 56–1B).

In this situation, a lax criterion might seem problematic because it would produce a large number of false alarms: patients who are healthy but told they might have a disease based on the test. However, it may well be the case that a miss is life threatening, whereas a false alarm leads to a stressful week as the patient awaits a more decisive test. In this situation, it is actually sensible to apply a lax criterion even if it leads to many false alarms. Alternatively, a false alarm may trigger a painful or risky procedure, in which case a more stringent criterion would be more appropriate. The medical analogy allows us to appreciate the strategic roles of the criterion setting. We praise and criticize decision-makers based on their policy, not on the noisy imperfections of the measurements.

The important point is that the criterion represents a decision rule, which instantiates knowledge about the problem and an attitude about the positive value associated with making correct choices (hits and correct rejections) and the negative value of making errors (misses and false alarms). Note that the application of different criteria does not change the fundamental characteristic of the evidence samples that is responsible for the accuracy of decisions. This is reflected by the overlap between the blue and red distributions, which does not change if a decision-maker adjusts her criterion. The curve in Figure 56–1C, termed the receiver operating characteristic (ROC), shows how changing the criterion affects the accuracy of the decision whether a stimulus (or cancer) is present or absent for all possible criteria. Each point on the curve is an ordered pair of the probability of a correct "yes" response (hits) versus an erroneous "yes" response (false alarms) associated with a given criterion (threshold). The ROC tells us something about the reliability of the measurement (ie, the separation between the two distributions) regardless of how the decision-maker uses it. The criterion tells us something about the decision-maker's policy. It bears on why two decision-makers receiving the same evidence might reach different decisions. Indeed, it is the policy, not the noise, that the decision-maker controls and for which she may be praised or criticized, that is, held responsible. We will think about this topic again when we discuss the trade-off between speed and accuracy.

The challenge for neuroscience is to relate the terms *signal*, *noise*, and *criterion* to neural representations of sensory information and operations upon those representations that result in a choice. We will develop these connections in subsequent sections. Here, we wish to seed an important insight about the term *noise* as it pertains to the neural representations of evidence. Decision-makers do not make the same decision even when confronting repetitions of identical facts or sensory stimuli. Some variability at some stage must creep into the process. The distinction between signal and noise need not devolve into scholastic arguments about chance and determinism. Any source of variance in the representation of the evidence is effectively noise if it is responsible for errors. If the brain did not distinguish such variability from the signal and thus made a mistake, we would be justified in construing this variability as unaccounted by the decision-maker.

Perceptual Decisions Involving Deliberation Mimic Aspects of Real-Life Decisions Involving Cognitive Faculties

The neural bases for more cognitive decisions have been examined by extending simple perceptual decisions in three ways: first, by moving beyond detection to a choice between two or more competing alternatives; second, by requiring the decision process to take time by involving consideration of many samples of evidence; and third, by considering decisions about matters involving values and preferences.

Vernon Mountcastle was the first to study perceptual decisions as a choice between two alternative interpretations of a sensory stimulus. He trained monkeys to make a categorical decision about the frequency of a fluttering pressure applied lightly to a fingertip (Figure 56–2). Since the *vibratory flutter* has an intensity that is easily detected, the decision is not

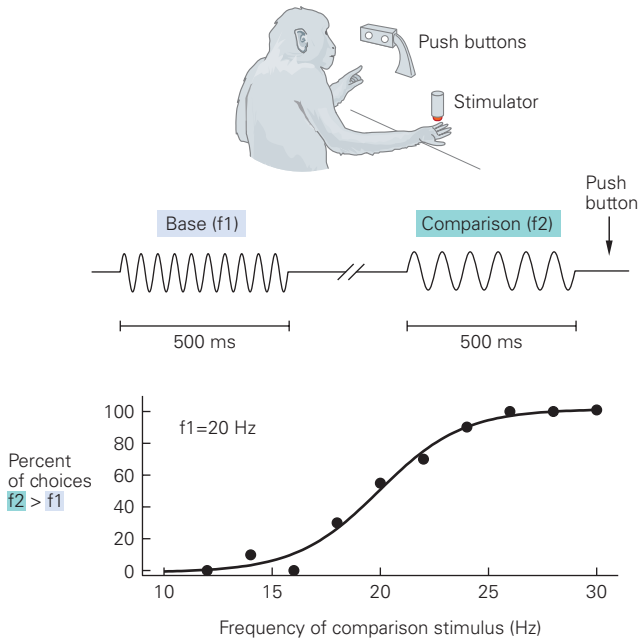

Figure 56–2 The discrimination of flutter-vibration frequency was the first perceptual decision studied in the central nervous system. A 20-Hz vibratory stimulus is applied to the finger on the right hand; following a delay period of several seconds, a second vibratory stimulus is applied. The monkey indicates whether the second vibration (**f2**) was at a higher or lower frequency than that of the first stimulus (**f1**) by pushing the left or right button with the other hand. The plots show that the proportion of trials in which the monkey decided that the comparison stimulus was greater than the reference depended on the magnitude and sign of the difference. With larger differences, the monkey almost always chose correctly, but when the difference was small, the choices were often incorrect. (Adapted from Romo and Salinas 2001.)

about whether the stimulus is present or absent but whether the vibration rate is fast or slow. On every trial of the experiment, the monkey experienced a reference frequency, f1, equal to 20 cycles per second (Hz). The pressure cycles are too fast to count; they feel more like a buzzing. The reference was then turned off, and after a few seconds, a second test stimulus, f2, was applied. The frequency of f2 was chosen from a range of values from 10 to 30 Hz. The monkey was rewarded for indicating whether the test frequency was higher or lower than the f1 reference.

We can represent the process conceptually using the same type of signal and noise distributions we drew for the detection problem (Figure 56–1D). Here, the "noise-only" distribution represents a quantity that is sampled in association with the 20-Hz reference, whereas the red distribution represents a quantity that is sampled in association with a test stimulus with a flutter frequency greater than 20 Hz. Mountcastle favored the idea that the brain obtained two samples of evidence—one accompanying the 20-Hz reference and the second from the test. The decision, higher or lower, could arise by evaluating the inequality—greater than or less than—or, equivalently, by subtracting the two samples and answering based on the sign of the difference. This was a terrific insight, but the neural recordings were out of step with the theory. Mountcastle's neural recordings explained the monkey's ability to detect vibratory stimulation as a function of intensity and frequency (Chapter 17)—a yes/no decision—but they were unable to explain the mechanism for the comparison between the two alternatives, whether f2 is greater or less than f1.

Two key elements were missing. First, to evaluate f2 versus f1, the brain needs a representation of frequency. Mountcastle found neurons in the somatosensory cortex and thalamus with firing rates that were phase-locked to frequencies of the flutter, and they could measure the reliability of this frequency locking, but they did not find neurons that were tuned to particular frequencies less than or greater than 20 Hz. Second, both representations need to be available at the same time in order to compare them. However, the neural responses to f1 lasted only as long as the flutter vibration. Mountcastle failed to observe neural responses that conveyed the representation of the reference frequency through the delay period up to the time that the test stimulus was presented. It was therefore impossible to study the neural operations corresponding to the decision process, which seemed to require some trace of the reference stimulus during analysis of the test.

These obstacles were overcome using a simpler task design and a different sensory modality. Inspired by Mountcastle, William Newsome trained monkeys to decide whether a field of dynamic random dots had a tendency to move in one direction or its opposite (eg, left or right). The random dot motion stimulus is constructed such that at one easy extreme all dots share the same direction of motion, say to the right. At the other easy extreme, all dots move to the left, and in between, the direction can be difficult to discern because many dots contribute only noise (Figure 56–3A).

Unlike the flutter vibration task, where a decision is rendered difficult by making the comparison frequencies more similar, the two directions of motion remain fixed and opposite for all levels of difficulty. The two directions were rendered less distinct by degrading the signal-to-noise ratio of the random dots. Each random dot appears only briefly, and then either reappears at a random location or at a displacement to support a consistent direction and speed. The probability of the latter (displacement) determines the motion

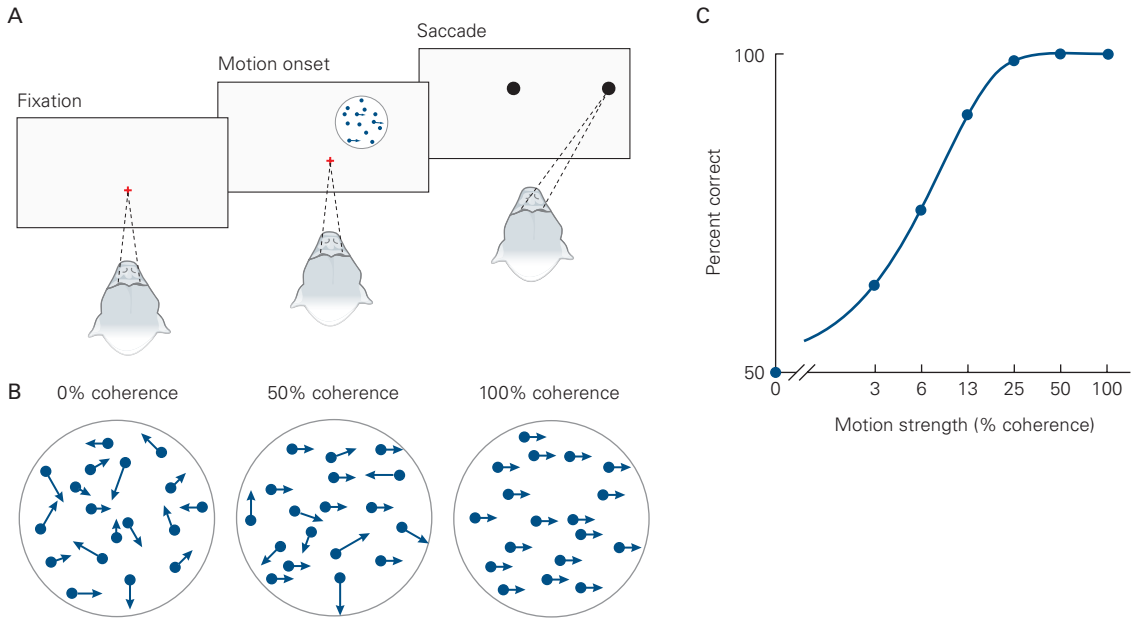

Figure 56–3 In the random dot motion discrimination task, the observer decides if the net motion of dots is in one direction or its opposite (eg, right or left).

A. The monkey maintains its gaze on a cross while viewing the random dot motion display. When the stimulus and fixation cross are extinguished, the monkey indicates its decision by shifting the gaze to the left or right choice targets and receives a reward if the decision is correct.

B. The difficulty of the decision is controlled by the coherence of dot motion. Each dot appears for only a few milliseconds at a random location and then reappears 40 ms later, either at a new random location or at a displacement consistent with a chosen speed and direction. The probability that a dot present at time t_1 undergoes displacement in the same direction at t_2 establishes the motion strength (% coherence). (Reproduced, with permission, from Britten et al. 1992. Copyright © 1992 Society for Neuroscience.)

C. The decision is more likely to be correct when the motion is stronger.

strength, which is commonly expressed on a 0 to 100 scale, termed the percentage coherence. At the most difficult extreme, 0% coherence, all dots are plotted at random locations in each successive frame, giving the appearance of dancing snowflakes with no dominant direction. At intermediate levels of difficulty, the dancing snowflakes give rise to a weak sense that the wind might be blowing them ever so slightly to the right or left. Any one dot is unlikely to be displaced more than once, so there is no feature to track.

This simple stimulus was originally developed by Anthony Movshon to promote a decision strategy that would benefit from integrating visual information across its spatial extent and as a function of time. Moreover, it satisfied another desideratum: The same neurons should inform the decision at all levels of difficulty. For a left versus right decision, direction-selective neurons in the visual cortex that are, say, sensitive to leftward motion emit signals that are relevant to the decision at all levels of difficulty. That would not be the case if difficulty were controlled by the angular difference between the two directions. Another advantage of this task over the vibration-flutter task is that there is only one stimulus presentation. There is no need to remember anything between a reference and a test stimulus. Finally, humans and monkeys perform this task at nearly identical levels. They answer perfectly for the strong-motion trials and make more errors when the strength of motion is reduced (Figure 56–3C). This establishes a platform for a quantitative reconciliation of decisions and neural activity. Is there a way to explain the likelihood that a decision will be accurate from measurements of the signal-to-noise ratio in the appropriate sensory neurons?

Neurons in Sensory Areas of the Cortex Supply the Noisy Samples of Evidence to Decision-Making

In higher mammals and primates, neurons that respond differentially to the direction of motion are first encountered in the primary visual cortex (area V1). They are a subset of the orientation-tuned simple

and complex cells discovered by Hubel and Wiesel (Chapter 22). These neurons project to a secondary visual cortical area, area MT.[1]

Area MT contains a complete map of the contralateral visual field, and almost all the neurons in area MT are direction selective. Neurons with similar direction preferences cluster together so that MT contains a map of both space and motion direction at each point in the visual field. Their receptive fields are larger than those of V1 neurons, and some manifest properties that are not evident in V1 (eg, pattern motion; Chapter 23), but most respond as if they integrate signals from V1 that share the same direction selectivity over a larger patch of the visual field. In Newsome's experiments, the random dot motion stimulus was contained in a circular aperture that matched the size of an MT neuron's receptive field. It was thus possible to measure the response of a neuron perfectly situated to convey evidence to the decision process on single trials.

It seemed possible that the neurons with receptive fields aligned to the random dot motion stimulus and a firing preference for one or the other direction under consideration might contribute the evidence used to make the decision. Indeed, we can begin to understand the monkey's perception of motion by applying the same signal-to-noise considerations to the MT neural responses. We consider two types of direction-selective neurons (Figure 56–4). One type responds better to rightward motion than to leftward motion, and it yields higher firing rates when the rightward motion is stronger. It also responds above baseline to the 0% coherence stimulus because the random noise contains all motion directions including leftward and rightward, and it yields lower firing rates (compared to 0% coherence) when the leftward motion is stronger (Figure 56–4B). The other type of neuron responds well to leftward motion. It exhibits the same pattern as the right-preferring type, only with the direction preferences reversed. The neural responses are noisy, so the firing rates on any trial or in any epoch may be conceptualized as a random draw from one of the distributions in Figure 56–4C. These distributions can be interpreted in two ways. The two curves might represent the possible firing rates of a rightward-preferring neuron when weak motion is to the right or left, respectively. They might also represent the possible firing rates of right- and left-preferring neurons, respectively, to the same weak rightward stimulus.

Because the responses of the two classes of neurons are available at the same time, we are able to characterize the evidence as the difference between the firing rates of the left- and right-preferring neurons. (The brain in fact relies on the difference between the averages from many left- and many right-preferring neurons.) We refer to such a quantity as a decision variable because the decision could be made by applying a criterion to this difference. Here, the criterion would be at zero. Thus, if the decision variable is positive, answer right; if it is negative, answer left.

Notice that when the stimulus is purely random (0% coherence), there is no correct answer. The monkey is rewarded randomly by the experimenter on a random half of the trials, and the monkey answers right and left with about equal probability. This is not because the monkey is guessing but because fluctuation in the random dot motion stimulus and the noisy firing rates of the right- and left-preferring neurons lead to variability in the evidence used to make the decision. This makes sense because the right- and left-preferring neurons respond equivalently to this type of stimulus. On some trials, the right-preferring neurons respond more than the left-preferring neurons, and the brain interprets this as evidence for rightward motion. On other trials, the left-preferring neurons respond more and the monkey chooses left.

Neuroscientists have been able to use a network of small populations of neurons to model the relation between the accuracy of an animal's choice versus motion strength, known as the *psychometric function*. The success of such models gives support to the idea that the signal and noise properties of cortical neurons can explain the fidelity of a perceptual decision, just as Mountcastle had hoped. This achievement was possible because of a clever experimental design that allowed the same neuron to participate in decisions across a wide range of difficulty. But are these neurons actually used to make the decision? Do they actually supply the noisy evidence that the monkey uses to make its decision?

We now know that they do. Because of the columnar organization of direction-selective neurons in area MT, it is possible to apply small currents through a microelectrode to excite a cluster of neurons sharing the same receptive field property. Newsome and colleagues placed the electrode in the middle of a cluster of neurons with receptive fields that were exactly aligned to the random dot motion stimulus. He reasoned that at weak stimulating currents the majority of stimulated

[1]The letters MT stand for middle temporal, a sulcus in the species of New World monkey in which the area was first discovered. This sulcus does not exist in Old World monkeys and humans, but the homologous area does, and it retains its original name. Area MT is sometimes referred to as area V5 (the fifth visual area) in humans. The name is unimportant, but the area is!

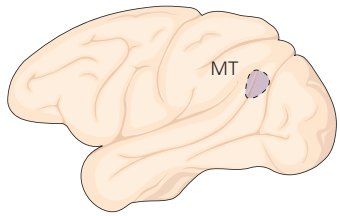

Figure 56–4 Neurons in area MT provide noisy evidence bearing on the direction of motion.

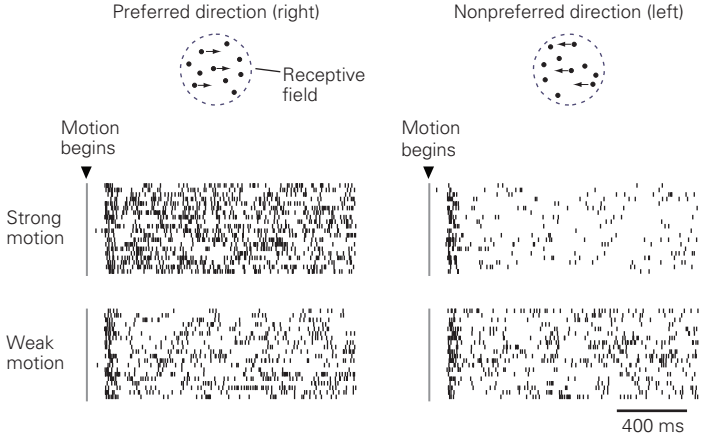
A. Responses from a right-preferring neuron during the discrimination task. The random dot movie is in the receptive field of the neuron. The panels in the left column of the 2 × 2 panel display show the neuron's responses to motion in its preferred direction, and panels in the right column show its responses to the nonpreferred direction. The panels in the top row show the neuron's responses to strongly coherent motion, and the bottom panels show the responses to weakly coherent motion. In each panel, the time of each action potential (spike) is represented by a small vertical tick mark. Each row of spikes in a panel shows the neuron's response to the motion stimulus in a single trial. (Adapted with permission from Mazurek et al. 2003.)

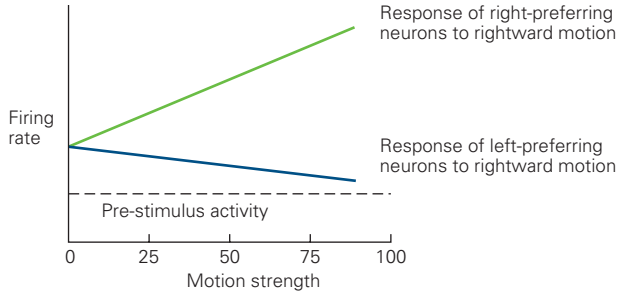
B. The mean firing rate varies as a function of motion strength. The neuron increases its firing rate above baseline even in response to the 0% coherence stimulus because the dynamic random dots contain all directions of motion, including the neuron's preferred direction. The firing rate then increases with stronger rightward motion. It decreases, relative to the response to 0% coherence, with stronger leftward motion. The responses of this right-preferring neuron to leftward motion are mirrored by the responses of a left-preferring neuron to rightward motion.

C. Probability distributions of the firing rates from left-preferring and right-preferring neurons to weak rightward motion. The right-preferring neuron tends to respond more, but the overlap of the distributions shows that it is possible for the left-preferring neuron to respond more than the right-preferring neuron on any given trial. These same considerations apply to the pooled signals from populations of right- and left-preferring neurons. The plot on the right shows the distribution of the difference between firing rates of the left-preferring neuron and the right-preferring neuron measured in response to the same stimulus over many trials. The decision is to choose right if this difference is positive and to choose left if it is negative. This rule would lead to correct rightward choices on 80% of the trials.

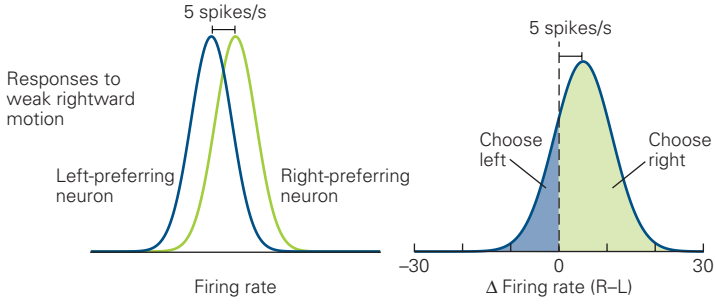
A Single trial responses from a right-preferring neuron



B Firing rate depends on motion strength and direction



C Noisy evidence for left and right are conceptualized as random samples from probability distributions



neurons were likely to share the same receptive field and the same direction preference. Newsome had the monkey decide between this direction and its opposite. For example, if these neurons preferred rightward motion, the weak currents caused the monkey to decide more often in favor of right (Figure 56–5).

We now refer to such weak stimulation, designed to affect a cluster of neurons within a 50- to 100μm radius, as *microstimulation*. Notably, microstimulation did not cause a hallucination of visual motion. It biased the monkey's decisions, which were guided mainly by the random dot motion stimulus. The monkey did not respond when the stimulus was not shown, and microstimulation did not affect the monkey's decisions when the random dots were presented at a location of the visual field outside the receptive field of the stimulated neurons. The microstimulation exerted its largest effect on choices when the motion strength was weakest. The stimulated neurons simply added a small amount of evidence for rightward motion, which is effectively evidence against leftward motion, as discussed below.

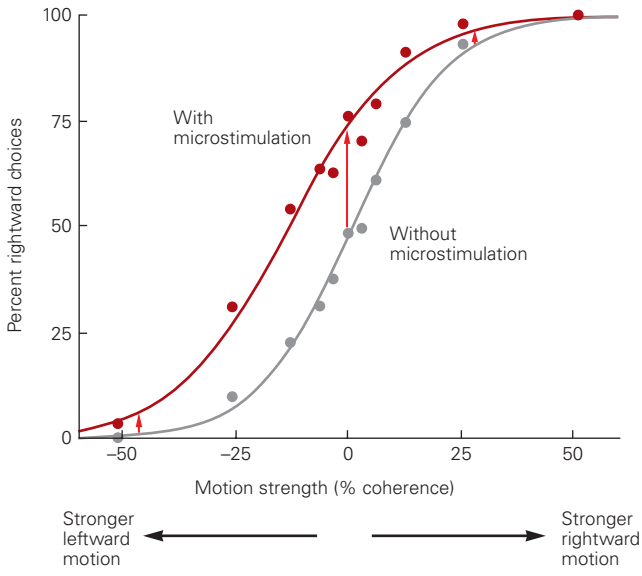


Figure 56–5 **Artificial activation of neurons that respond preferentially to rightward motion causes a monkey to decide that motion is rightward.** In the experiment, an electrode is placed in the middle of a patch of neurons in area MT that prefer the same direction of motion, say rightward. The random dot motion is shown in the receptive field of these neurons. A weak alternating current is applied on half of the trials during the presentation of the random dots movie. The amount of current activates about 200 to 400 neurons within 50 to 100 μm of the electrode tip. On trials with microstimulation, the monkey is more likely to choose the preferred direction of the simulated neurons. The effect is most pronounced when the decision is more difficult (**middle red arrow**). (Adapted, with permission, from Ditterich, Mazurek, and Shadlen 2003.)

The microstimulation experiment shows that the direction-selective neurons in area MT contribute evidence to the perceptual decision. However, the stimulated neurons do not necessarily need to affect the decision directly; they only have to participate in a neural circuit that lies in a causal chain. In addition, many more neurons in MT were not affected by the electrical stimulation but nonetheless responded to the same random dot patch in the same direction-selective manner. They are in other columns with receptive fields that are not centered on the stimulus but overlap it. If the electrode is moved to stimulate these neurons, they too cause the monkey to choose the preferred direction more often. These findings imply that in any one experiment the microstimulation only affects a small fraction of the neurons that contribute to the decision. Most respond at their usual firing rates to the random dot motion. The microstimulation only changes the total signal that the brain uses to make its decision by a small amount. No wonder the effect is only evident when the decision is difficult.

There is an important principle to be learned here. Had Newsome used only the easier conditions, the electrical stimulation would have yielded a null effect, and thus, the causal relationship between the neural activity and behavior would not have been established. The same pattern of effects has recently been established using techniques to turn neurons off. Silencing induces a bias in choices against the direction of the silenced neurons, but this too is only apparent on trials when the motion is difficult. Without evidence for sufficiency or necessity, a neuroscientist might conclude that the neurons in MT do not cause changes in perceptual decisions. This would be a mistake, notably one that is likely to be made in any experiment in which perturbations are restricted to a subset of the neurons involved in a computation. That is the rule, not the exception, for studies of higher cortical functions. It is only mitigated by studying behavior in conditions when a small difference to the total pool of neural signals might make a difference, as in the difficult (low signal-to-noise) regime employed in Newsome's experiments.

To summarize so far, the perceptual decision arises from a simple *decision rule*: the application of a criterion to the noisy evidence supplied by noisy direction-selective neurons in the visual cortex. We have characterized the noisy evidence as a single number: the difference in the mean firing rates from two opposing pools of direction-selective neurons. This account leaves out two important points: The operations that establish the decision variable must be carried out by neurons that receive information directly or indirectly from area MT, and these operations take time. As we will see, time is the key to understanding

decision-making, and it is also the factor that relates decision-making to higher cognitive function.

Accumulation of Evidence to a Threshold Explains the Speed Versus Accuracy Trade-Off

The decision rule considered so far is appropriate if the brain received only a brief snapshot of the motion, say for a tenth of a second. However, decision-making normally takes some time, so that when the viewing duration is longer, decisions tend to be more accurate. In fact, the strength of motion that is required to support 75% accuracy, termed the *sensory threshold*, decreases as a function of viewing duration. With more time, the decision-maker can achieve this level of accuracy with a weaker motion strength. Put another way, the sensitivity to weak motion improves as a function of viewing duration, t. Indeed, the sensitivity improves as a function of the square root of time ($\sqrt{t}$), which is the rate of improvement in the signal-to-noise ratio that one obtains by accumulating or averaging. The suggestion then is that the difference in firing rates of left- and right-preferring direction-selective neurons supplies the momentary evidence to another process that accumulates this noisy evidence as a function of time—in this case, two processes that accumulate evidence for left and right, respectively.

The accumulation of noisy evidence follows a path comprising random steps in both the positive and negative direction on top of a constant bias determined by the coherence and direction of the moving dots. This is termed a *biased random walk* or *drift plus diffusion* process (Figure 56–6). Because evidence for left is evidence against right (and vice versa), the two random walks are anticorrelated, albeit imperfectly so. The accumulations evolve with time and continue to do so until the stimulus is turned off or until one of the accumulations reaches an upper *stopping bound*, which determines the answer, left or right. Even the 0% coherence (pure noise) stimulus will reach a stopping bound eventually, but it is equally likely that the left or right accumulation will do so. When the random dot motion favors one direction, it is more likely that the corresponding accumulation determines the choice, and increasingly so with stronger motion. Such accumulations of noisy evidence are dynamic versions of the decision variable. The decision rule remains similar: Choose right if there is more evidence for right than left, and vice versa. The stopping bounds also explain another important feature of the decision—the time it takes to make it.

This simple idea thus explains the observed trade-off between the speed and accuracy of a decision. It specifies the exact relationship between the probability that each motion strength will lead to a correct choice and the amount of time that is taken, on average, to respond, termed the reaction time (Figure 56–6C). If the stopping bounds are close to the starting point of the accumulation, the decision will be based on very little evidence—fast but error prone. If the stopping bounds are further from the starting point, more accumulated evidence is needed to stop—slower but more likely to be correct. If the flow of information is cut off before either bound has been reached, the decision-maker may feel she has not yet reached an answer, but may nonetheless answer based on the accumulation that is closer to its stopping bound. This mechanism, termed *bounded evidence accumulation*, explains the effect of task difficulty on choice accuracy and the associated reaction times on a variety of perceptual tasks. It explains the degree of confidence that a decision-maker has in a decision and why such confidence depends on both the amount of evidence and deliberation time. It also explains the rate of improvement in accuracy when the experimenter controls viewing duration by $\sqrt{t}$, mentioned above, and it explains why this improvement saturates with longer viewing durations. The brain stops acquiring additional evidence when the accumulated evidence reaches a stopping bound.

Neurons in the Parietal and Prefrontal Association Cortex Represent a Decision Variable

Neurons in several parts of the brain, including the parietal and prefrontal cortices, change their firing rates to represent the accumulation of evidence—in the case of visual motion from area MT—bearing on the direction decision. The neurons that represent the accumulation differ from sensory neurons in two important ways. First, they can continue to respond for several seconds after a sensory stimulus has come and gone. Moreover, they seem to be capable of holding a firing rate at one level and then increasing or decreasing that level when new information arrives. This is exactly the type of feature one would like to see in a neuron that represents the accumulation of evidence. Second, such neurons tend to be associated with circuits that control the behavioral response that the monkey has learned to use to communicate its decision. Such neurons were first identified for their capacity to maintain persistent activity in the absence of a sensory stimulus or ongoing action. They were therefore thought to play a role in working (short-term) memory, planning an action, or maintaining attention at a location in the visual field (Figure 56–7).

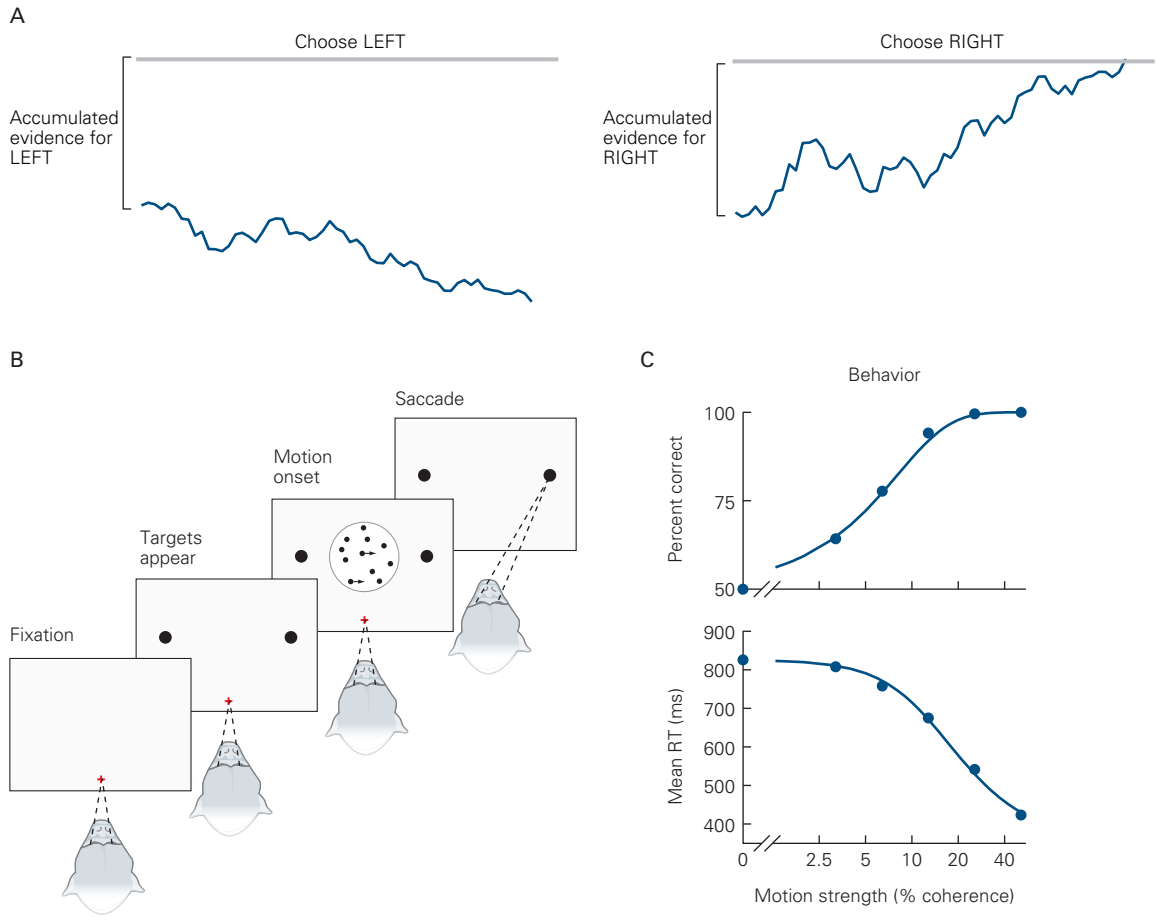

Figure 56–6 The speed and accuracy of a decision are explained by a process of evidence accumulation.

A. A decision and the time it takes to reach it are both explained by the accumulation of evidence, as a function of time, until there is sufficient evidence to terminate the decision in favor of one or the other choice. The cartoon illustrates a decision for rightward motion because the "choose right" accumulation was the first to reach the stopping bound (**thick gray lines**). Because the evidence is noisy, the accumulations resemble biased random walks, also known as drift-diffusion processes. For the decision between left and right motion, there are two accumulations. The one shown on the left accumulates evidence for left and against right. The one shown on the right accumulates evidence for right and against left. For this process, the bias (or drift rate) is the mean of the evidence samples depicted by the distribution of differences (right minus left) in Figure 56–4C. The process is a random walk because even if the motion is rightward, left-preferring neurons in area MT might respond more than right-preferring neurons at any instant. The two processes tend to evolve in an anticorrelated fashion because the random dot motion stimulus supplies the same noisy samples of evidence to both accumulations via the visual cortex. They are not perfectly anticorrelated because right- and left-preferring neurons introduce additional noise. Were the anticorrelation perfect (eg, if all the noise comes from the motion stimulus), the two processes could be represented by one accumulation that terminates at either an upper or lower stopping bound.

B. In a choice-reaction time task, the decision-maker reports a decision whenever ready with an answer. In this case, the monkey signals its choice by the direction of a saccade.

C. Graphs show a typical data set. In addition to the proportion of correct choices, the reaction time (**RT**), the time from onset of motion to the beginning of the eye movement response, also depends on the strength of motion. The total length of RT is the time to reach a decision, explained by the process in **A**, plus the time required to convey sensory information from the stimulus to the neurons that compute the decision and the time required to convert the decision to a motor response. (Adapted, with permission, from Gold and Shadlen 2007.)

It seemed possible that neurons whose activity represents a plan to act might also represent the formation of that plan during decision making. For example, if a monkey has learned to answer "rightward" by moving its hand to a target on a touch screen, the neurons of interest will tend to be active in association with that movement and they will decrease their activity if the monkey plans to reach to the opposite "leftward" target. Those neurons project to brain areas that command reach movements. If the monkey has learned to answer with an eye movement, the neurons that help to plan eye movements to the choice-target represent the decision variable. Such neurons have been studied extensively in the lateral intraparietal area (LIP). Indeed, these LIP neurons provided neuroscientists with the first view of a decision process as it unfolds in time.

Neurons that represent the evolving decision increase their firing rates gradually as the evidence mounts for one of the choices, and they decrease gradually when the evidence favors the other option (Figure 56–8). Their firing rates, plotted as a function of time, approximate a ramp: a baseline rate plus a constant multiplied by time, where the constant is proportional to the strength of the momentary evidence (eg, the average difference in the firing rates of the right- and left-preferring MT neurons). This captures the average firing rates across many trials, but it leaves out the critical point that the decision variable is an accumulation of both signal and noise. The signal is the mean of the difference. The noise is the variance—that is, the spread around the mean. The accumulated noise is obscured by the averaging in Figure 56–8, but it is apparent in the variability of firing rates across multiple decisions.

The responses start at a common level and evolve as the brain acquires more and more information, until something stops the process. A neural signature of the stopping rule is apparent in the responses aligned to the eye movement itself. The firing rate appears to reach the same level on trials that take as little as a few tenths of a second and trials that take as much as a full second. The level is achieved less than a tenth of a second before the eyes start to move. Of course, it takes less time to achieve this level if the firing rates are increasing at a rapid pace (eg, solid red trace in Figure 56–8). This suggests that the brain terminates the decision when the representation of accumulated evidence reaches a threshold. That is exactly what the bounded accumulation framework predicts. There appears to be no common level of activity in neurons that signal a rightward movement when the monkeys choose the opposite direction. Instead, another population of neurons that accumulate evidence for left (and against right) reaches their threshold and terminates the decision process when the monkey answers left (Figure 56–6A). The neurons that favor the right choice simply stop accumulating evidence at a time determined by the left choice neurons. This explains why the downward traces in Figure 56–8 do not reach a common level of activity around the time of the eye movement. It is not yet known where in the brain the threshold operation is applied. Computational theorists have proposed that a likely candidate is the striatum, a brain area involved in selecting between competing actions (Chapter 38), but there are many other candidate structures, including movement areas of the cortex and brainstem.

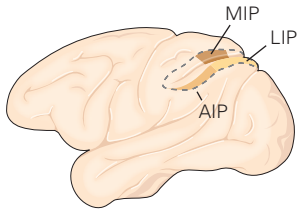
Area LIP is not the only part of the brain that represents the accumulation of evidence toward a decision, and LIP itself is not limited to making decisions about random dot motion. Many neurons in the parietal and prefrontal cortex exhibit persistent firing. In fact, the first brain areas shown to exhibit this type of activity were in the frontal lobe, rostral to the primary motor cortex, and some neurons with this property were found in the motor cortex itself. The persistent activity was thought to represent working memory for a location in space or a rule, category, or plan of action, as discussed in Chapter 52. But these neurons are also capable of representing graded levels of activity, suggesting a capacity to represent more analog quantities, like an evolving decision variable, the expected value of making an action, or working memory of a sensory quality, as we next consider.

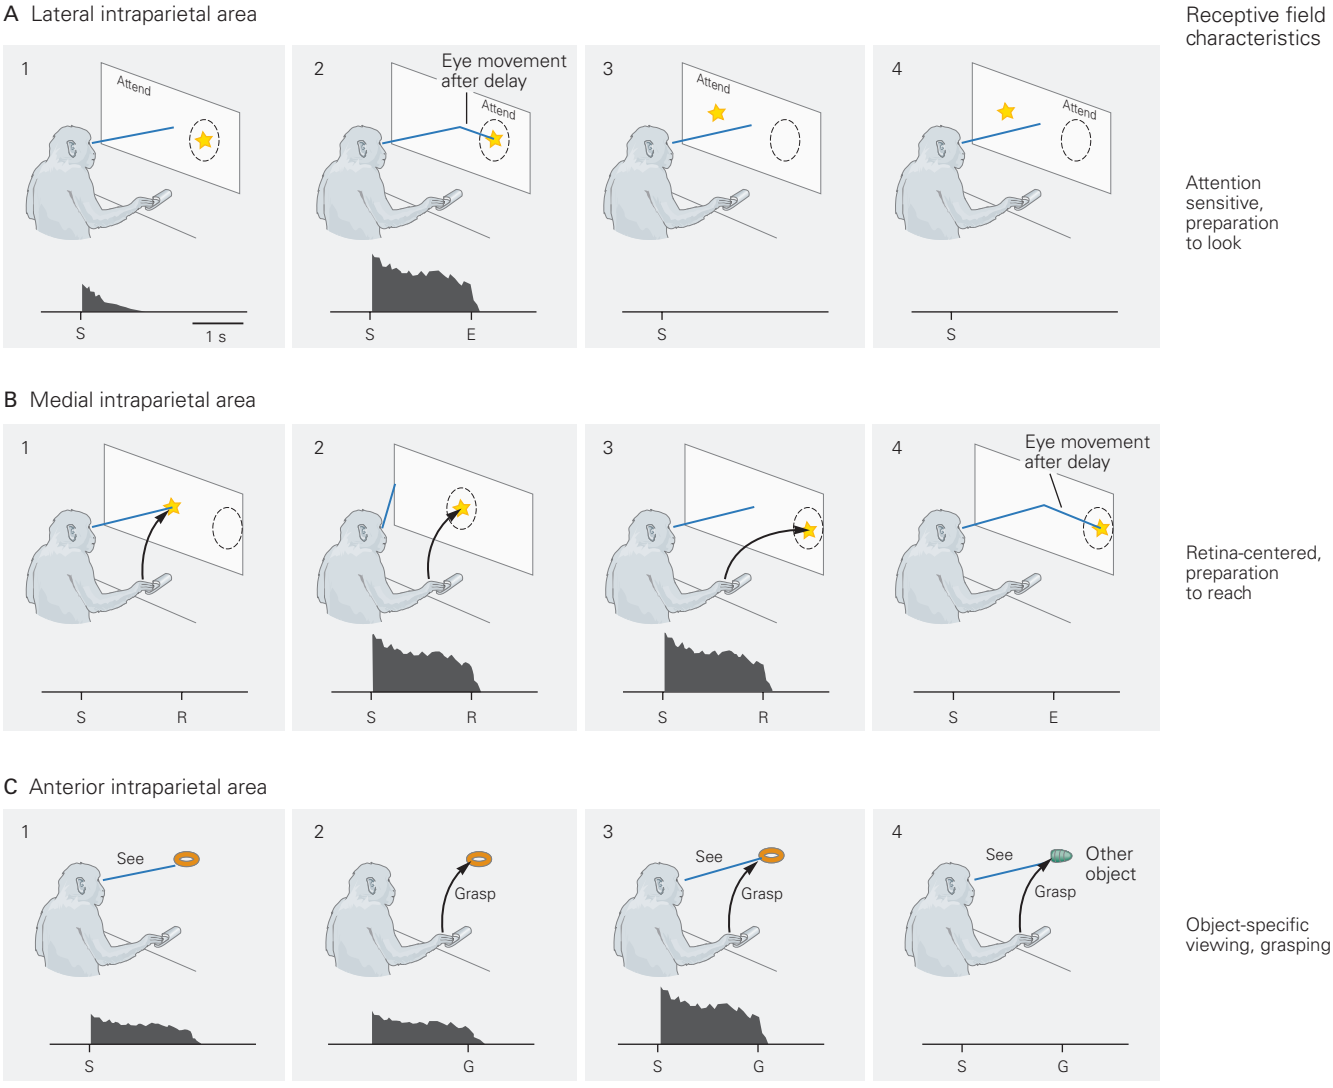
Twenty years after Mountcastle published his studies of flutter-vibration discrimination, his student Ranulfo Romo rejuvenated this line of research by focusing on neurons in the prefrontal cortex, which had the kind of persistent activity we have been discussing. Romo modified the task. The monkeys were still presented with two vibrating stimuli, separated by a delay, and were required to decide whether the vibration frequency of the second stimulus (f2) was greater or less than the vibration frequency of the first stimulus (f1). However, instead of using the same 20-Hz reference stimulus on all trials, the flutter frequency was varied across trials. He found that many neurons in the prefrontal cortex respond in a graded and persistent manner to the frequency of the first flutter-vibration stimulus during the delay period while the monkey awaited the second stimulus. Some neurons increased their firing rate as a function of the vibration frequency of f1, while others were more active with lower frequencies. These persistent neural responses were not observed by Mountcastle in his original studies. There is evidence that a decision variable is constructed in the ventral premotor cortex, where neurons respond

to the difference, f2 – f1. This is challenging to study because the decision variable does not evolve over a long time scale. There is no need to acquire many samples of evidence. All that is needed is an estimate of f2 and the application of a threshold. The flutter-vibration task complements the motion decision task by demonstrating the diverse functions of persistent activity. In the motion task, the persistence supports the computation of the decision variable—the accumulated evidence bearing on the decision alternatives. In the flutter-vibration task, the persistent activity represents a sensory quality—the frequency of the reference stimulus—through a delay period.

Perceptual Decision-Making Is a Model for Reasoning From Samples of Evidence

Most of the decisions animals and humans make are not about weak or noisy sensory stimuli. They are about activities, purchases, propositions, and menu items. They are informed by knowledge and





expectations derived from sources such as personal experience, books, friends, and spreadsheets. Some are based on internal (subjective) valuation or preference. Many involve reasoning from sources of evidence that may differ in reliability and that must be weighed against costs and benefits. To what extent do the neural mechanisms of perceptual decision-making apply to these other types of decisions?

Imagine the following scenario. As you leave your home in the morning, you realize that you will be outdoors from 4 to 5 pm and must decide whether to carry an umbrella. To make this interesting, assume this occurred before the age of the internet and accurate satellite weather prediction. You must decide based on yesterday's forecast of "possible chance of rain", the clear appearance of the sky at 7:00 am, a small drop in the barometric pressure compared to 1 hour before, and the observation that among a dozen pedestrians visible from your window only one seems to be carrying an umbrella. Let us assume further that you have experience with such decisions and have some sense of how reliable these indicators are. Finally, the cumbersomeness of carrying the umbrella is such that your decision boils down to a reasoned assessment of whether rain is more likely than not.

The right way to make this decision is to consider each of the indicators and ask how likely they would be if rain does or does not occur in the afternoon. These likelihoods are learned estimates of conditional probabilities, the probability of observing the indicator when it rains in the afternoon, and the probability of the same observation when it does not rain. For example, suppose through experience you have learned that the forecast, chance of rain, implies a 1 in 4 chance of rain. Then, the conditional probabilities are 1 in 4 and 3 in 4 that it will or will not rain, respectively, given the weather report. The ratio of these two probabilities is termed the likelihood ratio (LR), which is 1 in 3 in this case. If the LR is greater than 1, it favors rain, and if the LR is less than 1, it favors no rain. There is an LR for each of the four indicators. If the product of the four LRs is greater than 1, then you should carry the umbrella.

For reasons that will be clear in a moment, it is useful take logarithms of LRs, termed the log-likelihood ratio (logLR). This provides a more natural scale for belief, and it allows us to replace multiplication with addition [recall that $\log(xy)=\log(x)+\log(y)$]. To appreciate the scale, assume that the one passerby with an umbrella would be equally likely to carry the umbrella whether or not rain is a prospect. Both probabilities are 1 in 2. The LR is therefore 1, and the $\log(1)=0$, which corresponds to the intuition that this observation is uninformative. LRs greater than 1 have positive logarithms, and LRs less than 1 have negative logarithms, consistent with the way they bear on the prediction of rain.

Monkeys can be trained to perform a version of this weather prediction task. In the experiment depicted in

Figure 56–7 (Opposite) **Persistent neural activity maintains working memory, attention, and plans of action.** The monkey is asked to view a scene and respond to a visual stimulus (**S**) by either moving its eyes (**E**) or reaching (**R**) or grasping (**G**) with its hand. Each histogram represents the firing rate of a representative neuron as a function of time following presentation of the visual stimulus. The **dashed circles** show the *response fields*. This term is preferable to receptive and movement field because these neurons are neither purely sensory nor purely motor. The **blue line** shows where on the screen the monkey is asked to initially fixate its gaze.

A. Neurons in the lateral intraparietal area (**LIP**) fire when a monkey is preparing to make an eye movement to an object or when the monkey directs attention to the object's location. Most LIP neurons are not selective for object features such as shape and color. This neuron fires when the object is presented in the neuron's response field, which lies in the circled area to the right of where the monkey is looking (**1**). The neuron's firing is enhanced if the object is presented while the monkey's attention is directed to this location or if the monkey is asked to plan an eye movement to the location (**2**). The firing can persist for several seconds after the stimulus has been removed (**2**), thereby providing a potential mechanism for maintaining a short-term or working memory of its location. The neuron does not fire if an object is presented outside the neuron's response field (eg, to the left) (**3**) even if the monkey is asked to attend to the location of the neuron's response field (**4**). An object must appear there even if only briefly (**2**).

B. In the medial intraparietal area (**MIP**), neurons fire when the monkey is preparing to reach for a visual target. This neuron starts firing shortly after the appearance of a target in the response field of the neuron, in this case, a fixed angle to the right of where the monkey is looking, whether its gaze is on the left edge (**2**) or the center (**3**) of the screen, and it continues to fire as the monkey waits to reach. The neuron does not fire when the monkey reaches for a target at the center of its gaze (**1**) or when the monkey plans to shift its gaze to a target in the response field, without reaching (**4**). The physical direction of the reach is not a factor in the neuron's firing: It is the same in **1** and **2**, and yet the neuron fires only in **2**.

C. In the anterior intraparietal area (**AIP**), neurons fire when the monkey is looking at or preparing to grasp an object and are selective for objects of particular shapes. This neuron fires when the monkey is viewing a ring (**1**) or making a memory-guided reach to it in the dark (**2**). It fires especially strongly when the monkey is grasping the ring under visual guidance (**3**). It does not fire during viewing or grasping of other objects (**4**).

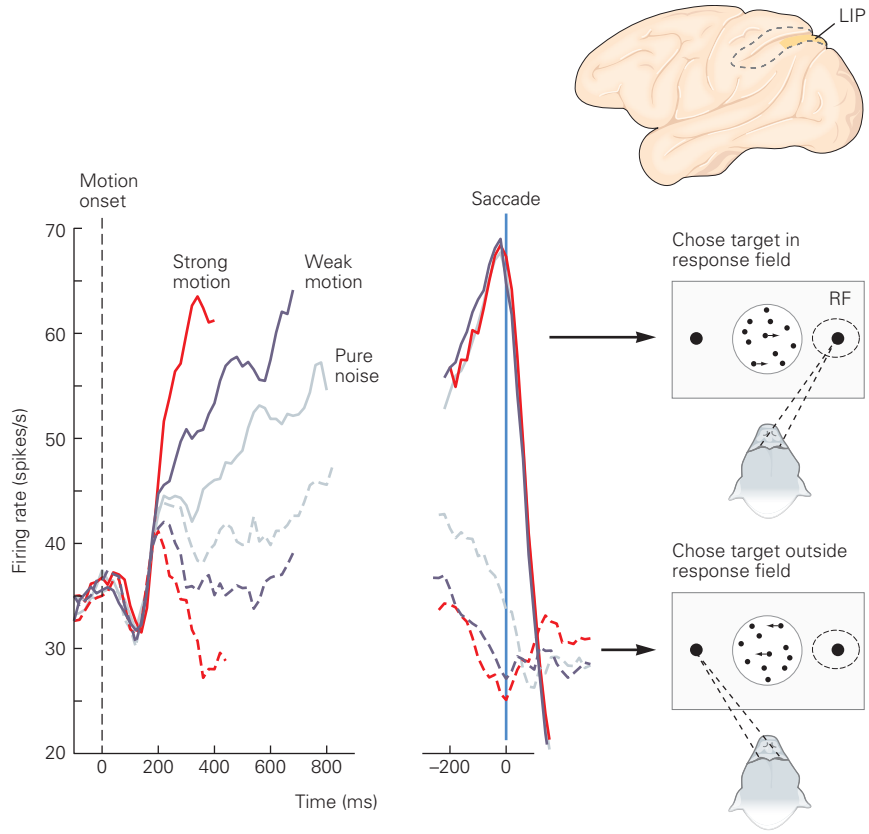


Figure 56–8 Neurons in the lateral intraparietal area (LIP) represent the accumulation of noisy evidence. These neural recordings were obtained while a monkey performed the reaction time version of the motion task. The traces are average firing rates from 55 neurons. The neurons were of the same type shown in Figure 56–7A.

The traces show average responses to three motion strengths: strong (**red**), weak (**purple**), and zero (pure noise, **gray**). The **solid traces** are from trials in which the monkey chose the target in the neuron's response field (**RF**; right choice). The **dashed traces** are from trials in which the monkey chose the target outside the neuron's response field (left choice). For the nonzero strengths, the direction of random dot motion was the direction the monkey chose (ie, only correct choices are shown). The responses in the plot on the left, which are aligned to the start of random dot motion, exhibit a gradual buildup of activity, leading to rightward choices, and a gradual decline in activity, leading to leftward choices. The rate of this buildup and decline reflects the strength and direction of motion. The responses on the right are to the same dot motion but are now aligned to the moment the monkey makes its eye movement (**saccade**) to indicate its choice and reveal its reaction time. The responses reach a common level just before the monkey makes its choice, consistent with the idea that a threshold applied to the firing rate establishes the termination of these trials. The responses do not reach a common level before leftward choices because these decisions were terminated when a separate population of neurons, with the left choice target in their response fields, reached a threshold firing rate. (Adapted, with permission, from Roitman and Shadlen 2002. Copyright © 2002 Society for Neuroscience.)

Figure 56–9, a monkey had to decide whether to look at a red or a green target, only one of which would lead to a reward. Before committing to red or green, the monkey was shown four shapes. Each served as an indicator about the location of the reward. The monkey had learned to associate predictive value with a total of 10 shapes, half of which favored reward at red, the other half at green. The shapes also differed in the reliability with which they predicted the reward location. The monkey learned to rely on these shapes rationally, making its decisions by combining evidence from each shape and by giving the more informative shapes more leverage on the choices.

While the monkeys made their decisions, neural activity was recorded from the same parietal area studied in the motion task. As before, the neurons responded in a way that revealed the formation of the decision for or against the choice target in their response field. When the red target was in the response field, the neuron assigned positive values

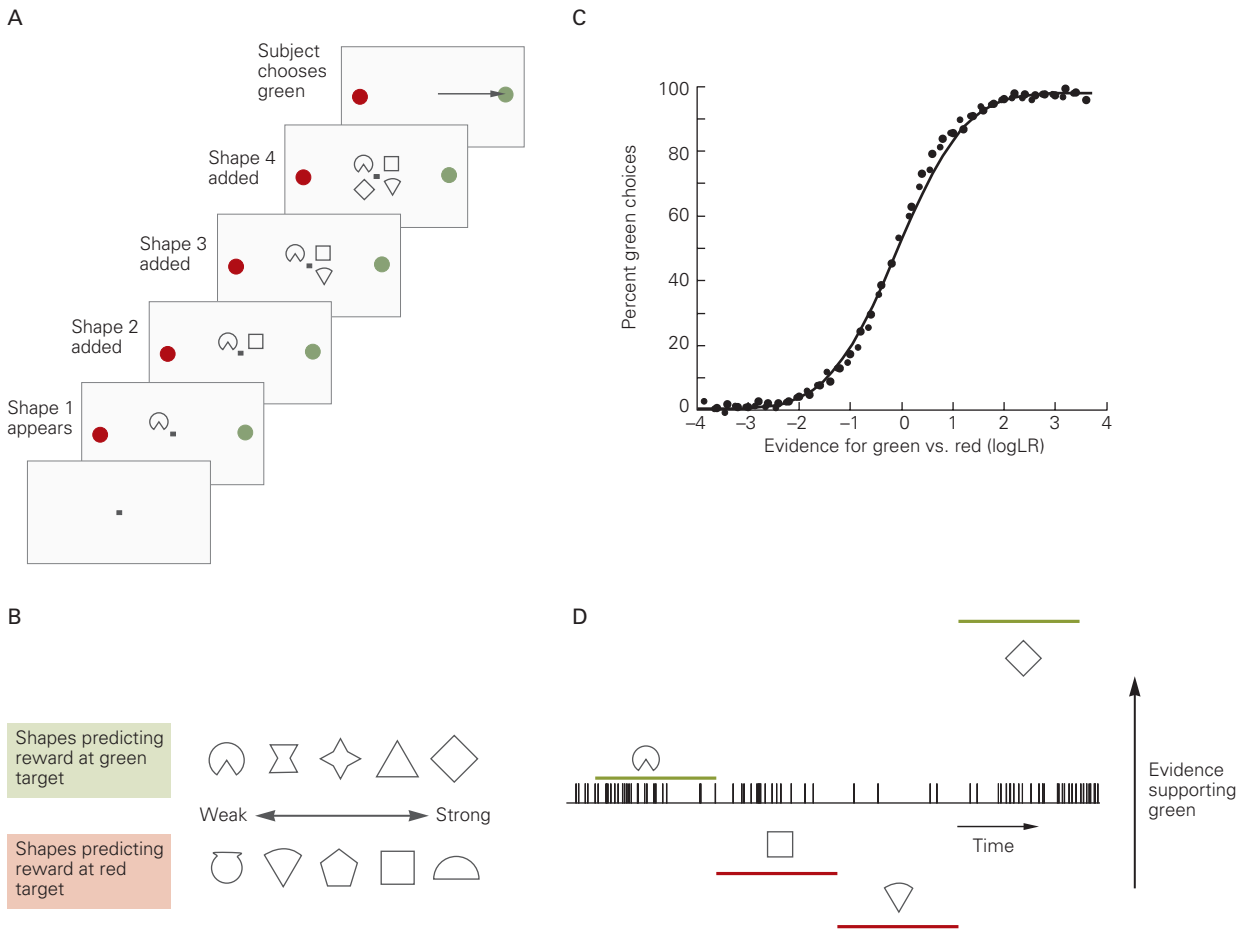

Figure 56–9 Evidence accumulation underlies probabilistic reasoning from evidentiary symbols.

A. A monkey was trained to make decisions based on a sequence of four shapes, drawn randomly with replacement from a set of 10. The shapes were added to the display sequentially every one-half second.

B. Each shape provides a different amount of evidence that a reward is associated with a red or green choice target. Some, like the diamond and semicircle, are highly reliable predictors that a reward will occur if the choice is for green or red, respectively. Others are less reliable predictors. The degree of reliability is quantified by the likelihood ratio or its logarithm. A good decision-maker should base the decision on the product of the likelihood ratios or the sum of their logarithms (**logLR**).

C. The monkey's decisions were guided by the probabilistic evidence from the four shapes. On trials in which the sum of the logLR from the four shapes strongly favored green, the monkey almost always chose green. When the sum was closer to 0, the monkey had to base its decision on weak evidence and chose less consistently. The pattern of choices demonstrates that the monkey assigned greater weight to the shapes that were more reliable (strong versus weak).

D. The same types of parietal neurons studied in the perceptual decision-making task represent the running sum of evidence bearing on the choice target in its response field. The spikes are shown from a single decision when the green target was in the neuron's response field. The **horizontal black line** below the spikes marks the neutral level of evidence for green versus red, such that the two choice targets are equally likely to be rewarded. The vertical position of the green or red lines associated with each successive presentation of an indicated shape show the cumulative evidence conferred by the shapes that the reward was at the green target. The first shape was weak evidence for green. The second and third shapes supplied mounting evidence against green (for red). Note the reduction in firing rate. The final shape provided strong evidence for green, such that the cumulative evidence from all the shapes favored green. Note the increase in firing rate. It is an example of a single neuron in the association cortex using persistent activity to compute quantities useful for decision-making. Based on the firing rates from many trials, it was shown that neurons encode the cumulative sum of the logarithm of the probability ratios—the logLR that a reward is associated with the choice target in the neuron's response field. (Adapted, with permission, from Yang and Shadlen 2007.)

to the red-favoring shapes and negative values to the green-favoring shapes. When the green target was in the response field, the signs were reversed. As shown in the example, the response changed discretely when each of the four shapes was presented, and it did so by an amount commensurate with the degree of reliability. In fact, the increment (or decrement) was proportional to the logLR assigned by the experimenter to the shape! The brain simply adds these logLRs to form a decision. And if the monkey is allowed to view as many shapes as it wants, it will typically stop when the accumulated evidence (in units of logLR) reaches a criterion level. The LIP neurons do the same thing they did in the motion decision. They produce firing rates that represent the cumulative sum of noisy increments and decrements.

By adding in units of logLR, the brain achieves reasoning from probabilistic cues in the way a statistician or actuary combines evidence from multiple sources. The experiment demonstrates that the mechanism used for perceptual decision-making is also at play in more complicated decisions that involve reasoning from more abstract sources of evidence. It speaks to the broader theme of this chapter: The study of decision-making offers insight into how the brain achieves a variety of cognitive functions.

Decisions About Preference Use Evidence About Value

Many, if not most, decisions made by humans and animals are expressions of preference, based on an assignment of value. In some instances, the value is innate. For example, most animals experience sweet as positive and bitter as negative (Chapter 29). In the vast majority of instances, however, value is learned through experience, or it is derived from reasoning based on other preferences. Unlike a decision about the direction of motion, a medical diagnosis, or the weather, a decision about which of a pair of items one prefers is not objectively right or wrong. It can only be said to be consistent or inconsistent with one's expression of value. In fact, our knowledge of a subject's valuation of an object may only be revealed to us by observing her choices.

Yet despite the qualitative difference between subjective and objective evidence, there are parallels between the neural mechanisms that support perceptual and value-based decisions. Decision-makers take more time to choose between items of similar value than items that differ substantially in value, and their choices are less consistent. In a typical experiment, the participant is asked to indicate the value of each item that they will later make choices about. For example, they might be asked how much they are willing to pay or they are asked to indicate a rating from highly undesirable through neutral to highly desirable. This procedure is typically repeated to provide a subjective value for each item to be used in the experiment.

The participant is then asked to decide between pairs of items. The difference in the subjective values communicated before the experiment provides an index of the difficulty of the decision between the items. It is analogous to motion coherence. A similar approach works with animals. For example, a monkey might demonstrate a preference for grape juice over apple juice, and then be asked to choose between a small volume of grape juice versus a large volume of apple juice. The decision is rendered more difficult by titrating the ratio of volumes to values that lead the monkey to choose either juice with equal tendency.

Two types of neurons associated with this type of value encoding have been identified. The first, typically located in the striatum, encodes the value associated with an action. The second, primarily in the orbitofrontal and cingulate cortex, appears to encode the value associated with specific items. Decisions about preference seem to arise from the same strategy that governs perceptual decisions. Just as a decision between left and right motion is guided by the difference in firing rates of left- and right-preferring sensory neurons, a decision between two items is based on the difference in activity of neurons encoding the values of each item. These neural representations are noisy, and this feature might explain why a decision-maker may make choices that are inconsistent with their values. It might also explain why decisions between items of similar value tend to take more time—a speed–consistency trade-off similar to the speed–accuracy trade-off discussed above.

The analogy to perceptual decision-making is appealing, but it misses the more interesting aspects of value-based decisions. As mentioned above, the value of most items is not given by biology but instead is learned. Further, there is no reason to assume that such value is monovalent. One may value an item differently, based on different qualities and considerations, and one or more of those qualities may dominate under different circumstances. Accordingly, the value of an item could appear to change simply by the occasion of its comparison to another item, which might invite emphasis on a more or less desirable aspect. Novelty, familiarity, and the value of exploration itself might also play a role in modifying a subjective valuation.

These considerations might contribute to the "noisy" representation of value that is thought to

explain inconsistencies and long decision times in preference choices. This type of noise belies processes that are far more complex than variability in random dot displays and the noisy spike rates of neurons. Such evaluative processes are likely to involve prospection and memory retrieval, which are only beginning to be understood at the neural level (Chapter 52). In the end, these processes must furnish samples of evidence bearing on the relative value of the items, and this evidence is either accumulated or evaluated individually against a criterion to halt the process with a decision.

Decision-Making Offers a Framework for Understanding Thought Processes, States of Knowing, and States of Awareness

States of knowledge have persistence. Even if they concern information derived from the senses, the knowledge of sensation generally outlasts the sensory activity itself. In this way, the state of knowledge resembles a perceptual decision—a commitment to a proposition about the object, based on sensory evidence. As we have seen, these states are often tied to possible behaviors rather than to the features of the sensory information. This is a position argued by many philosophers and the psychologist James J. Gibson.

This simple point can be made on empirical grounds. Persistent neural activity is not present in sensory areas of the brain unless a stimulus is unchanging and then only if the neurons do not adapt. Naturally, sensory neurons must change their response when the environment changes or the observer moves in the environment, whereas knowledge states persist through sensory changes and without a continuous stream of input. Indeed, persistent activity is apparent in areas of the brain that associate sources of information—from the senses and from memory—with circuits that organize behavior.

In the prefrontal cortex, persistent states represent plans of action, abstract rules, and strategies. In the parietal and temporal lobes, neural representations have the dual character of knowledge and the behavior that knowledge bears upon, such as making an eye movement or reaching, eating, or avoiding. The responses can resemble a spatial representation, as they do in area LIP, if the target of the projection is the eye movement system, but that is only because there is correspondence between space and action. A useful guide is to consider the source and target of the association. If the source is the visual cortex and the targets are premotor areas that control hand posture (eg, grip), as they do in the anterior intraparietal area (Figure 56–7C), the association area might convey knowledge about curvature, distance, convexity, and texture. One might be inclined to use terms borrowed from geometry to catalogue such knowledge, but it may be simpler to think about the repertory of hand shapes available to the organism. Importantly, the neurons in association cortex do not command an immediate action. They represent the possibility of acting in a certain way—an intention or provisional affordance (Box 56–1).

Let us defer for the moment the aspect of the knowledge state that includes conscious awareness and consider the simpler sense of knowledge as a state of possible utilization. Such preconscious ideation is probably the dominant state in which an animal interacts with the environment. It is arguably also the lion's share of human experience, although because we are not conscious of it, we underestimate its dominance. Two important insights emerge from this perspective. The first is that the correspondence between knowledge and neuronal activity lies at a level of brain organization between sensation and behavior. Although the flow of information from sensory epithelia (eg, the retina) through the primary cortical sensory areas is essential for perception, knowledge resulting from activity in higher brain regions has temporal flexibility and persistence not seen in lower brain regions—what the philosopher Maurice Merleau-Ponty termed the *temporal thickness of the present*.

The second insight is that the computation leading to a knowledge state has the structure of a decision—a provisional commitment to something approximating a possible selection from a submenu of the behavioral repertory. We might say that the parietal association neurons interrogate the sensory areas for evidence bearing on the possibility of a behavior: look there, reach there, posture the hand this way to grasp. Of course, neurons do not ask questions. Nevertheless, we can think of the circuits as if they scan the world looking for evidence bearing on a possible behavior. The type of information they can access is limited by functional and anatomical connectivity. The type of question is framed by the target of the projection, such as regions that control gaze, reaching, and grasping.

Sir Arthur Conan Doyle endowed Sherlock Holmes with the insight that the key to discovery was knowing where to look and what to look for. We acquire knowledge by controlling the brain's interrogation system. Some interrogations are automatic, whereas others are learned. An example of the former is a sudden change of brightness of an object in the visual field; it provides evidence bearing on the possibility of orienting the eyes or body toward it. An example

Box 56–1 Affordances, Perception, and Knowledge

James J. Gibson, known for his ecological theory of perception, referred to *affordances* as properties of objects and the environment. The term comes from the verb *afford*. An object affords possible behaviors, such as lifting, grabbing, filling, hiding in, drawing/writing upon (eg, parchment) or with (eg, a brush), or walking upon. The affordance refers to the potential behaviors of the animal. The same object, say a stone, could afford grasping, dropping, breaking (ie, used as a tool), throwing (as a missile weapon), or pinning (as a paperweight).

Gibson was widely criticized for claiming that perceptual processes picked up these affordances directly from the optical array, what he termed "direct perception." The term is commonly misunderstood as antithetical to computational accounts of information processing. By "direct perception," Gibson did not mean that there were no computations on the data received through the senses. He promoted the mathematical understanding of these operations. He meant that we do not perceive the intermediates.

We do perceive the parts of objects that are accidentally occluded by something in our line of sight, and we perceive the back of an opaque object that is occluded by its front. We do not perceive the outlines, the line art, and many other details, but that is not to say that they do not register on the retina and the visual cortex. Gibson held that representation of visual information is not a sufficient condition for perception. From the perspective of the neuroscience of decision-making, one might place emphasis on the representation of potential behavior—something like a provisional commitment to a plan.

Affordance still refers to a category of actions, but it is about the organization of the action (eg, throwing) or strategy, and also—but not necessarily—a quality of the object. The modifier, "provisional," emphasizes that the action may not actually ensue now or ever. This modifier would have been superfluous in Gibson's use of the term *affordance*, because an affordance was a property of the object (in his ecological framework) and therefore had a permanence independent of the perceiver.

of the latter draws on learning and foraging; we learn, through play and social interaction (eg, school), how to look for hidden items and how to explore in a goal-directed way.

The beautiful thing about this construction is that an answer to the question confers a kind of meaning. Even for such a mundane question like "Might I look there?," an affirmative answer—a decision to (possibly) look at an as yet undefined object in the periphery of one's visual field—confers a spatial knowledge about the item. Before we have looked directly at it to identify what it is, we know about its *thereness*. From the perspective of decision-making, the location of an object is not perceived because there is a neural activity in a map of the visual field. Rather, the location is perceived because some aspect of the visual field—a fleck of contrast, change in brightness, appearance or disappearance—answered the question above in the affirmative.

This way of thinking helps us understand the disease states known by the term *agnosia*, from the Greek word meaning "absence of knowledge." The classic example is visual hemineglect, which is caused by damage to the parietal lobe (Chapter 59). A patient with a right parietal lesion will ignore the left side of the visual field and also the left side of objects even when the entire object is in the right visual field (Figure 56–10; see also Figure 59–1). Unlike the left side blindness, called homonymous hemianopsia (or hemiblind), which accompanies damage to the right visual cortex (homonymous because it is the same regardless of which eye is used), the patient with a parietal lesion does not complain of an inability to see. She is unaware of the deficit, so much so that crossing a street is a major hazard.

A hemiblind patient with damage to the right visual cortex still expects to interrogate and receive information from the left visual field. When that patient receives no visual information, he knows to turn to face parallel to the street, thereby placing its contents in the intact right hemifield. In contrast, the patient with hemineglect does not interrogate the left hemifield in the first place. She does not perceive a lack of visual information because the apparatus to conduct the interrogation is not working. Like most deficits, there is enough redundancy in the brain (or the damage partial) that some visual capacities are present. In fact, when confronted with a single spot of light on a dark background, the same patient may report its presence accurately even in the affected hemifield.

There are other versions of hemineglect that involve an absence of knowledge of the body. For example, a patient with a right parietal injury may deny that her left arm is hers. She may recognize it as

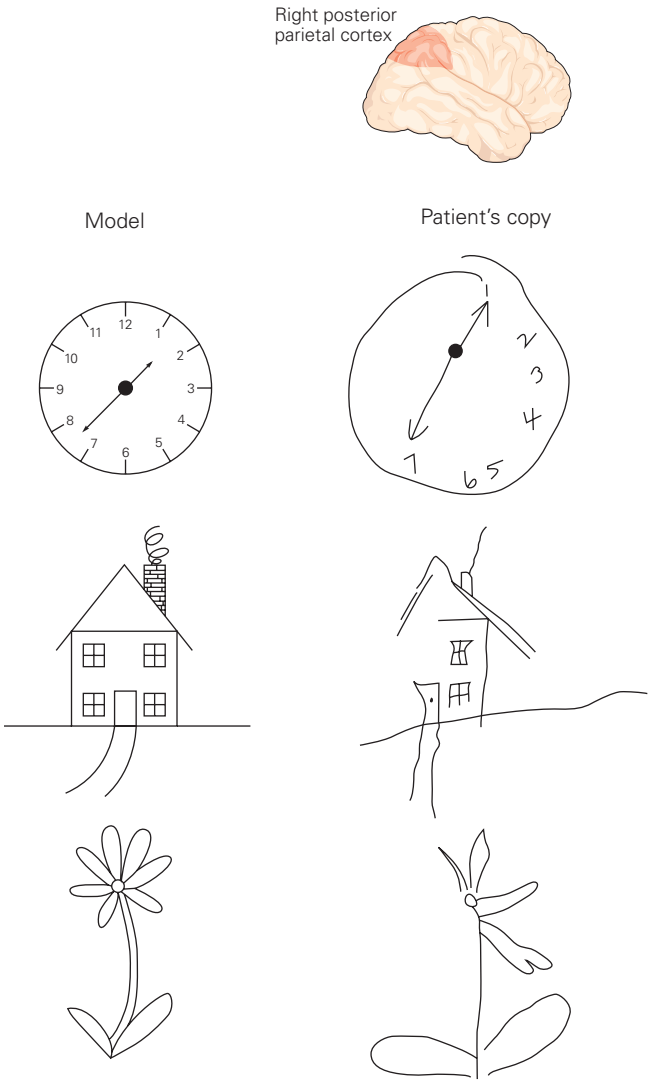

Figure 56–10 Damage to the parietal or temporal cortices results in agnosia, or deficits in knowing. After damage to the right parietal lobe, many patients are unaware of the left side of space or the left part of objects. The drawings on the right were made by patients with unilateral visual neglect following lesion of the right posterior parietal cortex. Agnosias can also be induced in healthy individuals by diverting attention (see Figure 25–8). (Reproduced, with permission, from Bloom F, Lazerson A. 1988. *Brain, Mind and Behavior*, 2nd ed., p. 300. New York: Freeman.)

an arm but deny that it is hers. When asked whose arm it is, she may express ignorance bordering on disinterest (personal experience). The syndrome is usually associated with some visual neglect as well and some weakness on the same side of the body suggestive of a more rostral and superior localization. Consider that the body's position is known to us partly through the somatosensory system, partly through the predicted consequences of our motor command, and partly through vision. The arm in particular is a common feature of our lower visual field. Indeed, we are accustomed to ignoring it.

These examples are the most common of the agnosias (which are thankfully rare). Other well-known examples involve problems in face recognition (prosopagnosia) and the perception of color (achromatopsia), both associated with lesions of the temporal lobe. The different types of agnosia have loose correspondence to the anatomical specializations we learned about in Chapter 24. In particular, the ventral extension of the central visual pathways into the temporal lobe is referred to as the "what" pathway, which contains circuits that are specialized for processing faces, objects, color, and semantic memory. The dorsal extension, which has been termed the "where" or "how" pathway, seems concerned with representations supporting localization.

An alternative formulation would characterize these streams in terms of associations with behaviorally relevant targets. For the dorsal stream, those are parietal areas with projections to motor systems that reach, look, or grasp. For the ventral stream, those are temporal lobe areas with projections to structures that guide foraging decisions to eat, avoid, hide, approach, mate, and communicate. The last few behaviors are social affordances conferred by color and facial identity/expression. With a small stretch of imagination, the organization of social affordances links to other functions of the temporal lobe (and temporal parietal junction) in humans. For example, these regions are associated with language comprehension and inference about what someone else is thinking. The former is associated with a devastating agnosia, known as Wernicke aphasia (Chapters 1 and 55); the latter is known as theory of mind and will be discussed below.

From the perspective of decision-making, perceiving, believing, and thinking have the character of a provisional commitment to a proposition. Brain states that correspond to a sense of knowing, be it perceiving or believing, share two important aspects with decision-making: an extended temporal profile that withstands changes in the sensory and motor streams (ie, a freedom from immediacy) and a propositional character captured by the term "affordance." Knowing is not solely about the information but is like the outcome of a decision to embrace a proposition: Might I do something, enact something, approach someone, or retain the possibility of trying the option I am not choosing now?

Two caveats deserve mention. This framework does not replace a computational account of

information processing, nor does it explain the neural mechanisms that support these computations. It mainly tells us about the level of brain organization that carries out these operations. For example, consider the search for the neurons that achieve knowledge about the color red, despite changes in the spectral content of the morning and evening light—a phenomenon known as *color constancy*. Instead of searching in sensory areas for neurons that respond selectively to red in this invariant way, one might look for neurons that guide the choice of ripe fruit. This does not obviate the computations required to recover the surface reflectance properties of the fruit's skin, despite variation in the spectral content of the illuminating light. The raw data for such computations are supplied by sensory neurons that lack color constancy and maintain temporal fidelity with changes in the environment. The knowledge state "red," however, is invariant to the illuminant and likely persistent. In animals that lack language, the knowledge state may not be dissociable from "ripe vegetation."

The second caveat is that we have not distinguished knowledge states that we are consciously aware of from those that we experience unconsciously. For example, as I make my way through the forest trying to find the creek that I hear burbling, my brain might consider locations of objects I pass that are graspable, attached to vegetation, and with color suggesting ripeness. I may be unaware of this consciously. Yet that evening in my search for food, I may return to this part of the forest, guided by these unconscious encounters. I may do this without knowing why, or the memory might pierce consciousness. All that has been said up to now could apply to conscious and nonconscious experience. We are now prepared to elucidate the difference.

Consciousness Can be Understood Through the Lens of Decision Making

Clearly, we are unaware of most of the operations that transpire in our brains, and this is true even for the processes that ultimately pierce consciousness. This is why Freud famously quipped that consciousness is overrated. Every thought that enters our awareness began as neural computation preceding the conscious awareness of that thought. Indeed, the sophistication of nonconscious mental processes, including those leading to "I've got it!" moments and the activities we perform while occupied by a phone call, involves decisions that transpire without conscious awareness.

It is difficult to study nonconscious processing because people deny experience of the process. Indeed, the term nonconscious experience seems like an oxymoron. The experimenter must find a way to prove that information processing has occurred despite the fact that the subject is unaware of it. In recent years, it has become possible to establish conditions whereby information is provided to a human subject that has a high likelihood of going unnoticed but is nonetheless able to influence behavior, thereby permitting scientific characterization of nonconscious mental processing (Chapter 59). This has encouraged neuroscientists to ask what it is about the neural activity that gives rise to the thoughts, perceptions, and movements that do reach conscious awareness. We will not review this vast topic here but instead share a pertinent insight: Viewed through the lens of decision-making, the problem of consciousness may be simpler than imagined.

Broadly speaking, two sets of phenomena fall under the heading consciousness. The first concerns levels of arousal. One is not conscious when one is asleep, under general anesthesia, comatose, or having a generalized seizure. One is fully conscious when awake, and there are levels of consciousness between these extremes. These states are associated with terms such as confusion, dissociation, stupor, and obtundation. Some alterations of consciousness are normal (eg, sleep), whereas others are induced by toxins (eg, alcohol), metabolic disturbances (eg, hypoglycemia), low oxygen, trauma (eg, concussion), or fever (eg, delirium).

The neuroscience underlying these states—and the transitions between them—is immensely important to medicine. We might classify this group of phenomena as neurology-consciousness. However, these topics are not what most people mean when they speak of the mystery of consciousness. This is partly because they are less mysterious but also because their characterization is more objective and the phenomena can be studied in animals. That said, there is much to be learned about the mechanisms responsible for sleep, awakening, anesthesia, and so forth. Much of the neuroscience is unfolding at a rapid pace (Chapter 44).

We will not say more about neurology-consciousness here, except to seed one useful insight. Imagine a mother and father sleeping comfortably in their bedroom as a storm ensues outdoors. There are also traffic sounds and even the occasional thunder. This scene goes on for some time, until the cry of a baby awakens the parents. This common occurrence tells us that the nonconscious brain is capable of processing sounds and deciding to become conscious. It decides, nonconsciously, that some sounds afford an opportunity for more sleep while others sound a call to nurture. This

decision is similar to the perceptual decisions considered earlier in this chapter. Both involve nonconscious processing of evidence. However, the commitment to awaken and parent is a decision to engage the environment consciously. This may be a touchstone between neurology-consciousness and the more intriguing consciousness that you are experiencing as you read these words (or so the authors hope).

When neuroscientists, psychologists, and philosophers ponder the mysteries of consciousness, they are referring to loftier themes than wakefulness. This loftier set of phenomena comprises awareness, imagery, volition, and agency. There is a subjective component to all conscious experience. The experience of conscious perception incorporates a sense that it is me that is beholding the content. It parallels the "me" in volition. It is not that my arm moved on its own; I made it move! We used the term deliberation earlier in this chapter to describe the thought process leading to a decision. Our use of the term was metaphorical. It describes a computation and a biological mechanism, but it does not require awareness. Actual deliberation implies conscious intention. We are aware of the steps of reasoning along the way. We could report, were we asked, about the evidence we relied upon—that is, the evidence we were consciously aware of during the decision and possibly some of the evidence we used nonconsciously were it accessible from memory to include in our report. Could the difference between conscious awareness of an item and nonconscious processing of that item be a mere matter of whether the brain has decided on the possibility of reporting? Could it be this simple?

Consider the following scenario. A psychologist concludes that a study participant has seen something nonconsciously because the item affected a subsequent behavior and the participant denies having seen it. Suppose the subsequent behavior involved reaching in the direction of the object. Based on what we know about decision-making, we would conclude that brain circuits like the ones discussed earlier received sufficient evidence to commit to the possibility of looking, reaching, and approaching, but there was insufficient evidence to commit to the possibility of reporting. Just as the brain entertains the possibility of looking, reaching, or grasping, it may also entertain the possibility of reporting. That is, reporting is also a *provisional affordance*.

Events afford the possibility of reporting, and this includes the nonconscious states of knowledge acquired through decision-making. Indeed, the event of having decided may be experienced consciously—the *aha* moment—by virtue of another decision to report. In the study scenario, the participant was not consciously aware of the item because her brain did not commit to a provisional report. The evidence did not satisfy a decision criterion like the termination bounds in the perceptual decision-making task considered earlier in the chapter.

This account provides a plausible explanation of the failure of the participant to report that she saw the item, but the mere entertaining of the possibility of reporting does not seem to explain the phenomenology of the perceptual experience itself, at least not at first glance. This explanation demands more careful consideration of the character of the report. Just as we attach states of spatial knowledge to configurations of the hand for reaching and grasping, we must consider the knowledge state that accompanies the affordance of reporting. Whether by language or gesture (eg, pointing), the report is a provisional communication with another agent or oneself (eg, in the future). It presumes knowledge about the mind of the receiver.

Cognitive scientists use the term *theory of mind* to refer to this type of knowledge or mental capacity. It can be demonstrated by asking someone to reason about the motivation behind another agent's actions, and it can be studied in animals and preverbal children by examining their reactions to another child or puppet. In one study protocol, two children witness a desired toy placed in a left or right container (Figure 62–2). The test child then witnesses the toy's displacement to the other container while the other child is absent. When that child returns, the experimenter assesses the test child's expectation of which container the returning child will open to find the toy. Children under 3 years old do not exhibit theory of mind by this assay. They think the returning child will open the container that contains the toy, not the one it was in before the transfer. Whether animals other than humans have theory of mind is controversial. We suspect there are inchoate forms of this capacity in the animal kingdom and in children under 3. When adults perform tasks that depend on theory of mind, the right temporal-parietal junction and superior temporal sulcus are active.

Theory of mind—in concert with narrative—has profound consequences for the knowledge state associated with the reporting affordance. Imagine a woman looking at a power drill resting on a table. She experiences the location of the drill, relative to her eyes and hand, as well as its texture and shape. It has a graspable surface that is partly in her line of sight and partly occluded (eg, the back). These are the knowledge states that arise through provisional commitments to look at, reach for, and grasp the drill. They are likely to involve neural activity similar to what is illustrated in Figure 56–7, and they are the outcome of simple decisions. The drill brings to mind other affordances

associated with its utility as a tool, its potential to make noise, and the potential danger posed by the sharp bit at one end. This is an elaborate, potentially rich collection of knowledge, but it could all be experienced nonconsciously. For example, if the woman were preoccupied with some other task, such as a phone conversation with her friend, she might nonetheless make use of these knowledge states.

But suppose there is a man on the other side of the table and suppose the woman—her brain, that is—has also reached a provisional commitment to report to the man about the drill between them. Consider the change to her knowledge state. The drill now has a presence not only in her visual field, relative to her gaze, her hand, and her repertory of actions, but also in the man's field of vision and his possible actions. The parts of the drill that are not in plain sight to her are known to be in the line of sight of the man. Indeed, her capacity for "theory of mind" also supplies knowledge that other parts of the drill are seen only by her and that the man could be experiencing those parts just as she experiences the parts that are not in her direct line of sight—that is, both preconsciously as occluded parts of the object and consciously as part of an object that could be seen directly from another vantage point. There is something about the drill that is at once private, public, and in the world—independent of either mind. The drill is there for the next person who enters the room, or an imagined person. The transformation of knowledge of the drill is from a collection of first-person experiences (eg, qualities and affordances) to a thing in the world that possesses an existence unto itself. It is conceivable that this state of knowledge is our conscious awareness of the world, or at least a part of it, for the knowledge state associated with a decision to report is further enriched by content of the report itself.

The report might be simple, like pointing to the location of a tool or a hiding spot, or it might involve narrative. In the case of the hiding spot, additional content might be conveyed to indicate that the enclosure affords safety from a predator or, alternatively, a predator's location. Many simple reports do not require narrative because items such as tools and enclosures persist and theory of mind presumes the affordance of a tool or a hiding place in another's mind, whereas events, which also afford the possibility of reporting, often require narrative because they are transient.

The knowledge state associated with narrative can incorporate history, simulation, prediction, etiology (eg, origin stories), purpose, and consequence. For the drill, narrative might enhance the knowledge state to include memory of the place of purchase, an episode in which it malfunctioned, and the mechanism of its detachable bit. Narrative allows us to reason in more complex environments than the scenarios considered earlier (eg, the umbrella example and the probabilistic reasoning task; Figure 56–9). We could not reason about science, medical diagnosis, and jurisprudence without origin stories, simulation, hypotheses, prospection, and counterfactuals. The evolutionary advantage of this capacity is obvious (at least for the time being, until it leads us to make the earth uninhabitable).

To summarize, the conscious awareness of an item might arise when the nonconscious brain reaches a decision to report the item to another mind. The intention is provisional in that no overt report—verbal or gesture—need occur, just as no eye movement need ensue for the parietal cortex to engage the possible intention of foveating. Just as the provisional intention to foveate corresponds to preconscious knowledge of the location of an as yet unidentified object in the periphery, the possibility of reporting to another agent (or self), about whom we have theory of mind, corresponds to the knowledge of an item in a way that satisfies most aspects of conscious awareness.

Naturally, our journey from perceptual decision-making through affordances to consciousness is at best incomplete. For example, it does not yet provide a satisfying account of what a conscious experience feels like. But it is a start, as it supplies a coarse explanation of why sensory information acquired through the eyes is experienced differently from auditory or somatosensory experiences, and it provides insight into the private aspects of perceptual awareness as well as our experience of objects as things in the world, independent of what they afford to the perceiver. These last features follow from the consideration of another agent's mind.

The view of consciousness from the perspective of decision-making is, if nothing else, simplifying. There is no reason to search for a special area of the brain that bestows consciousness, or a special neuron type, or a special ingredient in the representation of information (eg, an oscillation or synchronization), or a special mechanism. The mechanism might look like any other kind of provisional commitment—that is, a decision that confers a state of knowing but does not entail conscious awareness. Of course, brain activity itself is not conscious, just as the brain activity supporting a possible hand posture is not the hand posture itself. In this sense, the mechanism of consciousness is only different from other affordances because it involves reporting instead of reaching, looking toward, eating, drinking, hiding from, walking through, and mating. All are likely to involve decision formation and threshold detection.

Thus, by studying the neuroscience of decision-making, we are also studying the neuroscience of consciousness. There is still much to be learned about the mechanisms of the simplest decisions described in the first part of the chapter. For example, we do not know what sets the bounds and how thresholds are implemented in brain circuits. Nevertheless, answers to these and other fundamental questions are in the crosshairs of modern neuroscience, and therefore, so is human consciousness.

Highlights

1. A decision is a commitment to a proposition, action, or plan—among options—based on evidence, prior knowledge, and expected outcomes. The commitment does not necessitate immediate action or any behavior, and it may be modified.
2. Decision-making provides a window on the neuroscience of cognition. It models contingent behavior and mental operations that are free from the immediate demands of sensory processing and control of the body's musculature.
3. A decision is formed by applying a rule to the state of evidence bearing on the alternatives. A simple decision rule for choosing between two alternatives employs a criterion. If the evidence exceeds the criterion, then choose the alternative supported by the evidence; if not, choose the other alternative.
4. For certain perceptual decisions, the source of evidence and its neural representation are known.
5. The accuracy of many decisions is limited by considerations of the signal strength and its associated noise. For neural systems, this noise is attributed to the variable discharge of single neurons, hence the variable firing rate of small populations of neurons that represent the evidence.
6. Many decisions benefit from multiple samples of evidence, which are combined across time. Such decision processes take time and require neural representations that can hold and update the accumulated evidence (ie, the decision variable). Neurons in the prefrontal and parietal cortex, which are capable of holding and updating their firing rates, represent the evolving decision variable. These neurons are also involved in planning, attention, and working memory.
7. The speed–accuracy trade-off is controlled by setting a bound or threshold on the amount of evidence required to terminate a decision. It is an example of a policy that makes one decision-maker different from another.
8. Many decisions are about propositions, items, or goals that differ in value to the organism. Such value-based decisions depend on stored associations between items and valence.
9. The source of evidence for many decisions is memory and active interrogation of the environment—information seeking. These operations come into play when animals forage and explore, and when a jazz musician improvises.
10. Decision-making invites us to consider knowledge not as an emergent property of neural representations but the result of directed, mostly nonconscious interrogation of evidence bearing on propositions, plans, and affordances. The intention is provisional in that no overt action need ensue. Just as the provisional intention to foveate corresponds to preconscious knowledge of the location of an as yet unidentified object in the periphery, the possibility of reporting to another agent (or self), about whom we have theory of mind, corresponds to the knowledge of an item in the ways we are aware of it consciously.
11. Viewed through the lens of decision-making, conscious awareness of an item might arise when the nonconscious brain reaches a decision to report to another mind. The affordance has the quality of narrative, much like silent speech or the idea preceding its expression in language. It also imbues objects with a presence in the environment inhabited by other minds, hence independent of the mind of the perceiver. It confers private and public content to aspects of the object as perceived.

Bedroom at Arles by Vincent Van Gogh. Van Gogh wrote to his friend and fellow painter, Gaugin, that he had felt "my vision was strangely tired. Well, I rested for two and a half days, and then I got back to work. But not yet daring to go outside, I did . . . a no. 30 canvas of my bedroom with the whitewood furniture that you know. Ah, well, it amused me enormously doing this bare interior. With a simplicity à la Seurat. In flat tints, but coarsely brushed in full impasto, the walls pale lilac, the floor in a broken and faded red, the chairs and the bed chrome yellow, the pillows and the sheet very pale lemon green, the blanket blood-red, the dressing-table orange, the washbasin blue, the window green. I had wished to express *utter repose* with all these very different tones, you see, among which the only white is the little note given by the mirror with a black frame (to cram in the fourth pair of complementaries as well)." Van Gogh had psychotic episodes, but there is still debate about the cause—among the theories considered have been bipolar disorder, temporal lobe epilepsy, syphilis, schizophrenia, and even toxicity from the foxglove plant (a remedy for mental illness at the time) in combination with lead poisoning from his oil paints and the consumption of absinthe. (Van Gogh Museum, Amsterdam.)

IX Diseases of the Nervous System

> He remembered that during his epileptic fits, or rather immediately preceding them, he had always experienced a moment or two when his whole heart, and mind, and body seemed to wake up to vigour and light; when he became filled with joy and hope, and all his anxieties seemed to be swept away forever; these moments were but presentiments, as it were of the one final second (it was never more than a second) in which the fit came upon him. That second, of course, was inexpressible. When his attack was over, and the prince reflected on his symptoms, he used to say to himself: "These moments, short as they are, when I feel such extreme consciousness of myself, and consequently more of life than at other times, are due only to the disease—to the sudden rupture of normal conditions. Therefore they are not really a higher kind of life, but a lower." This reasoning, however, seemed to end in a paradox, and lead to the further consideration: —"What matter though it be only disease, an abnormal tension of the brain, if when I recall and analyze the moment, it seems to have been one of harmony and beauty in the highest degree—an instant of deepest sensation, overflowing with unbounded joy and rapture, ecstatic devotion, and completest life?" Vague though this sounds, it was perfectly comprehensible to Muishkin, though he knew that it was but a feeble expression of his sensations.*

WHAT, EXACTLY, IS THE NATURE OF THE RELATIONSHIP between the mind and the brain? Dostoevsky's own experience of epilepsy profoundly influenced his writing, and in this passage, he probes some of the most profound questions about human experience. Are our thoughts and moods simply transient combinations of chemicals and electrical signals? Do we have any influence over them? If not, can we be held responsible for our actions? What if some of our peak experiences are just happy chemical accidents? Or, as Prince Muishkin wonders, what if some of our peaks are happy accidents of disease? What, then, would it mean to "get better"? Individuals with bipolar disorder, for example, can have a very difficult time relinquishing the expansive feelings and creative energies that can accompany mania.

Although these profound questions are the purview of philosophers rather than neuroscientists, few circumstances bring the mind–brain relationship into question as sharply as becoming victim to a neurological or psychiatric disorder. The range of these conditions

*Dostoevsky F. *The Idiot*. Translated by Eva Martin. Project Gutenberg EBook, last updated May 13, 2017.

is very wide, from motor disturbances to epilepsy, schizophrenia, mood imbalances, cognitive disorders, neurodegeneration, and even aging. The more we learn, the more it becomes apparent that these diseases exert very broad effects that blur the boundaries between their classifications. So-called movement disorders such as Parkinson disease, for example, involve cognitive and affective changes; disorders of cognition such as autism or schizophrenia can have very physical manifestations.

Despite these somewhat fuzzy boundaries, each chapter in this section will examine the principles underlying each major class of disease from the perspective of neuroscience. The emphasis here is on molecular mechanisms, so far as they are currently understood. It is perhaps surprising that so many different disease conditions seem to converge on one physiological point: synaptic function. In autism and several psychiatric disorders, synaptic development goes awry; in epilepsy, abnormal ion channel activity disturbs the balance of synaptic input from excitatory and inhibitory neurons. Aging and neurodegenerative disorders bring about synaptic loss through gradual alterations in protein and RNA homeostasis that tax normal cellular functions.

This observation is offered to help give shape to the material you are about to encounter, but should not be used to oversimplify. Anyone tempted by reductionism would do well to engage with the works of great artists such as Dostoevsky and Van Gogh, who represent the complexities of human experience in all its anguish and glory.

Diseases of the Peripheral Nerve and Motor Unit

… to move things is all that mankind can do, for such the sole executant is muscle, whether in whispering a syllable or in felling a forest.

Charles Sherrington, 1924

A major task of the elaborate information processing that takes place in the brain is the contraction of skeletal muscles. The challenge of deciding when and how to move is, to a large degree, the driving force behind the evolution of the nervous system (Chapter 30).

In all but the most primitive animals, movement is generated by specialized muscle cells. There are three general types of muscles: Smooth muscle is used primarily for internal actions such as peristalsis and control of blood flow; cardiac muscle is used exclusively for pumping blood; and skeletal muscle is used primarily for moving bones. In this chapter, we examine a variety of neurological disorders in mammals that affect movement by altering either action potential conduction in a motor nerve, synaptic transmission from nerve to muscle, or muscle contraction itself.

In 1925, Charles Sherrington introduced the term *motor unit* to designate the basic unit of motor function—a motor neuron and the group of muscle fibers it innervates (Chapter 31). The number of muscle fibers innervated by a single motor neuron varies widely throughout the body depending on the dexterity of the movements being controlled and the mass of the body part to be moved. Thus, eye movements are finely controlled by motor units with fewer than 100 muscle

fibers, whereas in the leg, a single motor unit contains up to 1,000 muscle fibers. In each case, all the muscles innervated by a motor unit are of the same type. Moreover, motor units are recruited in a fixed order for both voluntary and reflex movements. The smallest motor units are the first to be recruited, joined later by larger units as muscle force increases.

The motor unit is a common target of disease. The distinguishing features of diseases of the motor unit vary depending on which functional component is primarily affected: (1) the cell body of the motor or sensory neuron, (2) the corresponding axons, (3) the neuromuscular junction (the synapse between the motor axon and muscle), or (4) the muscle fibers innervated by the motor neuron. Accordingly, disorders of the motor unit have traditionally been grouped into motor neuron diseases, peripheral neuropathies, disorders of the neuromuscular junction, and primary muscle diseases (myopathies) (Figure 57–1).

Patients with peripheral neuropathies experience weakness that arises from abnormal function of motor neurons or their axons, although problems with sensation can also occur since most peripheral neuropathies also involve sensory neurons. By contrast, in motor neuron diseases, the motor neurons and motor tracts in the spinal cord degenerate but sensory nerves are spared. In myopathies, weakness is caused by degeneration of the muscles with little or no change in motor neurons. In neuromuscular junction diseases, alterations in the neuromuscular synapse lead to weakness that may be intermittent. Clinical and laboratory studies usually distinguish disorders of peripheral nerves from those of the neuromuscular junction or muscle (Table 57–1).

Disorders of the Peripheral Nerve, Neuromuscular Junction, and Muscle Can Be Distinguished Clinically

When a peripheral nerve is cut, the muscles innervated by that nerve immediately become paralyzed and then waste progressively. Because the nerve carries sensory as well as motor fibers, sensation in the area innervated by the nerve is also lost and tendon reflexes are lost immediately. The term *atrophy* (literally, lack of nourishment) refers to the wasting away of a once-normal muscle; because of historical usage the term appears in the names of several diseases that are now regarded as neurogenic.

The main symptoms of the *myopathies* are due to weakness of skeletal muscle and often include difficulty in walking or lifting. Other less common symptoms include inability of the muscle to relax (myotonia), cramps, pain (myalgia), or the appearance in the urine of the heme-containing protein that gives muscle its red color (myoglobinuria). The *muscular dystrophies* are myopathies with special characteristics: The diseases are inherited, all symptoms are caused by weakness, the weakness becomes progressively more

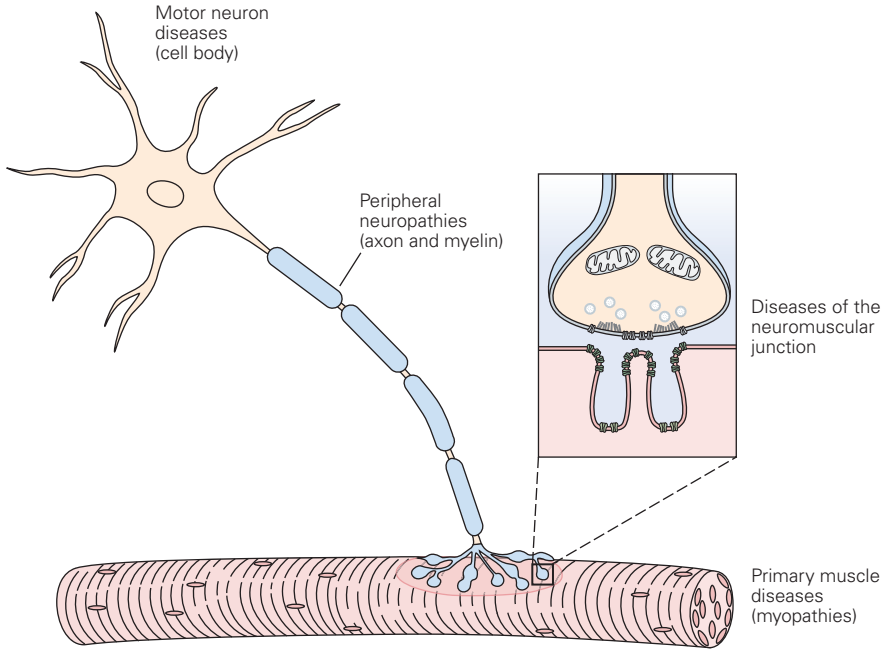

Figure 57–1 The four types of motor unit disorders. Motor unit disorders are categorized according to the part of the motor unit that is affected. Motor neuron diseases affect the cell body of the neuron, while peripheral neuropathies target the axon. Diseases of the neuromuscular junction affect the functioning of the synapse, and myopathies affect muscle fibers.

Table 57–1 Differential Diagnosis of Disorders of the Motor Unit

Finding	Nerve	Neuromuscular junction	Muscle
Clinical			
Weakness	++	+	++
Wasting	++	–	+
Fasciculations	+	–	–
Cramps	+	–	+/–
Sensory loss	+/–	–	–
Hyperreflexia, Babinski	+ (ALS)	–	–
Laboratory			
Elevated serum CPK	–	–	++
Elevated cerebrospinal fluid protein	+/–	–	–
Slowed nerve conduction	+	–	–
Response to repetitive stimulation	Normal	Decremental (MG) Incremental (LEMS)	Normal
Electromyography			
Fibrillation, fasciculation	++	–	+/–
Duration of potentials	Increased	Normal	Decreased
Amplitude of potentials	Increased	Normal	Decreased
Muscle Biopsy			
Isolated fiber atrophy	++	Normal	+/–
Grouped fiber atrophy	++	Normal	Normal
Muscle necrosis	Normal	Normal	++

ALS, amyotrophic lateral sclerosis; CPK, creatine phosphokinase; LEMS, Lambert-Eaton myasthenic syndrome; MG, myasthenia gravis.

severe, and signs of degeneration and regeneration are seen histologically.

Distinguishing neurogenic and myopathic diseases may be difficult because both are characterized by weakness of muscle. As a first approximation, weakness of the distal limbs most often indicates a neurogenic disorder, whereas proximal limb weakness signals a myopathy. The main clinical and laboratory features used for the differential diagnosis of diseases of the motor unit are listed in Table 57–1.

One test that is very helpful is needle electromyography (EMG), a clinical procedure in which a small needle is inserted into a muscle to record extracellularly the electrical activity of several neighboring motor units. Three specific measurements are important: spontaneous activity at rest, the number of motor units under voluntary control, and the duration and amplitude of action potentials in each motor unit. (Normal ranges of values have been established for the amplitude and duration of motor unit potentials; the amplitude is determined by the number of muscle fibers within the motor unit.)

In normal muscle, there is usually no activity outside the end-plate in the muscle at rest. During a weak voluntary contraction, a series of motor unit potentials is recorded as different motor units become recruited. In fully active normal muscles, these abundant potentials overlap in an interference pattern so that it is impossible to identify single potentials (Figure 57–2A).

In neurogenic disease, the partially denervated muscle is spontaneously active even at rest. The muscle may still contract in response to voluntary motor commands, but the number of motor units under voluntary control is smaller than normal because some motor axons have been lost. The loss of motor units is evident in the EMG during a maximal contraction, which shows a pattern of discrete motor unit potentials instead of the profuse interference pattern for normal muscles (Figure 57–2B). In recently denervated muscle, the EMG may also show spontaneous low-amplitude electrical potentials that correspond to the firing of a single muscle fiber, known as fibrillation potentials. As the neurogenic disease progresses, the amplitude and duration of individual motor unit potentials may increase because the remaining axons give off small branches that innervate the muscle fibers denervated

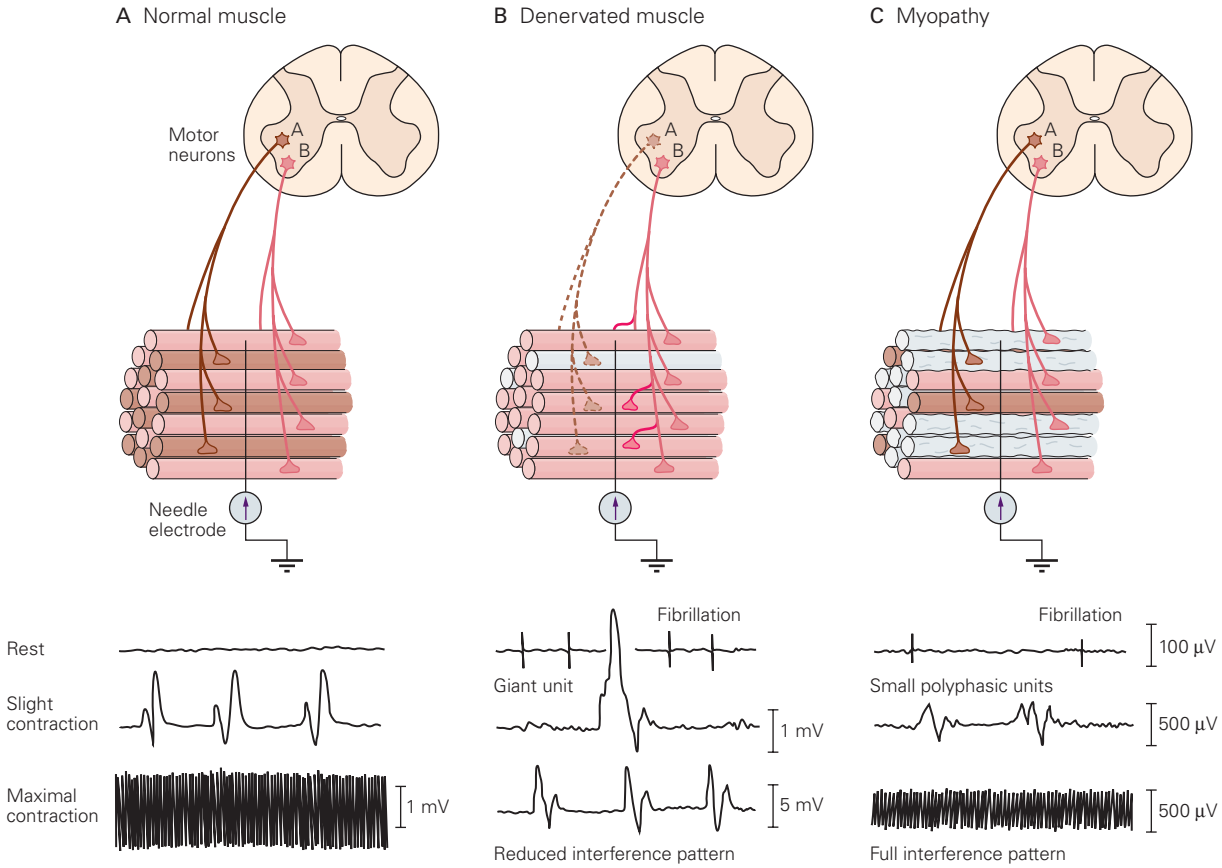

Figure 57–2 Electrical recording from skeletal muscle reveals different profiles in neuropathies and primary muscle diseases.

A. Typical activity in a normal muscle. The muscle fibers innervated by a single motor neuron are usually not adjacent to one another. When a motor unit potential is recorded by a needle electrode inserted into the muscle, the highly effective transmission at the neuromuscular junction ensures that each muscle fiber innervated by the same neuron will generate an action potential and contract in response to an action potential in the motor neuron. In the normal, resting muscle, there is no electrical activity recorded from muscle in the electromyogram (EMG). Slight activation of the muscle by a voluntary movement reveals characteristic extracellular electrical responses in muscle (motor unit potentials (MUPs)). Maximal muscle contraction produces a characteristic complex burst of electrical activity from muscle (the interference pattern).

B. When motor neurons are diseased, the number of motor units under voluntary control is reduced. The muscle fibers supplied by the degenerating motor neuron (cell A) become denervated and atrophic. However, the surviving neuron (cell B) sprouts axonal branches that reinnervate some of the denervated muscle fibers. Axons of the surviving motor neuron fire spontaneously even at rest, giving rise to fasciculations, another characteristic of motor neuron disease. Single denervated fibers also fire spontaneously, producing fibrillations (top trace). With loss of nerve input from motor neuron A and reinnervation of the denervated fibers by motor neuron B, activation of motor neuron B produces an enlarged MUP (giant motor unit). In this setting, there is simplification of the interference pattern.

C. When muscle is diseased (myopathy), the number of muscle fibers in each motor unit is reduced. Some muscle fibers innervated by the two motor neurons shrink and become nonfunctional. In the electromyogram, the motor unit potentials do not decrease in number but are smaller and of longer duration than normal and are polyphasic. Affected single muscle fibers sometimes contract spontaneously, producing fibrillation. When muscle is mildly activated, the MUPs show reduced amplitudes. After maximal muscle contraction, the interference pattern also shows a reduction in amplitude.

by the loss of other axons. Accordingly, surviving motor units contain more than the normal number of muscle fibers.

In myopathic diseases, there is no activity in the muscle at rest and no change in the number of motor units firing during a contraction. But because there are fewer surviving muscle fibers in each motor unit, the motor unit potentials are of longer duration and more complex, with alternating +/− polarity (polyphasic), and are smaller in amplitude (Figure 57–2C).

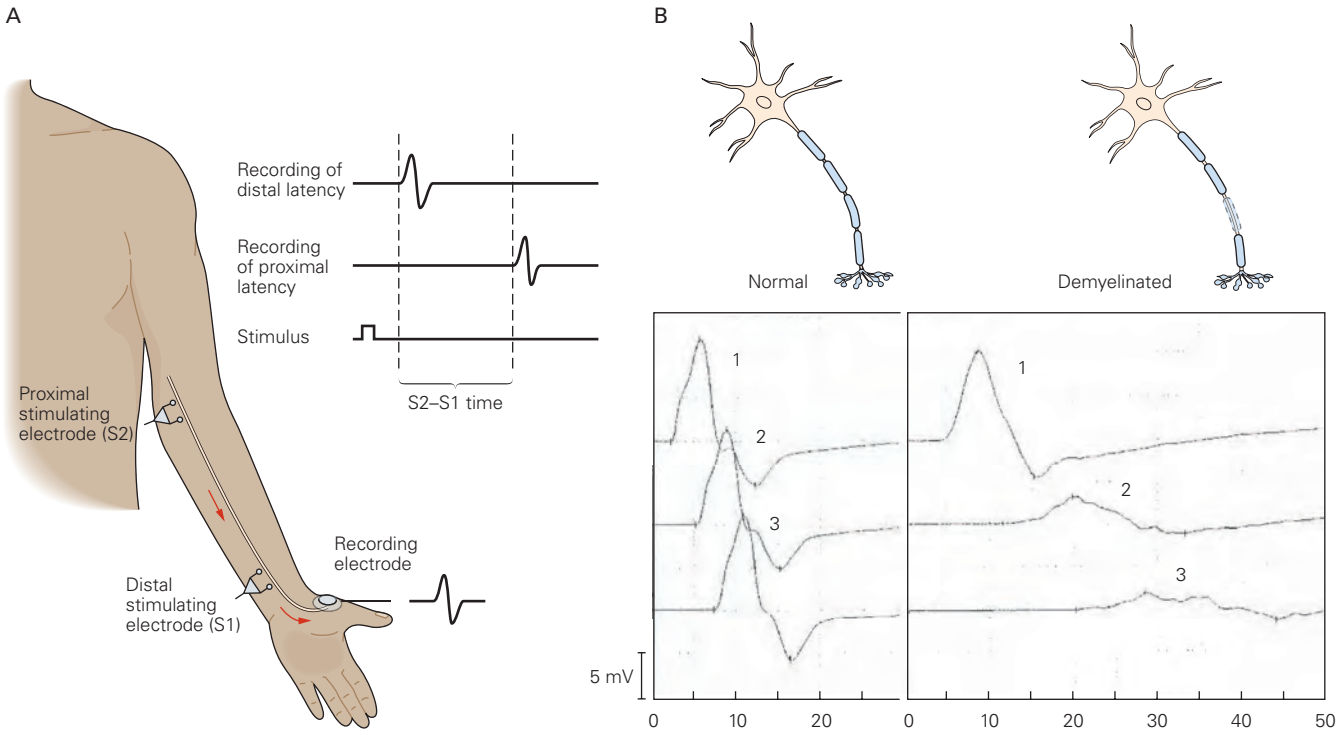

Figure 57–3 Motor nerve conduction velocity can be determined by recording the compound muscle action potential (CMAP) in response to electrical stimulation at different points along the nerve.

A. A shock is applied through a proximal surface stimulating electrode (**S2**) or through a distal stimulating electrode (**S1**), and the extracellular CMAP in the thumb is measured transcutaneously by the recording electrode. The time it takes the action potential to propagate from S2 to the muscle (t_{S2}) is the proximal latency; the time from S1 to the muscle (t_{S1}) is the distal latency. The distance between S1 and S2 divided by ($t_{S2} - t_{S1}$) gives the conduction velocity.

B. The waveforms of the thumb CMAPs elicited by stimulation of the motor nerve at the wrist (**1**), just below the elbow (**2**), and just above the elbow (**3**). In normal subjects (*left*), the waveforms are the same regardless of the site of stimulation. They are distinguished only by the longer time period required for the waveform to develop as the site of the stimulus is moved up the arm (away from the recording site). When the motor nerve is demyelinated between S1 and S2 but above the wrist, the CMAP is normal when stimulation occurs at the wrist (**1**) but delayed and desynchronized when stimulation is proximal to the nerve lesion (**2**, **3**). (Adapted, with permission, from Bromberg 2002.)

The conduction velocities of peripheral motor axons can also be measured through electrical stimulation and recording (see Figure 57–3). The conduction velocity of motor axons is slowed in demyelinating neuropathies but is normal in neuropathies without demyelination (axonal neuropathies).

Another test that helps to distinguish myopathic from neurogenic diseases is the measurement of serum enzyme activities. The sarcoplasm of muscle is rich in soluble enzymes that are normally found in low concentrations in the serum. In many muscle diseases, the concentration of these sarcoplasmic enzymes in serum is elevated, presumably because the diseases affect the integrity of surface membranes of the muscle, allowing the enzymes to leak into the bloodstream. The enzyme activity most commonly used for diagnosing myopathy is creatine kinase, an enzyme that phosphorylates creatine and is important in the energy metabolism of muscle.

Muscle histochemical appearance in a biopsy can also provide a useful diagnostic tool. Human muscle fibers are identified by histochemical reactions as type I or type II, which respectively are either aerobic (enriched for oxidative enzymes) or anaerobic (abundant glycolytic enzymes) (Chapter 31). All muscle fibers innervated by a single motor neuron are of the same histochemical type. However, the muscle fibers of one motor unit are normally interspersed among the muscle fibers of other motor units. In a cross section of healthy muscle, enzyme stains show that oxidative or glycolytic fibers are intermixed in a "checkerboard" pattern.

In chronic neurogenic diseases, the muscle innervated by a dying motor neuron becomes atrophic and some muscle fibers disappear. Axons of surviving neurons tend to sprout and reinnervate some of the adjacent remaining muscle fibers. Because the motor neuron determines the biochemical and thus histochemical properties of a muscle fiber, the reinnervated muscle fibers assume the histochemical properties of the innervating neuron. As a result, the fibers of a muscle in neurogenic disease become clustered by type (a pattern called fiber-type grouping).

If the disease is progressive and the neurons in the surviving motor units also become affected, atrophy occurs in groups of adjacent muscle fibers belonging to the same histochemical type, a process called group atrophy. In contrast, in myopathic diseases, the muscle fibers are affected in a more or less random fashion. Sometimes an inflammatory cellular response is evident, and sometimes there is prominent infiltration of the muscle by fat and connective tissue.

Fasciculations—visible twitches of muscle that can be seen as flickers under the skin—are often signs of neurogenic diseases. They result from involuntary but synchronous contractions of all muscle fibers in a motor unit. Fibrillations—spontaneous contractions within single muscle fibers—can also be signs of ongoing denervation of muscle. Fibrillations are not visible but can be recorded with an EMG. The electrical record of a fibrillation is a low-amplitude potential that reflects electrical activity in a single muscle cell. Electrophysiological studies suggest that fasciculations arise in the motor nerve terminal.

In diagnosing motor neuron disorders, clinicians have historically distinguished between so-called lower motor neurons and premotor neurons. Lower motor neurons are motor neurons of the spinal cord and brain stem that directly innervate skeletal muscles. Premotor neurons, also known as "upper" motor neurons, originate in the motor cortex and issue commands for movements to the lower motor neurons through their axons in the corticospinal (pyramidal) tract.

Diseases of upper motor neurons can be distinguished from those affecting lower motor neurons by distinct sets of symptoms. Disorders of lower motor neurons cause atrophy, fasciculations, decreased muscle tone, and loss of tendon reflexes, whereas disorders of upper motor neurons and their axons result in spasticity, overactive tendon reflexes, and abnormal plantar extensor reflex (the Babinski sign).

The primary symptom of disorders of the neuromuscular junction is weakness; in some neuromuscular junction diseases, this weakness is quite variable even over the course of a single day.

A Variety of Diseases Target Motor Neurons and Peripheral Nerves

Motor Neuron Diseases Do Not Affect Sensory Neurons (Amyotrophic Lateral Sclerosis)

The best-known disorder of motor neurons is amyotrophic lateral sclerosis (ALS; Lou Gehrig disease). "Amyotrophy" is another term for neurogenic atrophy of muscle; "lateral sclerosis" refers to the hardness felt when the pathologist examines the spinal cord at autopsy. This hardness results from the proliferation of astrocytes and scarring of the lateral columns of the spinal cord due to degeneration of the corticospinal tracts.

The symptoms of ALS usually start with painless weakness in a single arm or leg. Typically, the patient, often a man in his 40s or 50s, discovers that he has trouble in executing fine movements of the hands—typing, playing the piano, playing baseball, fingering coins, or working with tools. This focal weakness then spreads over 3 or 4 years to involve all four limbs, as well as the muscles of chewing, speaking, swallowing, and breathing.

Most cases of ALS involve both the upper and the lower motor neurons. Some motor neurons are spared, notably those supplying ocular muscles and those involved in voluntary control of bladder sphincters. The typical weakness of the hand is associated with wasting of the small muscles of the hands and feet and fasciculations of the muscles of the forearm and upper arm. These signs of lower motor neuron disease are often associated with hyperreflexia, an over-responsiveness in tendon reflexes characteristic of corticospinal upper motor neuron disease. The cause of most cases (90%) of ALS is not known; the disease is progressive and ultimately affects the muscles of respiration. There is no effective treatment for this fatal condition.

About 10% of cases are inherited in a dominant manner (Table 57–2). In North America, greater than 25% of inherited cases arise from mutations in the gene *C9orf72*. The offending genetic defect is an expansion in an intronic hexanucleotide repeat, from 30 or fewer in normal individuals to hundreds or even thousands in affected individuals. Besides giving rise to conventional ALS, mutations in *C9orf72* can also cause frontotemporal dementia. The toxicity of the mutant C9orf72 protein probably reflects both a reduction in total activity of the mutant protein and toxic effects of the intronic expansion. For example, the expanded intronic segments produce intranuclear deposits of RNA that likely sequester and inactivate important nuclear proteins. In addition, the expanded RNA is translated to

Table 57–2 Selected Amyotrophic Lateral Sclerosis Genes

				Proportion of ALS	
Gene	**Protein**	**Protein function**	**Mutations**	**Familial**	**Sporadic**
SOD1	Cu-Zn superoxide dismutase	Superoxide dismutase	>150	20%	2%
DCTN1	Dynactin subunit 1	Component of dynein motor complex	10	1%	<1%
ANG	Angiogenin	Ribonuclease	>10	<1%	<1%
TARDBP	TDP-43	RNA-binding protein	>40	5%	<1%
FUS	FUS	RNA-binding protein	>40	5%	<1%
VCP	Transitional endoplasmic reticulum ATPase	Ubiquitin segregase	5	1–2%	<1%
OPTN	Optineurin	Autophagy adaptor	1	4%	<1%
C9orf72	C9orf72	Possible guanine nucleotide exchange factor	Intronic GGGGCC	25%	10%
UBQLN2	Ubiquilin 2	Autophagy adaptor	5	<1%	<1%
SQSTM1	Sequestosome 1	Autophagy adaptor	10	<1%	?
FFN1	Profilin-1	Actin-binding protein	5	<1%	<1%
HNRNPA1	hnRNP A1	RNA-binding protein	3	<1%	<1%
MATR3	Matrin 3	RNA-binding protein	4	<1%	<1%
TUBA4A	Tubulin α-4A chain	Microtubule subunit	7	<1%	<1%
CHCHD10	Coiled-coil-helix-coiled-coil-helix domain-containing protein 10	Mitochondrial protein of unknown function	2	<1%	<1%
TBK1	Serine/threonine-protein kinase TBK1	Regulates autophagy and inflammation	10	1%	<1%

Source: Modified from Taylor, Brown, and Cleveland 2016.

produce peptides composed of repeated couplets of amino acids, such as poly-(glycine-proline) or poly-(proline-arginine); some of these are neurotoxic.

Two other genes commonly mutated in ALS are *SOD1* and *TDP43*. *SOD1* encodes the protein copper/zinc cytosolic superoxide dismutase, whereas *TDP43* encodes a 43-kD, RNA-interacting protein that is normally intranuclear but is mislocalized to the cytosol in most cases of ALS (both inherited and sporadic). Mutations in *SOD1* and several other ALS genes (eg, *ubiquilin-2*) destabilize the conformation of the protein product, promoting misfolding and causing adverse consequences to diverse subcellular processes and compartments. By contrast, mutations in *TDP43* and a few other ALS genes (eg, *FUS*) encoding RNA binding proteins act at the RNA level, impairing RNA homeostasis and perturbing critical processes such as surveillance of gene splicing. Infrequently, familial ALS is caused by mutations in genes encoding cytoskeletal proteins such as profilin-1, dynactin, or tubulin-A4.

Many studies suggest that mutant ALS-associated proteins tend to aggregate, particularly in membraneless organelles called stress granules that form in conditions of cellular distress. Several lines of investigation support the view that aggregates migrate and transmit pathology between adjacent cells, accounting for spread of the disease to different brain regions. Strikingly, mice that express high levels of defective SOD1 or profilin-1 proteins develop a lethal, adult-onset form of motor neuron disease, but mice expressing equivalently high levels of normal SOD1 or profilin-1 proteins do not. These findings are consistent with the concept that the defective protein has gained some sort of toxic function.

In the past 10 years, it has also become clear that motor neuron pathophysiology is modulated by the reactions of nonneural cells to degeneration in the motor neuron. Thus, in most cases of ALS, there are varying degrees of proliferation and activation of microglia, astrocytes, and some populations of lymphocytes, which may begin as compensatory responses but can eventually adversely affect the injured motor neurons. Genetic studies have underscored the importance of non–cell-autonomous factors, such as variants that reduce function of the microglial gene *TREM-2* and enhance the risk of developing not only ALS but also other neurodegenerative disorders (eg, Alzheimer disease).

Progressive bulbar palsy is a type of motor neuron disease in which damage is restricted to muscles innervated by cranial nerves, causing dysarthria (difficulty speaking) and dysphagia (difficulty swallowing). (The term "bulb" is used interchangeably with "pons," the structure at the base of the brain where motor neurons that innervate the face and swallowing muscles reside, and "palsy" means weakness). If only lower motor neurons are involved, the syndrome is called progressive spinal muscular atrophy.

Progressive spinal muscular atrophy is actually a developmental motor neuron disorder characterized by weakness, wasting, loss of reflexes, and fasciculations. Most cases arise in infancy and are caused by recessively inherited mutations in the gene encoding a protein called survival motor neuron (SMN). Survival in these cases is very short, although there are rare cases that begin in late childhood or even early adulthood and are associated with longer survival of many years. The SMN protein is implicated in trafficking RNA in and out of the nucleus and in the formation of complexes that are important in RNA splicing. The SMN locus on chromosome 5 in humans has two almost identical copies of the *SMN* gene: *SMN1* produces a full-length SMN protein, while alternative splicing of *SMN2* causes omission of the seventh exon in the gene, leading to expression of a small amount of full-length SMN and a shortened SMN. The clinical effect of the loss of full-length SMN from mutations at the main locus can be mitigated to some degree by the shortened SMN protein expressed by the *SMN2* gene (Figure 57–4A,B).

Two treatment strategies have achieved extraordinary benefits in spinal muscular atrophy. In one, small strings of approximately 20 nucleic acids (antisense oligonucleotides [ASO]s) are administered to alter splicing of the *SMN2* gene so that it produces higher levels of the full-length SMN protein (Figure 57-4A). This occurs because the ASO is targeted to bind to the SMN2 RNA and inhibit the action of the RNA binding protein hnRNPA1/A2 that normally leads the splicing machinery to skip exon 7. By blocking the binding of hnRNPA1/A2, the ASO blocks the inhibitory effect of hnRNPA1/A2 on splicing, promoting expression of full-length SMN protein (Figure 57–4B). It seems likely that ASOs will become powerful therapeutic tools with many applications. In this example, ASO is used to promote exon inclusion; as noted below in the discussion on muscle dystrophy, ASO can also be used to promote exon skipping. It can also be used in other paradigms to inhibit or enhance levels of target gene expression.

The second approach to treating spinal muscular atrophy has been to deliver the missing *SMN* gene to spinal motor neurons and muscle using high doses of intravenously infused adeno-associated virus carrying the *SMN1* gene. This, too, dramatically augments survival in infantile spinal muscular atrophy (Figure 57–4B).

ALS and its variants are restricted to motor neurons; they do not affect sensory neurons or autonomic neurons. The acute viral disease poliomyelitis is also confined to motor neurons. These diseases illustrate the individuality of nerve cells and the principle of selective vulnerability. The basis of this selectivity is, in general, not understood.

Diseases of Peripheral Nerves Affect Conduction of the Action Potential

Diseases of peripheral nerves may affect either axons or myelin. Because motor and sensory axons are bundled together in the same peripheral nerves, disorders of peripheral nerves usually affect both motor and sensory functions. Some patients with peripheral neuropathy report abnormal, frequently unpleasant, sensory experiences such as numbness, pins-and-needles prickling, or tingling. When these sensations occur spontaneously without an external sensory stimulus, they are called paresthesias.

Patients with paresthesias usually have impaired perception of cutaneous sensations (pain and temperature), often because the small fibers that carry these sensations are selectively affected. This is not always the case, however. Proprioceptive sensations (position and vibration) can be lost without loss of cutaneous sensation. Lack of pain perception may lead to injuries. The sensory deficits are more prominent distally (called a glove-and-stocking pattern), likely because the distal portions of the nerves are most remote from the cell body and therefore most susceptible to disorders that interfere with axonal transport of essential metabolites and proteins.

Peripheral neuropathy is first manifested by weakness that is usually distal. Tendon reflexes are usually

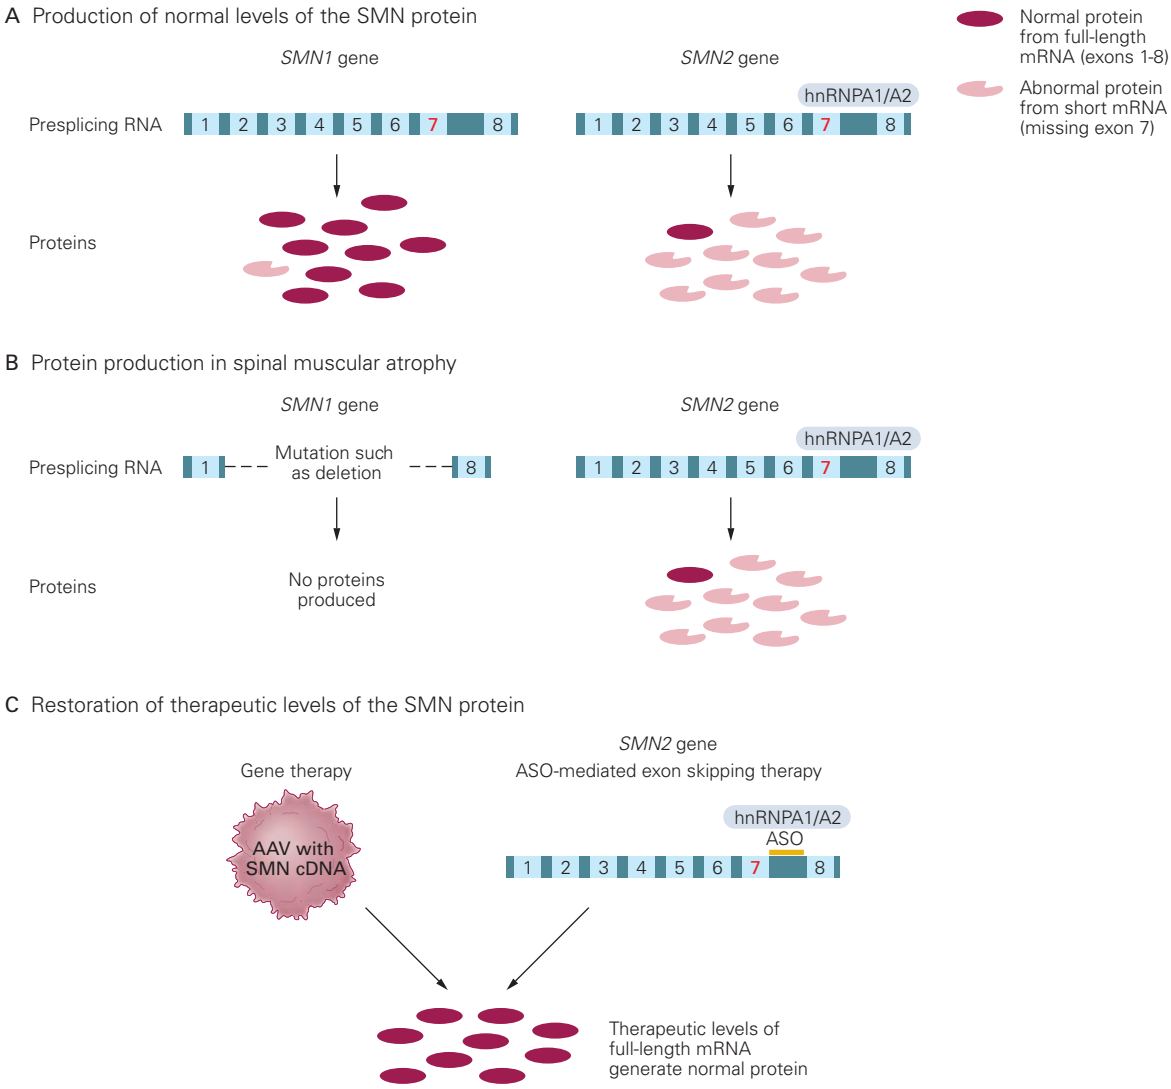

Figure 57–4 Spinal motor atrophy caused by defective survival motor neuron gene (*SMN1*) can be treated by gene replacement therapy or by manipulating splicing of *SMN2*.

A. Normally, most of the survival motor neuron (**SMN**) protein is produced from the *SMN1* gene, whose mRNA is spliced from eight exons. In normal circumstances, about 90% of the mRNA has all eight exons, yielding normal levels of the SMN protein. In the adjacent sister gene, *SMN2*, binding of the protein hnRNPA1/A2 to the *SMN2* transcript excludes exon 7; *SMN2* therefore makes a shortened SMN protein.

B. In spinal muscular atrophy, genetic lesions (commonly deletions) in *SMN1* lead to a marked reduction in levels of total SMN protein.

C. When SMN1 protein is absent, one therapeutic approach is to replace the missing *SMN1* gene using an adeno-associated viral vector (**AAV**) to deliver the missing gene to the central nervous system and muscle. An alternative approach is to deliver an antisense oligonucleotide (**ASO**) that blocks the effect of hnRNPA1/A2, thereby enhancing production of a full-length mRNA (with all eight exons) from *SMN2*. This restores SMN protein levels.

depressed or lost, fasciculation is seen only rarely, and wasting does not ensue unless the weakness has been present for many weeks.

Neuropathies may be either acute or chronic. The best-known acute neuropathy is Guillain-Barré syndrome. Most cases follow respiratory infection or infectious diarrhea, but the syndrome may occur without apparent preceding illness. The condition may be mild or so severe that mechanical ventilation is required. Cranial nerves may be affected, leading to paralysis of ocular, facial, and oropharyngeal muscles. The disorder is attributed to an autoimmune attack on peripheral nerves by circulating antibodies. It is therefore treated by removing the offending antibodies by

infusions of gamma globulin and plasmapheresis (a procedure in which blood is removed from a patient, cells are separated from the antibody-carrying plasma, and the cells alone are returned to the patient).

The chronic neuropathies vary from mild to incapacitating or even fatal conditions. There are many varieties, including genetic diseases (acute intermittent porphyria, Charcot-Marie-Tooth disease), metabolic disorders (diabetes, vitamin B_{12} deficiency), toxicities (lead), nutritional disorders (alcoholism, thiamine deficiency), carcinomas (especially carcinoma of the lung), and immunological disorders (plasma cell diseases, amyloidosis). Some chronic disorders, such as neuropathy due to vitamin B_{12} deficiency in pernicious anemia, are amenable to therapy.

In addition to being acute or chronic, neuropathies may be categorized as demyelinating (in which the myelin sheath breaks down) or axonal (in which the axon is affected). In demyelinating neuropathies, as might be expected from the role of the myelin sheath in saltatory conduction, conduction velocity is slowed. In axonal neuropathies, the myelin sheath is not affected and conduction velocity is normal.

Axonal and demyelinating neuropathies may lead to positive or negative symptoms and signs. The negative signs consist of weakness or paralysis, loss of tendon reflexes, and impaired sensation resulting from loss of motor and sensory nerves. The positive symptoms of peripheral neuropathies consist of paresthesias that arise from abnormal impulse activity in sensory fibers and either spontaneous activity of injured nerve fibers or electrical interaction (cross-talk) between abnormal axons, a process called ephaptic transmission to distinguish it from normal synaptic transmission. It is not known why damaged nerves become hyperexcitable. Even lightly tapping the site of injury can evoke a burst of painful sensations in the region over which the nerve is distributed.

Negative symptoms, which have been studied more thoroughly than positive symptoms, can be attributed to three basic mechanisms: conduction block, slowed conduction, and impaired ability to conduct impulses at higher frequencies. Conduction block was first recognized in 1876 when the German neurologist Wilhelm Erb observed that stimulation of an injured peripheral nerve below the site of injury evoked a muscle response, whereas stimulation above the site of injury produced no response. He deduced that the lesion blocked conduction of impulses of central origin, even when the segment of the nerve distal to the lesion was still functional. Later studies confirmed this conclusion by showing that selective application of diphtheria and other toxins produces conduction block by causing demyelination only at the site of application (Figure 57–5).

Why does demyelination produce nerve block, and how does it lead to slowing of conduction velocity? Conduction velocity is much more rapid in myelinated fibers than in unmyelinated axons for two reasons (Chapter 9). First, there is a direct relationship between conduction velocity and axon diameter, and myelinated axons tend to be larger in diameter. Second, membrane capacitance in the myelinated regions of the axon is lower than at the unmyelinated nodes of Ranvier, greatly speeding up the rate of depolarization and thus conduction. With demyelination, the spatial distribution of ion channels along the denuded axon is not optimal for supporting action potential propagation and may even cause a failure of conduction. When myelin is disrupted by disease, the action potentials in different axons of a nerve begin to conduct at slightly different velocities. As a result, the nerve loses its normal synchrony of conduction in response to a single stimulus. (Figure 57–2 shows how conduction velocities are measured in peripheral nerves.)

This slowing and loss of synchrony are thought to account for some of the early clinical signs of demyelinating neuropathy. For example, functions that normally depend on the arrival of synchronous bursts of neural activity, such as tendon reflexes and vibratory sensation, are lost soon after the onset of a chronic neuropathy. As demyelination becomes more severe, conduction becomes blocked. This block may be intermittent, occurring only at high frequencies of neural firing, or complete (Figure 57–3).

The Molecular Basis of Some Inherited Peripheral Neuropathies Has Been Defined

Myelin proteins are affected in a group of demyelinating hereditary peripheral neuropathies collectively termed Charcot-Marie-Tooth (CMT) disease. CMT is characterized by muscle weakness and wasting, loss of reflexes, and loss of sensation in the distal parts of the limbs. These symptoms appear in childhood or adolescence and are slowly progressive.

One form (type 1) has the features of a demyelinating neuropathy (Figure 57–5). Conduction in peripheral nerves is slow, with histological evidence of demyelination followed by remyelination. Sometimes, the remyelination leads to gross hypertrophy of the nerves. Type 1 disorders are inexorably progressive, without remissions or exacerbations. Another form (type 2) has normal nerve conduction velocity and is considered an axonal neuropathy without demyelination. Both types 1 and 2 are inherited as autosomal dominant diseases.

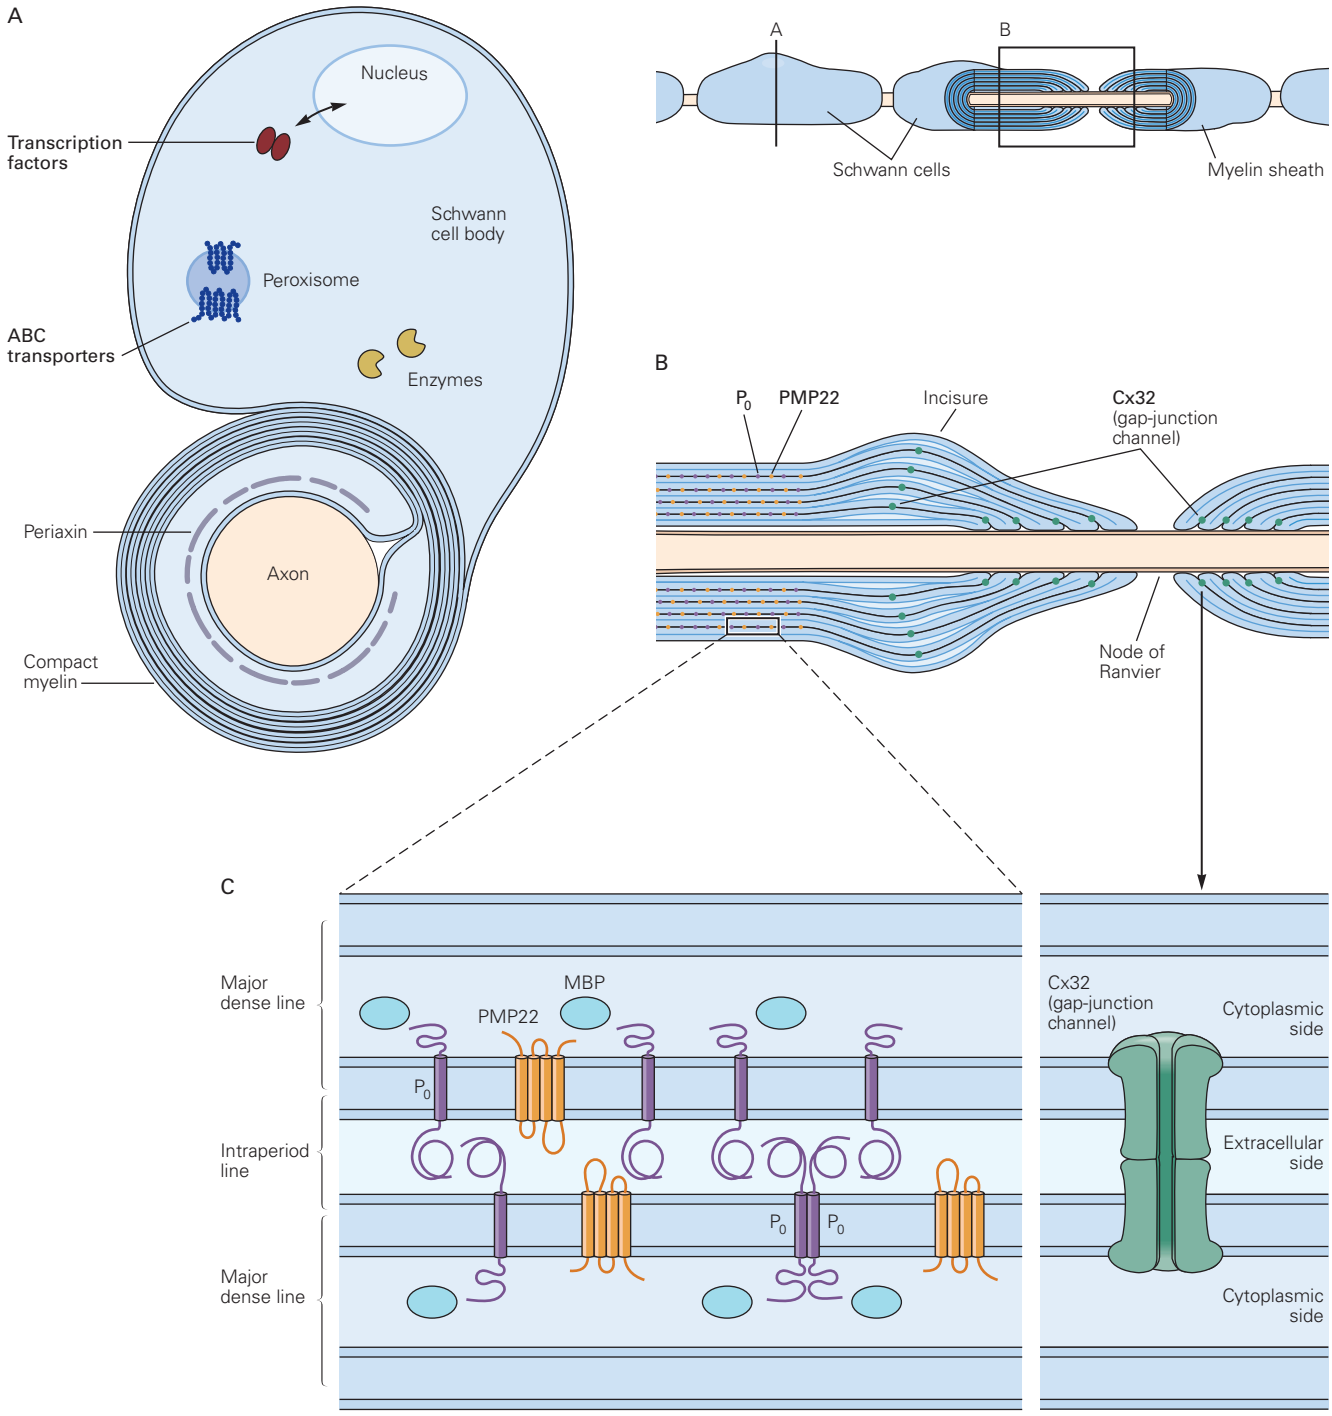

Figure 57–5 Gene defects in components of myelin cause demyelinating neuropathies.

A. Myelin production and function in the Schwann cell can be adversely affected by many genetic defects, including abnormalities in transcription factors, **ABC** (ATP-binding cassette) transporters in peroxisomes, and multiple proteins implicated in organizing myelin. Viewed microscopically at high power, the site of apposition of the intracellular faces of the Schwann cell membrane appears as a dense line, whereas the apposed extracellular faces are described as the "intraperiod line" (see part **C**). (Adapted from Lupski 1998.)

B. Peripheral axons are wrapped in multiple layers of thin sheaths of myelin that are processes of Schwann cells. The myelin is compact and tight except near the nodes of Ranvier and at focal sites described as "incisures" by Schmidt and Lanterman. Three myelin-associated proteins are defective in three different demyelinating neuropathies: P_0 (Dejerine-Sottas infantile neuropathy), peripheral myelin protein (**PMP22**) (Charcot-Marie-Tooth neuropathy type 1), and connexin-32 (**Cx32**) (X-linked Charcot-Marie-Tooth neuropathy). (Adapted from Lupski 1998.)

C. The rim of cytoplasm in which myelin basic protein (**MBP**) is located defines the major dense line, whereas the thin layer of residual extracellular space defines the intraperiod line. Mutations in PMP22 and P_0 genes adversely affect the organization of compact myelin. (Adapted, with permission, from Brown and Amato 2002.)

Type 1 disease is attributed to mutations on two different chromosomes (locus heterogeneity). The more common form (type 1A) is linked to chromosome 17, while the less common form (1B) is localized to chromosome 1. The genes at these loci have been directly implicated in myelin physiology (Figure 57–5). Type 1A involves a defect in peripheral myelin protein 22, and type 1B the myelin protein P_0. Moreover, an X-linked form of demyelinating neuropathy occurs because of mutations in the gene expressing connexin-32, a subunit of the gap-junction channels that interconnect myelin folds near the nodes of Ranvier (Figure 57–5B,C). Still other genes have been implicated in inherited demyelination.

Some of the genes and proteins implicated in axonal neuropathies are shown in Figure 57–6 and Table 57–3. Genes encoding the neurofilament light subunit and an axonal motor protein related to kinesin, which is important for transport along microtubules, are mutated in two types of axonal neuropathies. Defects in these genes are associated with peripheral neuropathies with prominent weakness. The mechanisms by which genes alter axonal function in other axonal neuropathies are less evident.

As noted above, a wide range of problems other than genetic mutations lead to peripheral neuropathies. Particularly striking are nerve defects associated with the presence of autoantibodies directed against ion channels in distal peripheral nerves. For example, some individuals with motor unit instability (cramps and fasciculations), as well as sustained or exaggerated muscle contractions caused by hyperexcitability of motor nerves, have serum antibodies directed against one or more axonal voltage-gated K^+ channels. The prevailing view is that binding of the autoantibodies to the channels reduces K^+ conductance and thereby depolarizes the axon, leading to augmented and sustained firing of the distal motor nerve and associated muscle contractions. Alterations in ion channel function underlie a variety of neurological disorders, as in acquired disorders of channels in the neuromuscular junction and inherited defects in voltage-gated channels in muscle (discussed below).

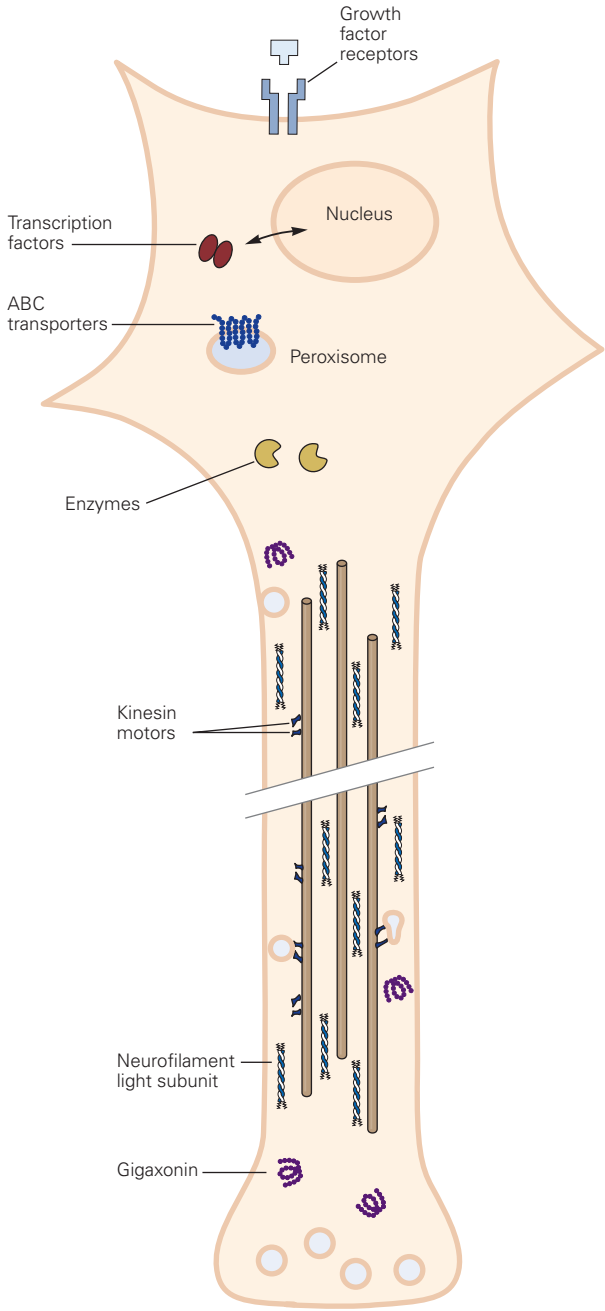

Figure 57–6 Gene defects that cause axonal neuropathies. These include defects in receptors for growth factors, ABC (ATP-binding cassette) transporters in peroxisomes, cytosolic enzymes, microtubule motor proteins like the kinesins, neurofilament proteins, and other structural proteins such as gigaxonin. (Adapted, with permission, from Brown and Amato 2002.)

Disorders of Synaptic Transmission at the Neuromuscular Junction Have Multiple Causes

Many diseases involve disruption of chemical transmission between neurons and their target cells. By analyzing such abnormalities, researchers have learned a great deal about the mechanisms underlying normal synaptic transmission as well as disorders caused by dysfunction at the synapse.

Table 57–3 Representative Peripheral Neuropathy Genes

Site of primary defect	Protein	Disease
Myelin	Proteolipid myelin protein 22	Charcot-Marie-Tooth disease (CMT)
	Proteolipid protein P_0	Infantile CMT (Dejerine-Sottas neuropathy)
	Connexin-32	X-linked CMT
Axon	Kinesin KIF1Bβ motor protein	Motor predominant neuropathy
	Heat shock protein 27	Motor predominant neuropathy
	Neurofilament light subunit	Motor predominant neuropathy
	Tyrosine kinase A receptor	Congenital sensory neuropathy
	ABC1 transporter	Tangier disease
	Transthyretin	Amyloid neuropathy

Diseases that disrupt transmission at the neuromuscular junction fall into two broad categories: those that affect the presynaptic terminal and those that primarily involve the postsynaptic membrane. In both categories, the most intensively studied cases are autoimmune and inherited defects in critical synaptic proteins.

Myasthenia Gravis Is the Best-Studied Example of a Neuromuscular Junction Disease

The most common and extensively studied disease affecting synaptic transmission is myasthenia gravis, a disorder at the neuromuscular junction in skeletal muscle. Myasthenia gravis (the term means severe weakness of muscle) has two major forms. The most prevalent is the autoimmune form. The second is congenital and heritable; it is not an autoimmune disorder and is heterogeneous. Fewer than 500 of these congenital cases have been identified, but they have provided information about the organization and function of the human neuromuscular junction. This form is discussed later in the chapter.

In autoimmune myasthenia gravis, antibodies are produced against components of the postsynaptic end-plate in muscle, such as the nicotinic acetylcholine (ACh) receptor and muscle-specific tyrosine kinase (MuSK). Anti–ACh receptor antibodies interfere with synaptic transmission by reducing the number of functional receptors or by impeding the interaction of ACh with its receptors. As a result, communication between the motor neuron and the skeletal muscle becomes weakened. This weakness always affects cranial muscles—eyelids, eye muscles, and oropharyngeal muscles—as well as limb muscles. Its severity of symptoms varies over the course of a single day, from day to day, or over longer periods (giving rise to periods of remission or exacerbation), making myasthenia gravis unlike most other diseases of muscle or nerve. The weakness is reversed by drugs that inhibit acetylcholinesterase, the enzyme that degrades ACh. As one example, when patients are asked to look upward in a sustained gaze, the eyelids tire after several seconds and droop downward (ptosis). Like decremental responses on EMG, this fatiguability and drooping reverse after treatment with inhibitors of acetylcholinesterase (Figure 57–7).

When a motor nerve is stimulated at rates of two to five stimuli per second, the amplitude of the compound

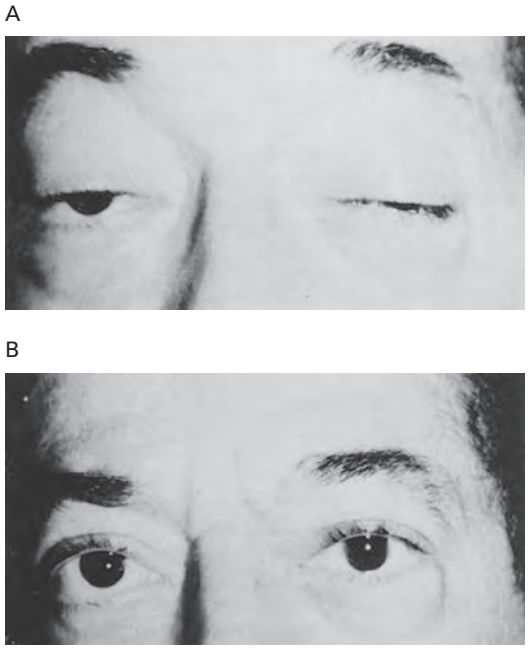

Figure 57–7 Myasthenia gravis often selectively affects the cranial muscles. (Reproduced, with permission, from Rowland, Hoefer, and Aranow 1960.)

A. Severe drooping of the eyelids, or ptosis, is characteristic of myasthenia gravis. This patient also could not move his eyes to look to either side.

B. One minute after an intravenous injection of 10 mg of edrophonium, an inhibitor of acetylcholinesterase, both eyes are open and can be moved freely.

action potential evoked in normal human muscle remains constant. In myasthenia gravis, the amplitude of the evoked compound action potential decreases rapidly. This pattern of decremental response of the compound muscle action potential to repetitive stimulation of the motor nerve mirrors the clinical symptom of fatiguability in myasthenia. Moreover, this abnormality resembles the pattern induced in normal muscle by d-tubocurarine (the active compound in curare), which blocks nicotinic ACh receptors and inhibits the action of ACh at the neuromuscular junction. Neostigmine (Prostigmin), which inhibits acetylcholinesterase and thus increases the duration of action of ACh at the neuromuscular junction, reverses the decrease in amplitude of evoked compound action potentials in myasthenic patients (Figure 57–8).

About 15% of adult patients with myasthenia have benign tumors of the thymus (thymomas). As the symptoms in myasthenic patients are often improved by removal of these tumors, some element of the thymoma may stimulate autoimmune pathology. Indeed, myasthenia gravis often affects people who have other autoimmune diseases, such as rheumatoid arthritis, systemic lupus erythematosus, or Graves disease (hyperthyroidism).

Normally, an action potential in a motor axon releases enough ACh from synaptic vesicles to induce a large excitatory end-plate potential with an amplitude of about 70 to 80 mV relative to the resting potential of –90 mV (Chapter 12). Thus, the normal end-plate potential is greater than the threshold needed to initiate an action potential, about –45 mV. In normal muscle, the difference between the threshold and the actual end-plate potential amplitude—the safety factor—is therefore quite large (Figure 57–8). In fact, in many muscles, the amount of ACh released during synaptic transmission can be reduced to as little as 25% of normal before it fails to initiate an action potential.

The density of ACh receptors is reduced over time in myasthenia. This reduces the probability that a molecule of ACh will find a receptor before it is hydrolyzed by the acetylcholinesterase. In addition, the geometry of the end-plate is also disturbed in myasthenia (Figure 57–9). The normal infolding at the junctional folds is reduced and the synaptic cleft is enlarged. These morphological changes increase the diffusion of

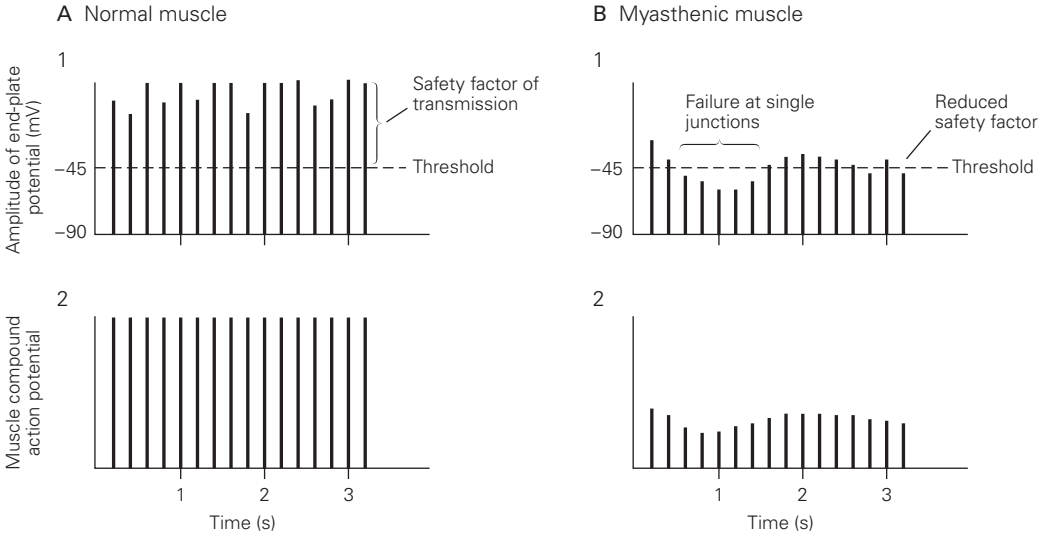

Figure 57–8 Synaptic transmission at the neuromuscular junction fails in myasthenia gravis. (Reproduced, with permission, from Lisak and Barchi 1982.)

A. In the normal neuromuscular junction, the amplitude of the end-plate potential is so large that all fluctuations in the efficiency of transmitter release occur well above the threshold for a muscle action potential. This results in a large safety factor for synaptic transmission (**1**). Therefore, during repetitive stimulation of the motor nerve, the amplitude of the compound action potentials, representing the contributions from all muscle fibers in which synaptic transmission is successful in triggering an action potential, is constant and invariant (**2**).

B. In the myasthenic neuromuscular junction, postsynaptic changes reduce the amplitude of the end-plate potential so that under optimal circumstances the end-plate potential may be just sufficient to produce a muscle action potential. Fluctuations in transmitter release that normally accompany repeated stimulation now cause the end-plate potential to drop below this threshold, leading to conduction failure at that junction (**1**). The amplitude of the compound action potentials in the muscle declines progressively and shows only a small and variable recovery (**2**).

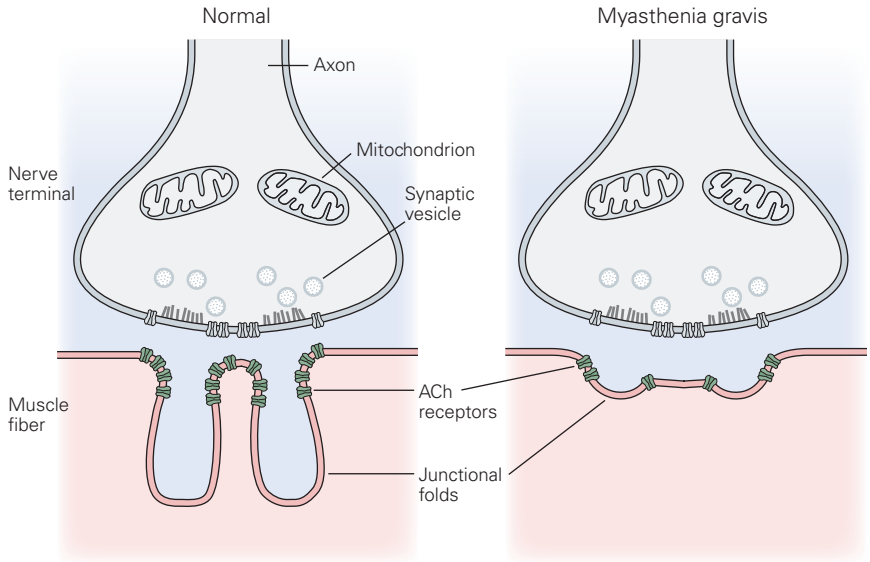

Figure 57–9 **Morphological abnormalities of the neuromuscular junction are characteristic of myasthenia gravis.** At the neuromuscular junction, acetylcholine (**ACh**) is released by exocytosis of synaptic vesicles at active zones in the nerve terminal. Acetylcholine flows across the synaptic cleft to reach ACh receptors that are concentrated at the peaks of junctional folds. Acetylcholinesterase in the cleft rapidly terminates transmission by hydrolyzing ACh. The myasthenic junction has reduced numbers of ACh receptors, simplified synaptic folds, a widened synaptic space, but a normal nerve terminal.

ACh away from the synaptic cleft and further reduce the probability of ACh interacting with the few remaining functional receptors. As a result, the amplitude of the end-plate potential is reduced to the point where it is barely above threshold (Figure 57–8).

Thus, in myasthenia, synaptic transmission is readily blocked even though the vesicles in the presynaptic terminals contain normal amounts of ACh and the process of transmitter release is intact. Both the physiological abnormality (the decremental response) and the clinical symptoms (muscle weakness) are partially reversed by drugs that inhibit acetylcholinesterase. This is because the released ACh molecules remain unhydrolyzed for a longer time, and this increases the probability that they will interact with receptors.

How do antibodies cause the symptoms of myasthenia? The antibodies do not simply occupy the ACh binding site. Rather, they appear to react with epitopes elsewhere on the receptor molecule. This increases the turnover of nicotinic ACh receptors, probably because myasthenic antibodies bind and cross-link the receptors, triggering their degradation (Figure 57–9). In addition, some myasthenic antibodies bind proteins of the complement cascade of the immune system, causing lysis of the postsynaptic membrane.

Despite the evidence documenting the primary role of antibodies against the nicotinic ACh receptor in myasthenia, about one-fifth of patients with myasthenia do not have these antibodies—including some who respond to anti-immune therapy like plasmapheresis. Instead, the majority of these patients have antibodies to other postsynaptic proteins, such as MuSK (*mu*scle-specific trk-related receptor with a *K*ringle domain) and lipoprotein-related protein 4 (LPR4), which is an activator of MuSK. MuSK is a muscle-specific receptor tyrosine kinase that interacts with another postsynaptic protein, agrin, to organize the nicotinic ACh receptors into clusters at the neuromuscular junction (Chapter 48); it appears to be functionally important both during development and in the adult. The anti-MuSK antibodies block some of the normal clustering of the nicotinic ACh receptors following the interaction of agrin with MuSK. Anti-LPR4 antibodies also block ACh receptor clustering.

Treatment of Myasthenia Is Based on the Physiological Effects and Autoimmune Pathogenesis of the Disease

Anticholinesterases, especially pyridostigmine, provide some symptomatic relief but do not alter the basic disease. Immunosuppressive therapies such as corticosteroids and azathioprine or related drugs suppress antibody synthesis. Intravenous infusions of pooled immunoglobulins reduce levels of the pathogenic autoantibodies and ameliorate symptoms, often within a few days. An analogous benefit is achieved by plasmapheresis, which involves filtering the plasma. Although the benefit of these interventions is short-lived, it may be sufficient to prepare a patient for thymectomy or to support the patient through more severe episodes.

There Are Two Distinct Congenital Forms of Myasthenia Gravis

In two distinct types of myasthenia, symptoms may be present from birth or shortly thereafter. In neonatal

myasthenia, the mother herself has autoimmune myasthenia that is transmitted passively to the newborn via the immune system. In congenital myasthenia, the infant has an inherited defect in some component of the neuromuscular junction, rather than an autoimmune disease, and thus does not have serum antibodies to the nicotinic ACh receptor or MuSK.

Congenital myasthenic syndromes fall into three broad groups based on the site of the defect in the neuromuscular synapse: presynaptic, synaptic cleft, and postsynaptic forms. Clinical features common to all three types include a positive family history, weakness with easy fatigability (present since infancy), drooping of the eyelids (ptosis), a decremental response to repetitive stimulation on EMG, and negative screening for anti-nicotinic ACh receptor antibodies. Subnormal development of the skeletal muscles reflects the fact that normal function at the neuromuscular synapse is required to maintain normal muscle bulk.

In one presynaptic form of congenital myasthenia, the enzyme choline acetyltransferase is absent or reduced in the distal motor terminal. This enzyme is essential for the synthesis of ACh from choline and acetyl-CoA (Chapter 16). In its absence, the synthesis of ACh is impaired. The result is weakness that usually begins in infancy or early childhood. In another presynaptic form of congenital myasthenia, the number of quanta of ACh released after an action potential is less than normal; the molecular basis for this defect is not known.

Congenital myasthenia may also result from the absence of acetylcholinesterase in the synaptic cleft. In this circumstance, end-plate potentials and miniature end-plate potentials are not small, as in autoimmune myasthenia, but are markedly prolonged, which may explain the repetitive response of the evoked muscle potential in those patients. Cytochemical studies indicate that ACh-esterase is absent from the basement membranes. At the same time, nicotinic ACh receptors are preserved.

The physiological consequence of ACh-esterase deficiency is sustained action of ACh on the end-plate and ultimately the development of an end-plate myopathy. This myopathy indicates that skeletal muscle can react adversely to excessive stimulation at the neuromuscular junction. In treating this disorder, it is critical to avoid using agents that inhibit ACh-esterase, which can increase the electrical firing at the end-plate and thereby exacerbate the muscle weakness.

The majority of congenital myasthenia cases are caused by primary mutations in the genes encoding different subunits of the ACh receptor. The *slow channel syndrome* is characterized by prominent limb weakness but little weakness of cranial muscles (the reverse of the pattern usually seen in autoimmune myasthenia, where muscles of the eyes and oropharynx are almost always affected). End-plate currents are slow to decay, and there is abnormal prolongation of channel opening. The mutations probably act both by increasing the affinity of the nicotinic ACh receptor for ACh, thereby prolonging the effects of this transmitter, and by directly slowing the channel closing rate. In some instances, quinidine is effective therapy for slow channel syndrome because it blocks the open receptor-channel. As with ACh-esterase mutations, end-plate function degenerates due to excessive postsynaptic stimulation, so anticholinesterase medications are potentially dangerous.

In the fast channel syndrome, a different set of mutations in one or more nicotinic ACh receptor subunits leads to an accelerated rate of channel closing and end-plate current decay. The fast channel syndrome may respond to either acetylcholinesterase inhibitors or 3,4-diaminopyridine. The latter blocks a presynaptic potassium conductance and thereby increases the probability of quantal release of ACh, probably by prolonging the action potential.

Lambert-Eaton Syndrome and Botulism Also Alter Neuromuscular Transmission

Some patients with cancer, especially small-cell cancer of the lung, have a syndrome of proximal limb weakness and a neuromuscular disorder with characteristics that are the opposite of those seen in myasthenia gravis. Instead of a decline in synaptic response to repetitive nerve stimulation, the amplitude of the evoked potential increases; that is, neuromuscular transmission is facilitated. Here, the first postsynaptic potential is abnormally small, but subsequent responses increase in amplitude so that the final summated potential is two to four times the amplitude of the first potential.

This disorder, *Lambert-Eaton syndrome*, is attributed to the action of antibodies against voltage-gated Ca^{2+} channels in the presynaptic terminals. It is thought that these antibodies react with the channels, degrading the channels as the antibody–antigen complex is internalized. Calcium channels similar to those of presynaptic terminals are found in cultured cells from the small-cell carcinoma of the lung; development of antibodies against these antigens in the tumor might be followed by pathogenic action against nerve terminals, another kind of molecular mimicry.

A facilitating neuromuscular block is also found in human botulism, as the botulinum toxin also impairs release of ACh from nerve terminals. Both botulism

and Lambert-Eaton syndrome are ameliorated by administration of calcium gluconate or guanidine, agents that promote the release of ACh. These drugs are less effective than immunosuppressive treatments for long-term control of Lambert-Eaton syndrome, which is chronic. Botulism, on the other hand, is transient, and if the patient is kept alive during the acute phase by treating symptoms, the disorder disappears in weeks as the infection is controlled and botulinum is inactivated.

Diseases of Skeletal Muscle Can Be Inherited or Acquired

The weakness seen in any myopathy is usually attributed to degeneration of muscle fibers. At first, the missing fibers are replaced by regeneration of new fibers. Ultimately, however, renewal cannot keep pace and fibers are progressively lost. This leads to the appearance of compound motor unit potentials of brief duration and reduced amplitude. The decreased number of functioning muscle fibers then accounts for the diminished strength, whether the skeletal muscle disease is inherited or acquired.

Dermatomyositis Exemplifies Acquired Myopathy

The prototype of an acquired myopathy is dermatomyositis, defined by two clinical features: rash and myopathy. The rash has a predilection for the face, chest, and extensor surfaces of joints, including the fingers. The myopathic weakness primarily affects proximal limb muscles. The rash and weakness usually appear simultaneously and become worse in a matter of weeks. The weakness may be mild or life-threatening.

This disorder affects children or adults. About 10% of adult patients have malignant tumors. Although the pathogenesis is not known, dermatomyositis is thought to be an autoimmune disorder of small intramuscular blood vessels.

Muscular Dystrophies Are the Most Common Inherited Myopathies

The best-known inherited muscle diseases are the muscular dystrophies; several major types are distinguished by clinical and genetic patterns (Table 57–4). Some types are characterized by weakness alone (Duchenne, facioscapulohumeral, and limb-girdle dystrophies); others (eg, the myotonic muscular dystrophies) have additional clinical features. Most are recessively inherited and begin in early childhood (Duchenne, Becker, and limb-girdle dystrophy); less frequently, the dystrophies are dominantly inherited (facioscapulohumeral or myotonic dystrophy). The cardinal trait of limb-girdle dystrophies is slowly progressive proximal weakness; in the myotonic muscular dystrophies, progressive weakness is accompanied by severe muscle stiffness.

Duchenne muscular dystrophy affects only males because it is transmitted as an X-linked recessive trait. It starts in early childhood and progresses relatively rapidly, so that patients are in wheelchairs by age 12 and usually die in their third decade. This dystrophy is caused by mutations that severely reduce levels of dystrophin, a skeletal muscle protein that apparently confers tensile strength to the muscle cell. In a related inherited muscle disorder, Becker muscular dystrophy, dystrophin is present but is either abnormal in size or reduced in quantity. Becker dystrophy is thus typically much milder, although there is considerable clinical variability according to how much dystrophin is retained; individuals with Becker dystrophy typically are able to walk well into adulthood, albeit with weakness of the proximal leg and arm muscles.

Dystrophin is encoded by the *DMD* gene, the second largest human gene, spanning about 2.5 million base pairs, or 1% of the X chromosome and 0.1% of the total human genome (Figure 57–10A). It contains at least 79 exons that encode a 14-kb mRNA. The inferred amino acid sequence of the dystrophin protein suggests a rod-like structure and a molecular weight of 427,000, with domains similar to those of two cytoskeletal proteins, alpha-actinin and spectrin. Dystrophin is localized to the inner surface of the plasma membrane. The amino terminus of dystrophin is linked to cytoskeletal actin, whereas the carboxy terminus is linked to the extracellular matrix by transmembrane proteins (Figure 57–11).

The majority of boys with Duchenne muscular dystrophy have a deletion in the *DMD* gene; about a third have point mutations. In either case, these mutations introduce premature stop codons in the mutant RNA transcripts that prevent synthesis of full-length dystrophin. Becker dystrophy is also caused by deletions and missense mutations, but the mutations do not introduce stop codons. The resulting dystrophin protein is nearly normal in length and can at least partially substitute for normal dystrophin (Figure 57–10B). Some boys with Duchenne dystrophy benefit from treatment with ASOs that cause skipping of specific mutant exons, generating a shortened but partially functional dystrophin protein (Figure 57–10C). Another promising approach is to deliver a form of the *DMD* gene to the muscle using adeno-associated virus. While the full-length *DMD* gene is too large to fit

Table 57–4 Representative Muscular Dystrophy Genes

Site of primary defect	Protein	Disease
Extracellular matrix	Collagen VI α1, α2, and α3	Bethlem myopathy
	Merosin laminin α2-subunit	Congenital myopathy
Transmembrane	α-Sarcoglycan	LGMD-2D
	β-Sarcoglycan	LGMD-2E
	χ-Sarcoglycan	LGMD-2C
	σ-Sarcoglycan	LGMD-2F
	Dysferlin	LGMD-2B, Miyoshi myopathy
	Caveolin-3	LGMD-1C, rippling muscle disease
	α7-Integrin	Congenital myopathy
	XK protein	McLeod syndrome
Submembrane	Dystrophin	Duchenne, Becker dystrophies
Sarcomere/myofibrils	Tropomyosin B	Nemaline rod myopathy
	Calpain	LGMD-2A
	Titin	Distal (Udd) dystrophy
	Nebulin	Nemaline rod myopathy
	Telethonin	LGMD-2G
	Skeletal muscle actin	Nemaline rod myopathy
	Troponin	Nemaline rod myopathy
Cytoplasm	Desmin	Desmin storage myopathy
	αβ-Crystallin	Distal myofibrillar myopathy
	Selenoprotein	Rigid spine syndrome
	Plectin	Epidermolysis bullosa simplex
Sarcoplasmic reticulum	Ryanodine receptor	Central core disease, malignant hyperthermia
	SERCA1	Brody myopathy
Nucleus	Emerin	Emery-Dreifuss dystrophy
	Lamin A/C	Emery-Dreifuss dystrophy
	Poly A binding protein, repeat	Oculopharyngeal dystrophy
Enzymes/miscellaneous	Myotonin kinase, CTG repeat	Myotonic dystrophy
	Zinc finger 9, CCTG repeat	Proximal myotonic dystrophy
	Epimerase	Inclusion body myositis
	Myotubularin	Myotubular myopathy
	Chorein	Chorea-acanthocytosis
Golgi apparatus	Fukutin	Fukuyama congenital dystrophy
	Fukutin-related peptide	Limb-girdle dystrophy
	POMT1	Congenital muscular dystrophy
	POMGnT1	Congenital muscular dystrophy

LGMD, limb-girdle muscular dystrophy.

within that virus, there is evidence that some truncated versions of dystrophin retain partial function; indeed, severely shortened dystrophins have been discovered in patients with very mild forms of Becker dystrophy. Packaging of genes encoding mini-dystrophins into the adeno-associated virus is feasible, permitting delivery to skeletal muscle and improvement of the dystrophic process (Figure 57–10C).

The discovery of the affected gene product in Duchenne muscular dystrophy by Louis Kunkel in the mid-1980s stimulated rapid discovery of numerous other novel muscle proteins, some with an intimate relationship to dystrophin. As a result, the primary genetic and protein defects underlying most major muscular dystrophies have now been identified (Figure 57–11). From these, several themes have emerged in our understanding of the biology of the muscular dystrophies.

First, and perhaps most important, is the concept that normal muscle requires a functional unit linking the contractile proteins through dystrophin to a complex of dystrophin-associated transmembrane proteins (sarcoglycans, β-dystroglycan) that, in turn, are linked to proteins at the membrane surface (eg, α-dystroglycan) and the extracellular matrix (eg, laminin). Disruption of this linked network due to a mutation in one of the proteins leads to reductions in levels of many of the proteins (Table 57–4).

Second, some of these proteins have attached sugar groups that are critical for binding the extracellular matrix proteins. Genetic defects in several of the intracellular Golgi proteins (fukutin, fukutin-related peptide, POMT1, POMTGn1) impair the deposition of the sugars (glycosylation) of the transmembrane proteins, often leading to aberrant muscle development and pronounced clinical pathology, not only in muscle but sometimes in the brain.

Third, the integrity of the extracellular matrix is essential for normal muscle function: Defects in extracellular matrix proteins (laminin α2 or α7-integrin) also cause muscular dystrophies.

Fourth, other proteins (eg, dysferlin), distinct from those complexed with dystrophin, mediate membrane repair after injury. Whereas dystrophin is important in maintaining the tensile strength and integrity of the muscle membrane, dysferlin and its binding partner caveolin-3 are central to generating rafts of vesicles that coalesce and heal breaches that occur in the muscle membrane.

It is of clinical interest that disorders due to defects in many of these proteins are less aggressive and more slowly disabling than those in Duchenne dystrophy. Defects in this diverse group of skeletal muscle proteins lead to the limb-girdle phenotype, characterized by slowly progressive proximal weakness of the arms and legs. Most are recessively inherited; mutations in both copies of a particular gene prevent expression of the normal protein product and lead to loss of function of that protein. Some limb-girdle genes are dominantly transmitted; mutations in only one copy of the gene in a pair can cause pathology. As in most primary muscle diseases, in the limb-girdle phenotype, weakness is prominent in the torso and in proximal muscles of the arms and legs. Why this pattern is so common is not known, especially since the affected proteins are expressed in both distal and proximal muscles. The pattern of degeneration most likely reflects muscle use. The proximal muscles are, on average, more subject to low-level but chronic contractile activity because they serve as antigravity muscles.

Myotonic dystrophy has several distinctive features including an autosomal inheritance pattern, weakness that is predominantly distal, involvement of nonmuscle tissues, and striking muscle stiffness (*myotonia*). The stiffness is induced by excessive electrical discharges of the muscle membrane associated with voluntary muscle contractions or percussion or electrical stimulation of the muscle. It is most intense within the first few movements after a period of rest and improves with continued muscular activity ("warm-up" phenomenon). Patients typically have difficulty relaxing the grip of a handshake for several seconds, opening the eyelids after forceful squinting, or moving their legs with the first few steps after rising from a chair. EMG demonstrates that the muscle cell membrane is electrically hyperexcitable in myotonic dystrophy; after a contraction, bursts of repetitive action potentials wax and wane in amplitude and frequency (20–100 Hz) over several seconds and thereby delay relaxation (Figure 57–12A). This sustained contraction is truly myogenic and independent of nerve supply because it persists after blockade of either the incoming motor nerve or neuromuscular transmission with agents such as curare.

The manifestations of myotonic dystrophy are not confined to muscles, however. Almost all patients have cataracts; affected men commonly have testicular atrophy and baldness and often develop cardiac conduction system defects that lead to irregularities in the heartbeat. The primary genetic defect is a dominantly transmitted expansion of a triplet of base pairs (CTG) in a noncoding region of a gene (myotonin kinase) on chromosome 19. RNA transcripts of the expanded CTG segments accumulate in the nucleus and alter splicing of several critical genes, including the ClC-1 Cl^- channel. Loss of function of this channel leads to

excessive electrical activity in skeletal muscle and, as a consequence, myotonia. As discussed below, direct mutations in the same Cl^- channel gene can lead to a similar abnormal pattern of muscle activity.

Some Inherited Diseases of Skeletal Muscle Arise From Genetic Defects in Voltage-Gated Ion Channels

The electrical excitability of skeletal muscle is essential to the rapid and nearly synchronous contraction of an entire muscle fiber. The depolarizing end-plate potential at the neuromuscular junction triggers an action potential that propagates longitudinally along the surface of the muscle fiber and radially inward along the transverse tubules, invaginations of the fiber membrane in apposition with the sarcoplasmic reticulum (Chapter 31).

Depolarization of the transverse tubules induces a conformational change in L-type voltage-gated Ca^{2+} channels that is directly transmitted to Ca^{2+} release channels (the ryanodine receptors) in the sarcoplasmic reticulum, causing the channels to open. The release of Ca^{2+} from the sarcoplasmic reticulum raises myoplasmic Ca^{2+} and thus activates adenosine triphosphate (ATP)-dependent movement of actin-myosin filaments.

Normally, one action potential is generated in a muscle fiber for each end-plate potential. Repolarization of the muscle action potential depends on inactivation of Na^+ channels and the opening of delayed-rectifier voltage-gated K^+ channels similar to those in axons. This repolarization is also augmented by Cl^- influx through the ClC-1 Cl^- channels. Inherited muscle diseases arise from mutations in any one of these channels.

The electrical coupling of the end-plate potential to depolarization of the transverse tubules is disrupted in several inherited diseases of muscle. These disorders reflect a variety of defects in excitability, ranging from complete failure of action potential generation to prolonged bursts of repetitive discharges in response to a single stimulus (Figure 57–12). The derangements of muscle fiber excitability are transient and result in periodic paralysis from reduced excitability or myotonia from hyperexcitability. Between episodes, muscle function is normal. These are rare diseases of skeletal muscle, with a prevalence of 1 per 100,000 or less. Inheritance is autosomal dominant, except for one form of myotonia.

Weakness may be so severe during an attack of periodic paralysis that a patient is bedridden for hours, unable to raise an arm or leg off the bed. Fortunately, during such attacks, the muscles of respiration and swallowing are spared, so life-threatening respiratory arrest does not occur; consciousness and sensation are also spared. Attack frequency varies from almost daily to only a few in a lifetime.

During an attack, the resting potential of affected muscles is depolarized from a normal value of –90 mV

Figure 57–10 (Opposite) Two forms of muscular dystrophy are caused by deletion mutations in the dystrophin gene. (After Hoffman and Kunkel 1989.)

A. The relative position of the *DMD* gene within the Xp21 region of the X chromosome. An enlargement of this locus shows the 79 exons (**light blue lines**) and introns (**dark blue lines**) defining the gene with about 2.0×10^6 base pairs. Transcription of the gene gives rise to mRNA (about 14×10^3 base pairs), and translation of this mRNA gives rise to the protein dystrophin (molecular weight 427,000).

B. A deletion that disrupts the reading frame results in the clinically severe Duchenne muscular dystrophy, whereas a deletion that preserves the reading frame usually results in the clinically milder Becker muscular dystrophy. In both cases, the gene is transcribed into mRNA and the exons flanking the deletion are spliced together. 1. If the borders of neighboring exons do not maintain the translational reading frame, then incorrect amino acids are inserted into the growing polypeptide chain until an abnormal stop codon is reached, causing premature termination of the protein. The truncated protein may be unstable, may fail to be localized in the membrane, or may fail to bind to glycoproteins. Functional dystrophin is then almost totally absent. 2. If the deletion preserves the reading frame, a dystrophin molecule is produced with an internal deletion but intact ends. Although the protein is smaller than normal and may be present in less than normal amounts, it can often suffice to preserve some muscle function.

C. One approach to correcting a deletion of the *DMD* gene is to induce formation of an mRNA transcript that skips one or more exons to restore the reading frame. For example, when there is a deletion of exons 48, 49, and 50, the splicing of exon 47 to exon 51 yields a transcript that is out of frame, in which a stop codon is introduced, preventing production of dystrophin. However, addition of an antisense oligonucleotide (**ASO**) that binds exon 51 and prevents its splicing will promote the in-frame splicing of exon 47 to exon 52. Although this transcript is slightly shorter than normal, as is the resulting dystrophin protein, the protein will nonetheless function well enough to ameliorate the muscle degeneration. Another therapeutic approach is to deliver a short form of the dystrophin gene (mini- or micro-dystrophin, ~30% of the full-length protein) to the muscle using adeno-associated virus (**AAV**); full-length dystrophin is too large to be delivered within the AAV.

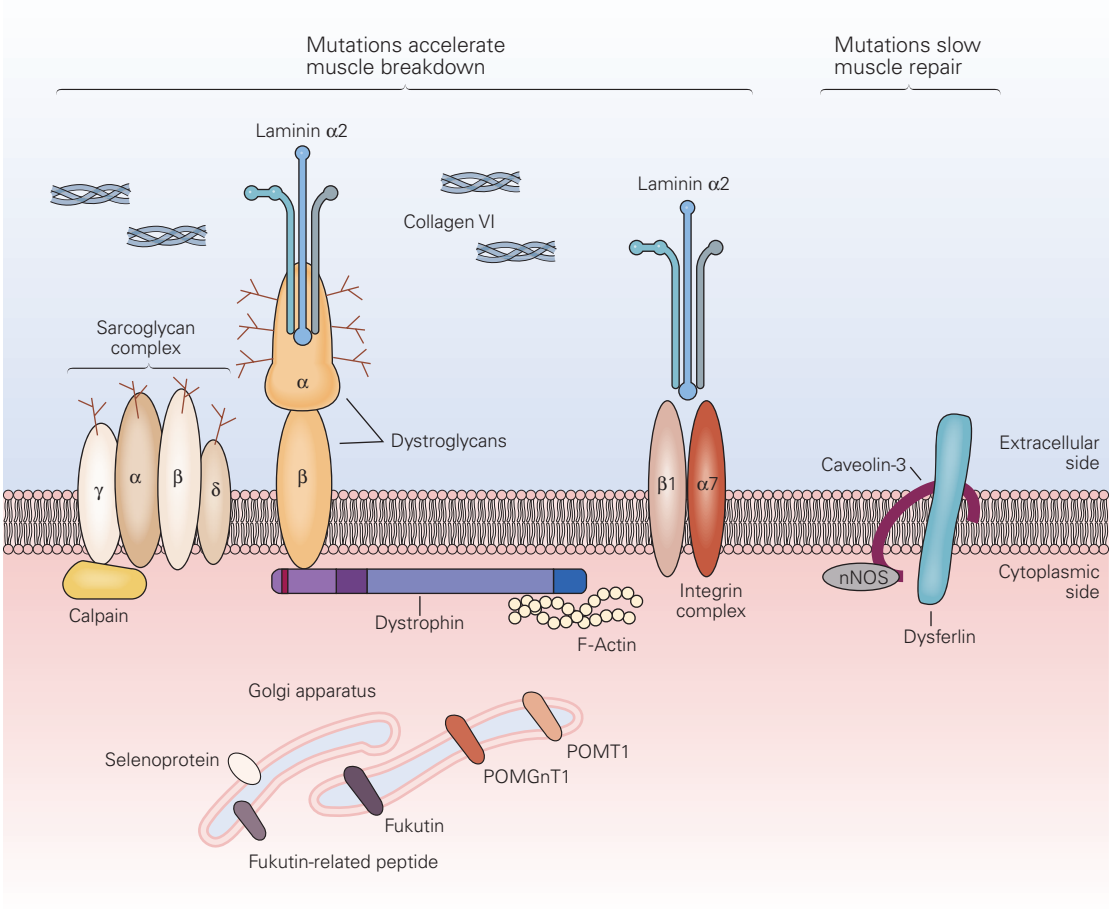

Figure 57–11 **In muscular dystrophy, mutated proteins either weaken the muscle cell membrane or slow its repair after injury.** For example, a deficiency of dystrophin, a submembrane protein, causes Duchenne muscular dystrophy. Dystrophin interacts with complexes of other membrane proteins that are mutated in other dystrophies, including the dystroglycans and the sarcoglycans, which are closely associated with extracellular proteins such as laminin α2 and collagen. Several other proteins mutated in different forms of muscular dystrophy are normally present in the Golgi apparatus, where they are essential for adding sugar groups to membrane proteins. These include **POMT1** (protein-O-mannosyl transferase 1), **POMGnT1** (protein-O-mannosyl α-,2-*N*-acetylglucosaminyl transferase), fukutin, fukutin-related peptide, and a selenoprotein. Dysferlin, which is mutated in still other dystrophies, is involved in the repair of skeletal muscle membrane after injury. (Adapted, with permission, from Brown and Mendell 2005.)

to about –60 mV. At this potential, most Na^+ channels are inactivated, rendering the muscle fiber chronically refractory and thus unable to generate action potentials. Recovery of strength occurs spontaneously and is associated with repolarization to a resting potential within a few millivolts of normal and recovery of excitability.

Two variants of periodic paralysis have been delineated. Hyperkalemic periodic paralysis attacks occur during periods of high venous K^+ (≥6.0 mM versus normal levels of 3.5–4.5 mM). Ingesting foods with high K^+ content such as bananas or fruit juice may trigger an attack. Conversely, hypokalemic periodic paralysis presents as episodic weakness in association with low blood K^+ (≤2.5 mM). Affected muscle is paradoxically depolarized in the setting of reduced extracellular K^+, which shifts the reversal potential for K^+ to more negative values. Both forms are inherited as autosomal dominant traits.

Hyperkalemic periodic paralysis is caused by missense mutations in a gene that encodes the pore-forming subunit of a voltage-gated Na^+ channel

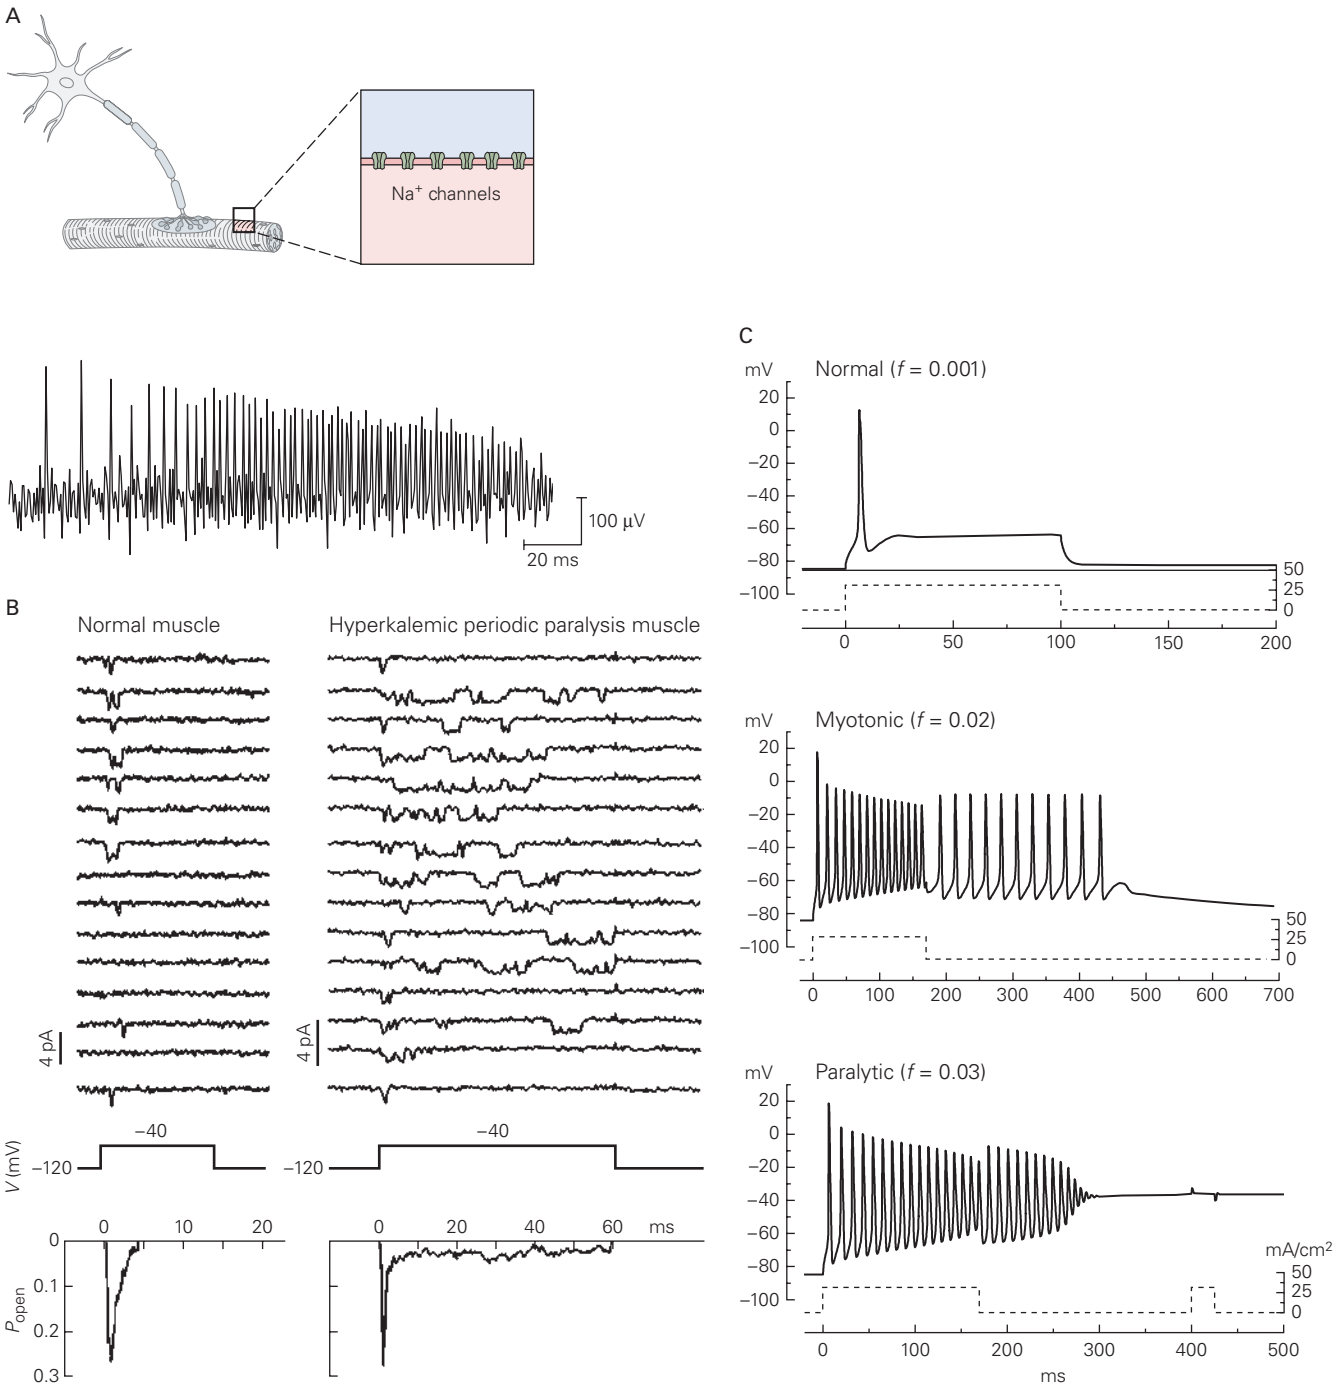

Figure 57–12 Myotonia or paralysis can result from genetically altered function in ion channels in skeletal muscle.

A. The electrical signature of myotonia (muscle stiffness) is a rapid burst of action potentials in response to a single stimulus. The action potentials, here shown in extracellular recordings, vary in amplitude and wax and wane in frequency. Such a burst may follow a voluntary muscle contraction or a mechanical stimulus, such as percussion of the muscle.

B. Cell-attached patch recordings from cultured human muscle cells. In normal muscle, the Na^+ channels open early and briefly in response to a 60 msec voltage-clamp depolarization from –120 mV to –40 mV. In muscle from patients with hyperkalemic periodic paralysis (defective M1592V Na^+ channel), the prolonged openings and reopenings indicate impaired inactivation. The probability of channel opening (obtained by averaging individual records) persists in the hyperkalemic muscle following inactivation. (Reproduced, with permission, from Cannon 1996.)

C. Even modest disruption of Na^+ channel inactivation is sufficient to produce bursts of myotonic discharges or depolarization-induced loss of excitability. These computer simulation records show muscle voltage in response to depolarizing current injection (**dashed line**). Among the total pool of mutant channels, a small fraction (*f*) fails to inactivate normally. In these simulations, *f* was varied from normal to values appropriate for myotonic or paralytic muscle. (Reproduced, with permission, from Cannon 1996.)

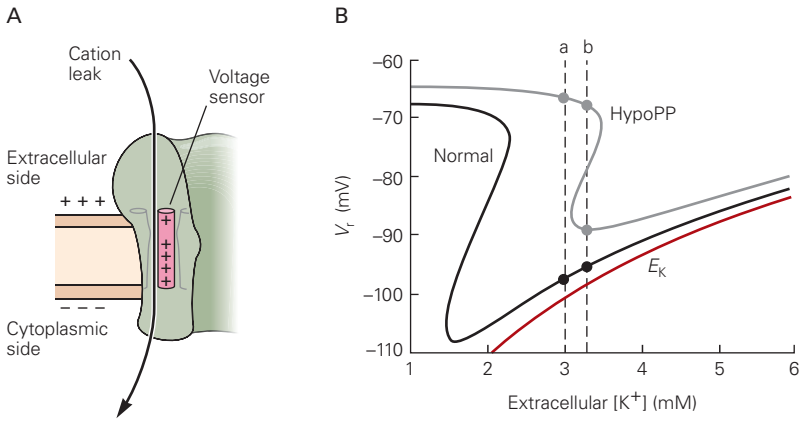

Figure 57–13 Hypokalemic periodic paralysis (HypoPP) is caused by leaky ion channels.

A. In HypoPP, missense mutations in the voltage-sensor domains create leaky Ca^{2+} or Na^+ channels that allow cation influx via an anomalous pathway separate from the channel pore.

B. Although this leak is small (~0.5% of the total resting membrane conductance), model simulations show that it causes an increased susceptibility to depolarization of resting potential (V_r), resulting in inexcitability and weakness as the external $[K^+]$ is lowered. This paradoxical depolarization of V_r diverges from the Nernst potential for K^+ (E_K) because of loss of the contribution from the inward rectifier K^+ channel in low $[K^+]$. Normally, this depolarization occurs only at extremely low $[K^+]$ (<2 mM) and is not seen in healthy people, but for patients with HypoPP, the cation leak shifts the depolarization point into the physiological range of $[K^+]$. For this simulation, in 3.3 mM $[K^+]$ (**line b**), excitability is preserved for normals (V_r = –95.6 mV), whereas HypoPP fibers may be excitable (V_r = –89 mV) or refractory and inexcitable (V_r = –67.7 mV). Reduction of $[K^+]$ to 3.0 mM (**line a**) results in complete loss of excitability for all HypoPP fibers (–66.3 mV) and retained excitability for normal fibers (V_r = –97.8 mV). (Adapted, with permission, from Cannon 2017.)

expressed in skeletal muscle. The resulting mutant Na^+ channels have inactivation defects. Subtle inactivation defects produce myotonia, whereas more pronounced defects result in chronic depolarization and loss of excitability with paralysis (Figure 57–12A–C). Hypokalemic paralysis is caused by missense mutations in the voltage-sensor domains of either Ca^{2+} channels or Na^+ channels in skeletal muscle. Disruption of the voltage-sensor domain allows an influx of ion current through an anomalous pathway, separate from the channel pore (Figure 57–13). This current "leak" in resting fibers produces a susceptibility to depolarization and loss of excitability in low extracellular K^+. A rare form of periodic paralysis that is characterized by weakness, developmental defects, and cardiac irritability is caused by primary mutations in an inwardly rectifying K^+ channel important for the resting potential (Figure 57–13).

In myotonia congenita, muscle stiffness is present from birth and is nonprogressive. Unlike myotonic dystrophy, there is no muscle wasting, permanent muscle weakness, or other organ involvement. Congenital myotonia is a consequence of mutations in the gene coding for the ClC-1 Cl^- channel in skeletal muscle membrane (Figure 57–14). The resultant decrease

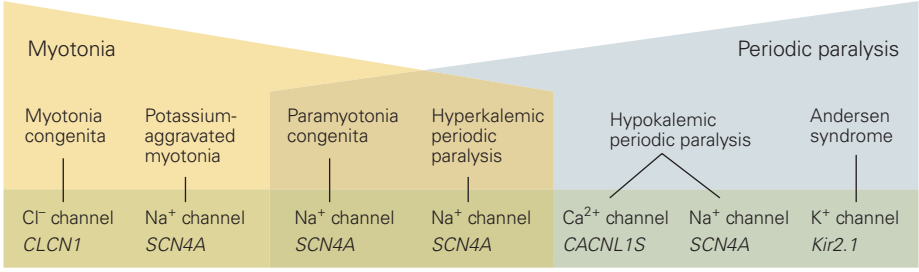

Figure 57–14 The myotonias and periodic paralyses are caused by mutations in genes that code for diverse voltage-gated ion channels in the skeletal muscle membrane. Some of these channel disorders are characterized only by myotonia, some by periodic paralysis without myotonia, and some by both myotonia and paralysis. Some clinical disorders (eg, hypokalemic periodic paralysis) can arise from defects in different channels in different individuals.

in Cl^- influx leads to membrane depolarization and repetitive firing. The disease is inherited as a dominant, semi-dominant, or recessive trait.

Highlights

1. Distinct disorders arise from pathology in different components of the motor unit. Pure motor diseases such as amyotrophic lateral sclerosis or spinal muscular atrophy are caused by loss of motor neurons, whereas combined motor and sensory features are present in most peripheral nerve disorders. These disorders usually spare eye movements and the eyelids.
2. Pure motor weakness, sometimes highly variable in severity over time, is also caused by disorders of the neuromuscular junction, which may begin early in life (congenital or neonatal myasthenia) or in childhood or adulthood (commonly autoimmune myasthenia gravis). The latter often involves eyelids and facial muscles.
3. Many forms of weakness are caused by mutations in genes that are important in skeletal muscle. These disorders usually become evident in infancy or childhood, involve the proximal more than the distal muscles, and progress relentlessly. Some (eg, Duchenne muscular dystrophy) also entail degeneration of cardiac muscle.
4. Inherited diseases of skeletal muscle with transient episodes of weakness (periodic paralysis) or involuntary after-contractions lasting seconds (myotonia) are caused by missense mutations in voltage-gated ion channels. During an episode of weakness, muscle fibers are depolarized and refractory from conducting action potentials. This intermittent failure to maintain the resting potential may arise from gain-of-function mutations in Na^+ channels, loss-of-function mutations in K^+ channels, or anomalous leakage currents in Na^+ or Ca^{2+} channels. Myotonia is a hyperexcitable state of skeletal muscle caused by Cl^- channel loss-of-function or Na^+ channel gain-of-function mutations.
5. Studies of the diseases of the peripheral nervous system show the powerful synergy between clinical and basic neuroscience. For most of the disorders inherited as Mendelian traits, molecular genetic analyses have led to the description of causative defects in muscle and nerve proteins, beginning only with the clinical data in affected families and DNA from family members.
6. Small animal models of many of these disorders, with precisely defined genetic defects, are proving invaluable for the analysis of mechanisms of disease pathogenesis and studies of new treatments. Combined with innovation in new biological therapies (gene therapy, gene silencing), these models have led to transformative successes in human trials (eg, spinal muscular atrophy).
7. In several of these disorders, a new generation of molecular therapies (eg, antisense oligonucleotides or viral-mediated gene delivery) that augment function of the mutant genes is substantially improving clinical outcomes.

Seizures and Epilepsy

Until quite recently, the function and organization of the human cerebral cortex—the region of the brain concerned with perceptual, motor, and cognitive functions—has eluded both clinicians and neuroscientists. In the past, the analysis of brain function relied largely on observations of loss of brain functions resulting from brain damage and cell loss caused by strokes or trauma. These natural experiments provided much of the early evidence that distinct brain regions serve specific functions, or as the famous American neurologist C. Miller Fisher said, "We learn about the brain 'stroke by stroke.'" Observation of patients with seizures and epilepsy has been equally important in the study of brain function because the behavioral consequences of these disorders of neural *hyperactivity* inform clinicians how activation affects the brain regions from which they originate.

Temporary disruptions of brain function resulting from abnormal, excessive neuronal activity are called seizures, whereas the chronic condition of repeated seizures is called epilepsy. For centuries, understanding the neurological origins of seizures was confounded by the dramatic, and sometimes bizarre, behaviors associated with seizures. The chronic condition of epilepsy was widely associated with possession by evil spirits, yet seizures also were thought to be a sign of oracular, prescient, or special creative powers.

The Greeks in the time of Hippocrates (circa 400 BC) were aware that head injuries to one side of the brain could cause seizure activity on the opposite side of the body. In those earlier times, the diagnosis of epilepsy was probably much broader than the contemporary definition. Other causes of episodic unconsciousness, such as syncope as well as mass hysteria and

psychogenic seizures, were almost certainly attributed to epilepsy. Moreover, historical writings typically describe generalized convulsive seizures involving both cerebral hemispheres; thus, it is likely that seizures involving a very limited area of the brain were misdiagnosed or never diagnosed at all. Even today, it can be difficult for physicians to distinguish between episodic loss of consciousness and the various types of seizures. Nevertheless, as our ability to treat and even cure epilepsy continues to improve, these diagnostic distinctions take on increasing significance.

The early neurobiological analysis of epilepsy began with John Hughlings Jackson's work in London in the 1860s. Jackson realized that seizures need not involve loss of consciousness but could be associated with localized symptoms such as the jerking of an arm. His observation was the first formal recognition of what we now call partial (or focal) seizures. Jackson also observed patients whose seizures began with focal neurological symptoms, then progressed to convulsions with loss of consciousness by steadily involving adjacent regions in an orderly fashion (the so-called Jacksonian march). His observations gave rise to the concept of the motor homunculus (the anatomical map representing the body organization or "wiring diagram" over the cortical surface) long before functional organization was established using electrophysiological techniques (Chapter 4).

Another pioneering development that presaged modern therapy was the first surgical treatment for epilepsy in 1886 by the British neurosurgeon Victor Horsley. Horsley resected cerebral cortex adjacent to a depressed skull fracture and cured a patient with focal motor seizures. Related medical innovations include the first use of phenobarbital as an anticonvulsant in 1912 by Alfred Hauptmann, the development of electroencephalography by Hans Berger in 1929, and the discovery of the anticonvulsant properties of phenytoin (Dilantin) by Houston Merritt and Tracey Putnam in 1937. The birth of routine surgical treatment for epilepsy dates to the early 1950s, when Wilder Penfield and Herbert Jasper in Montreal stimulated the cortex and pinpointed the motor and sensory maps before removing the epileptic focus. As in any chronic disease, the physiological features of seizures are not the only consideration in the care and management of patients with epilepsy. Psychosocial factors are also extremely important. The diagnosis of epilepsy has consequences that can affect all aspects of everyday life, including educational opportunities, driving, and employment. Although many societal limitations imposed on epileptics are appropriate—most would agree that patients with epilepsy should not be commercial pilots—a diagnosis of epilepsy can result in inappropriately negative effects on educational opportunities and employment. To improve this situation, physicians have a duty to educate themselves and the public on the underlying science of epilepsy and its major comorbidities, including cognitive problems and depression.

Classification of Seizures and the Epilepsies Is Important for Pathogenesis and Treatment

Not all seizures are the same. Thus, the pathogenesis and classification of seizures must take into account their clinical characteristics as well as acquired and genetic factors in each patient. Seizures and the chronic condition of repetitive seizures (epilepsy) are common. Based on epidemiological studies in the United States, 1% to 3% of all individuals living to the age of 80 will be diagnosed with epilepsy. The highest incidence occurs in young children and the elderly.

In many respects, seizures represent a prototypic neurological disease in that the symptoms include both "positive" and "negative" sensory or motor manifestations. Examples of positive signs that can occur during a seizure include the perception of flashing lights or the jerking of an arm. Negative signs reflect impairments of normal brain function such as an impairment of consciousness and cognitive awareness or even transient blindness, speech arrest, or paralysis. These examples underscore a general feature of seizures: The signs and symptoms depend on the location and extent of brain regions that are affected. Finally, the manifestations of seizures result in part from synchronous activity triggered in surrounding tissue with normal cellular and network properties. The latter activity is particularly important in the spread of a seizure beyond its original boundaries—seizures quite literally hijack the normal functions of the brain.

Seizures Are Temporary Disruptions of Brain Function

Seizures have been classified clinically into two categories, focal or generalized, based on their onset (Table 58–1). This classification is conceptually simple, but because several terms have been used over the years to refer to the same condition, the binary nature may have been obscured. Nonetheless, this classification of seizures has proven extremely useful to clinicians, and anticonvulsant medications are targeted to one or the other type.

Other motor
Nonmotor (absence)
Unknown onset
Motor
Tonic-clonic
Other motor
Nonmotor
Unclassified

Source: Commission on Classification and Terminology of the International League Against Epilepsy, 2017.

Focal onset (also called partial) seizures originate in a small group of neurons (the seizure focus), and thus the symptoms depend on the location of the focus within the brain. Focal onset seizures can occur either without alteration of consciousness (often called simple partial) or with alteration of consciousness (often called complex partial). A typical focal onset seizure might begin with jerking in the right hand and progress to clonic movements (ie, jerks) of the entire right arm. If a focal onset seizure progresses further, the patient may lose consciousness, fall to the ground, rigidly extend all extremities (tonic phase), then have convulsive jerking in all extremities (clonic phase).

A focal onset seizure can be preceded by telltale symptoms called *auras*. Common auras include unprovoked and often vivid sensations such as a sense of fear, a rising feeling in the abdomen, or even a specific odor. The novelist Fyodor Dostoyevsky described his auras as a "feeling … so strong and sweet that for a few seconds of such bliss I would give ten or more years of my life, even my whole life perhaps." The aura is a product of electrical activity in the seizure focus and thus represents the earliest seizure manifestation. The time after a seizure but before the patient returns to his or her normal level of neurological function is called the post-ictal period.

Generalized onset seizures constitute the second main category. They begin without an aura or focal onset and involve both hemispheres from the onset. Thus, they are sometimes called primary generalized seizures to avoid confusion with seizures that secondarily generalize following a focal onset. Generalized onset seizures can be further divided into motor (convulsive) or nonmotor types depending on whether the seizure is associated with tonic-clonic movements.

The prototypic nonmotor generalized onset seizure is the *typical absence seizure* in children (formerly called petit mal). These seizures begin abruptly, usually last less than 10 seconds, are associated with staring and sudden cessation of all motor activity, and result in loss of awareness but not loss of posture. Patients appear as if in a trance, but the episodes are so brief that their occurrence can be missed by a casual observer. Unlike a focal onset seizure, there is no aura before the seizure or confusion after the seizure (the post-ictal period). Patients may exhibit mild motor manifestations such as eye blinking, but do not fall or have tonic-clonic movements. Typical absence seizures have very distinctive electrical characteristics on the electroencephalogram (EEG) known as a spike-and-wave pattern.

Some generalized onset seizures involve only abnormal (myoclonic, clonic, or tonic) movements or a sudden loss of motor tone (atonia). The most common motor type of generalized onset seizure is the tonic-clonic (formerly called *grand mal*) seizure. Such seizures begin abruptly, often with a grunt or cry, as tonic contraction of the diaphragm and thorax forces expiration. During the tonic phase, the patient may fall to the ground in a rigid posture with clenched jaw, lose bladder or bowel control, and become blue (cyanotic). The tonic phase typically lasts 30 seconds before evolving into clonic jerking of the extremities lasting 1 to 2 minutes. This active phase is followed by a post-ictal phase during which the patient is sleepy, disoriented, and may complain of headache and muscle soreness.

A generalized onset tonic-clonic seizure can be difficult to distinguish on purely clinical grounds from a focal seizure with a brief aura, which then rapidly progresses to a generalized tonic-clonic seizure. This distinction is not academic, as it can be vital to pinpointing the underlying cause and choosing the proper treatment. However, some seizures are simply difficult to classify because of undetermined onset.

Epilepsy Is a Chronic Condition of Recurrent Seizures

Recurrent seizures constitute the minimal criterion for the diagnosis of epilepsy. The oft-quoted clinical rule, "A single seizure does not epilepsy make," emphasizes this point, and even repeated seizures in response to a provocation such as alcohol withdrawal are not considered epilepsy. Various factors that contribute to a clinical pattern of recurrent seizures—the

underlying etiology of the seizures, the age of onset, or family history—are ignored in the classification scheme for seizures in Table 58–1. The classification of the epilepsies evolved primarily based on clinical observation rather than a precise cellular, molecular, or genetic understanding of the disorder. The factors influencing seizure type and severity can often be recognized as patterns of signs and symptoms, referred to as *epilepsy syndromes*. Such factors include the age of seizure onset, whether the seizures are inherited, and certain patterns on the EEG. The recognition of these syndromes has played a role in the recent discovery of single gene mutations as a cause of seizure disorders.

The primary variables in the classification of the epilepsies are whether or not a focal brain abnormality can be identified (localization-related versus generalized epilepsies) and whether there is an identifiable cause (symptomatic) or not (unknown, often called idiopathic). The great majority of adult-onset epilepsies are classified as symptomatic localization-related epilepsies. This category includes such causes as trauma, stroke, tumors, and infections. A large number of individuals have adult-onset epilepsies without a clearly defined cause.

Unfortunately, despite the usefulness of this classification scheme, many epilepsy syndromes do not fit neatly. One expects (and hopes) that this classification will be greatly refined as criteria include the underlying etiologies rather than just clinical phenotype.

The Electroencephalogram Represents the Collective Activity of Cortical Neurons

Because neurons are excitable cells, it should not be surprising that seizures result directly or indirectly from a change in the excitability of single neurons or groups of neurons. This view dominated early experimental studies of seizures. To study such effects, electrical recordings of brain activity can be made with intracellular or extracellular electrodes. Extracellular electrodes sense action potentials in nearby neurons and can detect the synchronized activity of ensembles of cells called *field potentials*.

At the slow time resolution of extracellular recording (hundreds of milliseconds to seconds), field potentials can appear as single transient changes called spikes. These spikes reflect action potentials in many neurons and should not be confused with spikes in recordings of single neurons, which are individual action potentials that last only 1 or 2 ms. The EEG thus represents a set of field potentials as recorded by multiple electrodes on the surface of the scalp (Figure 58–1).

Because the electrical activity originates in neurons in the underlying brain tissue, the waveform recorded by the surface electrode depends on the orientation and distance of the electrical source with respect to the electrode. The EEG signal is inevitably distorted by the filtering and attenuation caused by intervening layers of tissue and bone that act in the same way as resistors and capacitors in an electric circuit. Thus, the amplitude of EEG signals (measured in microvolts) is much smaller than the voltage changes in a single neuron (millivolts). High-frequency activity in single cells, such as action potentials, is filtered out by the EEG signal, which primarily reflects slower voltage changes across the cell membrane, such as synaptic potentials.

Although the EEG signal is a measure of the extracellular current caused by the summated electrical activity of many neurons, not all cells contribute equally to the EEG. The surface EEG reflects predominately the activity of cortical neurons in close proximity to each of the set of EEG electrodes on the scalp. Thus, deep structures such as the base of a cortical gyrus, mesial walls of the major lobes, hippocampus, thalamus, or brain stem do not contribute directly to the surface EEG. The contributions of individual nerve cells to the EEG are discussed in Box 58–1.

The surface EEG shows patterns of activity—characterized by the frequency and amplitude of the electrical activity—that correlate with various stages of sleep and wakefulness (Chapter 44) and with some pathophysiological processes such as seizures. The normal human EEG shows activity over the range of 1 to 30 Hz with amplitudes in the range of 20 to 100 μV. The observed frequencies have been divided into several groups: alpha (8–13 Hz), beta (13–30 Hz), delta (0.5–4 Hz), and theta (4–7 Hz).

Alpha waves of moderate amplitude are typical of relaxed wakefulness and are most prominent over parietal and occipital sites. During intense mental activity, beta waves of lower amplitude are more prominent in frontal areas and over other regions. Alerting relaxed subjects by asking them to open their eyes results in so-called desynchronization of the EEG with a reduction in alpha activity and an increase in beta activity (Figure 58–1B). Theta and delta waves are normal during drowsiness and early slow-wave sleep; if they are present during wakefulness, it is a sign of brain dysfunction.

As neuronal ensembles become synchronized, as when a subject relaxes or becomes drowsy, the summated currents become larger and can be seen as abrupt changes from the baseline activity. Such "paroxysmal" activity can be normal, eg, the episodes of high-amplitude activity (1–2 seconds, 7–15 Hz) that occur during sleep (sleep spindles). However, a sharp

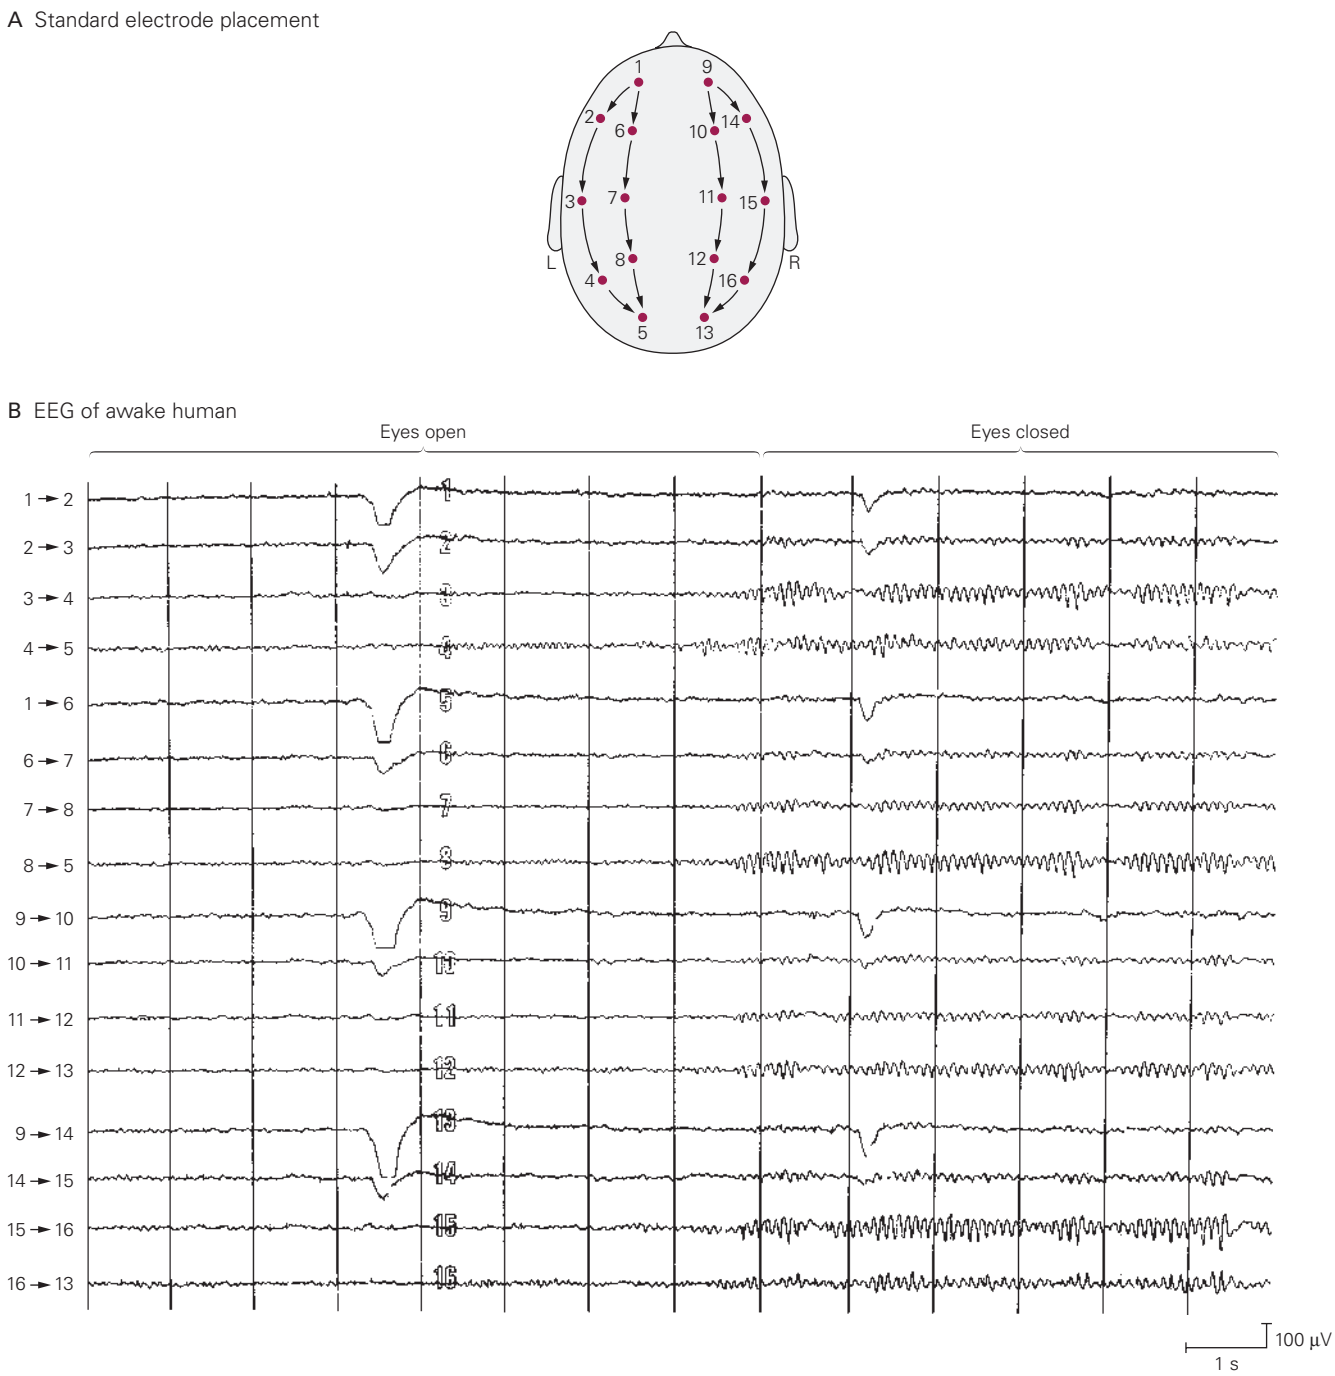

Figure 58–1 The normal electroencephalogram (EEG) in an awake human subject.

A. A standard set of placements (or montage) of electrodes on the surface of the scalp. The electrical response at each site reflects the activity between two of the electrodes.

B. At the beginning of the recording, the EEG shows low-voltage activity (~20 µV) over the surface of the scalp. The **vertical lines** are placed at 1-second intervals. During the first 8 seconds, the subject was resting quietly with eyes open, and then the subject was asked to close his eyes. With the eyes closed, larger-amplitude activity (8–10 Hz) develops over the occipital region (sites 3, 4, 8, 12, 15, and 16). This is the normal alpha rhythm characteristic of the relaxed, wakeful state. Slow large-amplitude artifacts occur at 3.5 seconds when the eyes blink and at 9 seconds when the eyes close.

Box 58–1 The Contribution of Individual Neurons to the Electroencephalogram

The contribution of the activity of single neurons to the electroencephalogram (EEG) can be understood by examining a simplified cortical circuit and some basic electrical principles. Pyramidal neurons are the major projection neurons in the cortex. The apical dendrites of these cells, which are oriented perpendicular to the cell surface, receive a variety of synaptic inputs. Thus, synaptic activity in the pyramidal cells is the principal source of EEG activity.

To understand the contribution of a single neuron to the EEG, consider the flow of charge produced by an excitatory postsynaptic potential (EPSP) on the apical dendrite of a cortical pyramidal neuron (Figure 58–2). Ionic current enters the dendrite at the site of generation of the EPSP, creating what is commonly called a current sink. It then must complete a loop by flowing down the dendrite and back out across the membrane at other sites, creating a current source.

The voltage signal created by a synaptic current is approximately predicted by Ohm's law ($V = IR$, where V is voltage, I is current, and R is resistance). Because the membrane resistance (R_m) is much larger than that of the salt solution that constitutes the extracellular medium (R_e), the voltage recorded across the membrane with an

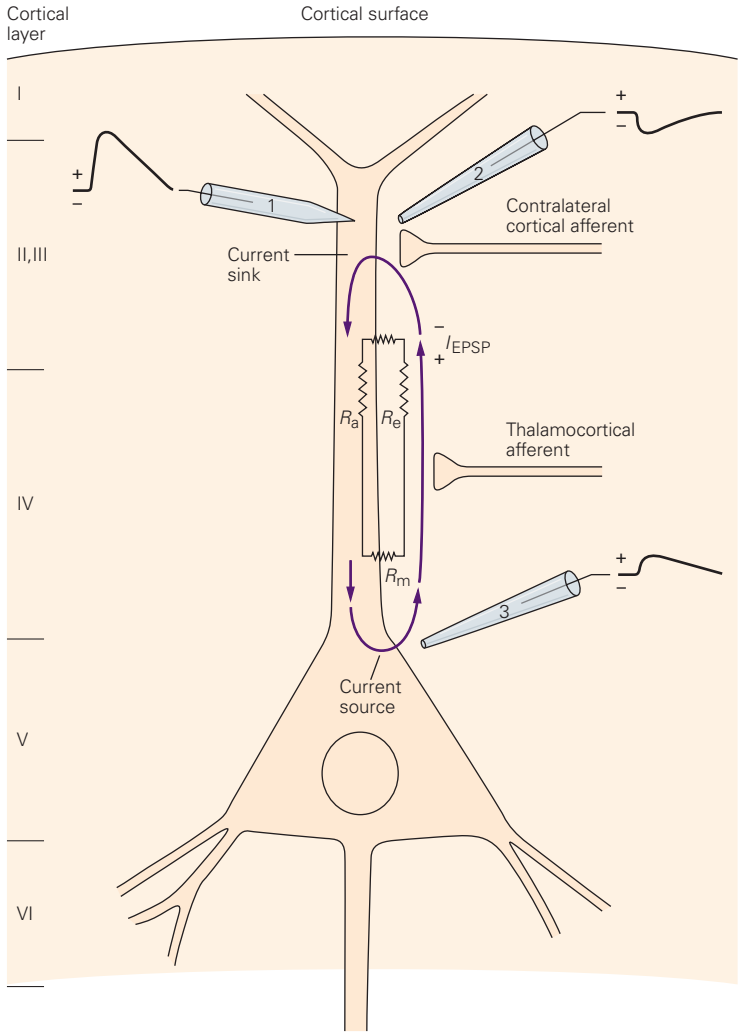

Figure 58–2 The pattern of electrical current flow for an excitatory postsynaptic potential (EPSP) initiated at the apical dendrite of a pyramidal neuron in the cerebral cortex. Activity is detected by three electrodes: an intracellular electrode inserted in the apical dendrite (**1**), an extracellular electrode positioned near the site of the EPSP in layer II of the cortex (**2**), and an extracellular electrode near the cell body in layer V (**3**). At the site of the EPSP (current sink), positive charge flows across the cell membrane (I_{EPSP}) into the cytoplasm, down the dendritic cytoplasm, and then completes the loop by exiting through the membrane near the cell body (current source). The potentials recorded by the extracellular electrodes at the sink and at the source have opposite polarity; the potentials recorded by the intracellular electrode have the same polarity regardless of the site. R_m, R_a, and R_e are the resistances of the membrane, cytoplasm, and extracellular space, respectively.

intracellular electrode (V_m) is also larger than the voltage at an extracellular electrode positioned near the current sink (V_e).

At the site of generation of an EPSP, the extracellular electrode detects the voltage change due to charge flowing away from the electrode into the cytoplasm as a negative voltage deflection. However, an extracellular electrode near the current source records a signal of opposite polarity (compare electrodes 1 and 3 in Figure 58–2). The situation is reversed if the site of the EPSP generation is on the basal segment of the apical dendrites.

In the cerebral cortex, excitatory axons from the contralateral hemisphere terminate primarily on dendrites in layers II and III, whereas thalamocortical axons terminate in layer IV (Figure 58–2). As a result, the activity measured by a surface EEG electrode will have opposite polarities for these two inputs even though the electrical event (membrane depolarization) is the same.

Similarly, the origin or polarity of cortical synaptic events cannot be unambiguously determined from surface EEG recordings alone. EPSPs in superficial layers and inhibitory postsynaptic potentials (IPSPs) in deeper layers both appear as upward (negative) potentials, whereas EPSPs in deeper layers and IPSPs in superficial layers have downward (positive) potentials (Figure 58–3).

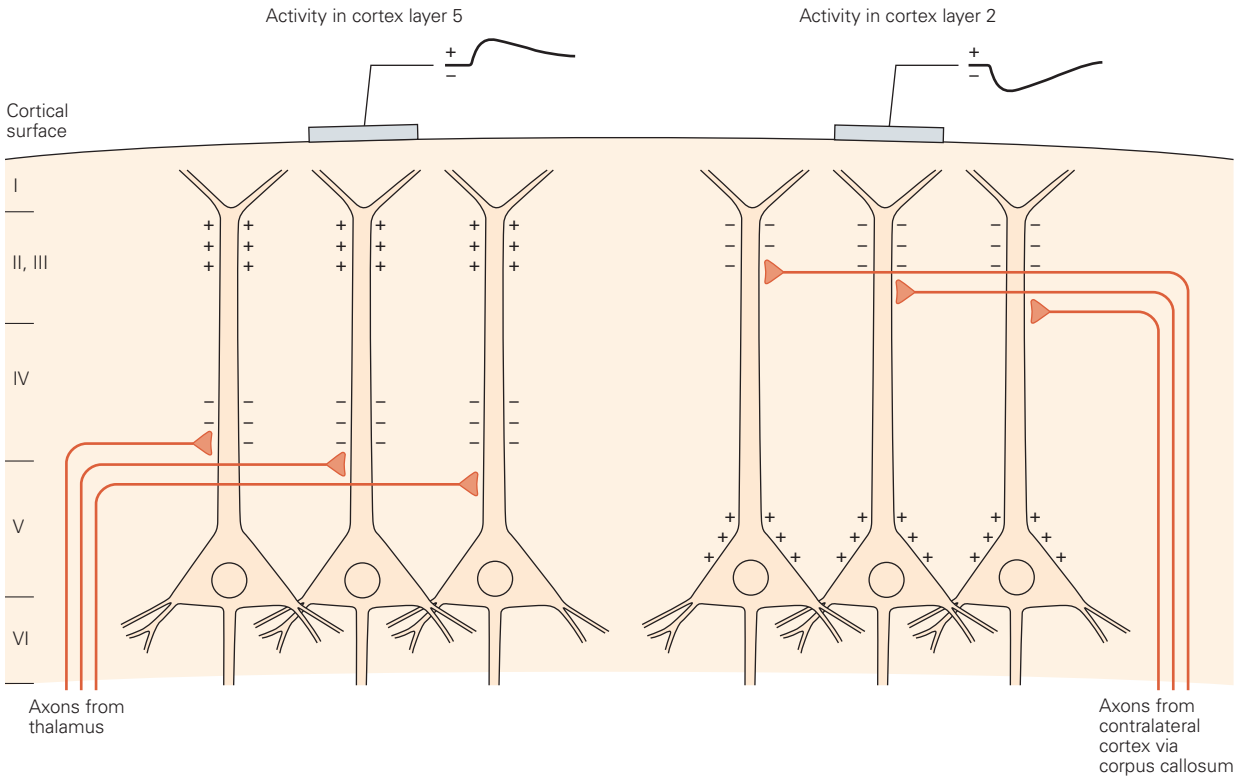

Figure 58–3 Surface electroencephalogram (EEG) recordings do not unambiguously indicate the polarity of synaptic events. The polarity of the surface EEG depends on the location of the synaptic activity within the cortex. A thalamocortical excitatory signal in layer V causes an upward voltage deflection at the surface EEG electrode because the electrode is nearer the current source. In contrast, an excitatory signal from the contralateral hemisphere in layer II causes a downward deflection because the electrode is nearer the sink.

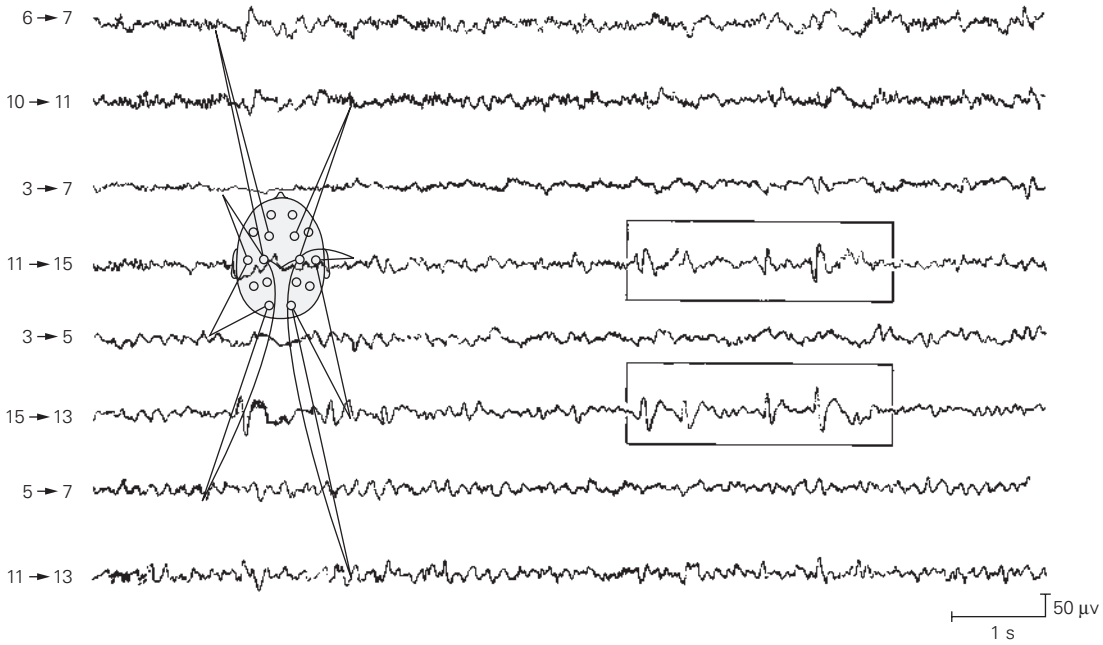

Figure 58–4 The electroencephalogram (EEG) can provide clues to the location of a seizure focus. Each trace represents the electrical activity between pairs of scalp electrodes as indicated in the electrode map. For example, electrode pairs 11–15 and 15–13 measure activity from the right temporal area. EEG activity in a patient with epilepsy shows sharp waves in the electrodes over the right temporal area (record enclosed in boxes). Such paroxysmal activity arises suddenly and disrupts the normal background EEG pattern. The focal abnormality may indicate that the seizure focus in this patient is in the right temporal lobe. Because the patient had no clinical seizures during the recording, these are interictal spikes (see Figure 58-7). (Adapted, with permission, from Lothman and Collins 1990.)

wave or EEG spike can also provide a clue to the location of a seizure focus in a patient with epilepsy (Figure 58–4). New recording and analytical methods such as spectral analysis of the EEG are increasingly being used to detect abnormal zones of synchrony (fast ripples) within a seizure focus.

Focal Onset Seizures Originate Within a Small Group of Neurons

Despite the variety of clinically defined seizures, important insights into the generation of seizure activity can largely be understood by comparing the electrographic patterns of focal onset seizures with those of generalized onset seizures.

The defining feature of focal onset seizures is that the abnormal electrical activity originates from a *seizure focus*. The seizure focus is considered to be nothing more than a small group of neurons, perhaps 1,000 or so, that have enhanced excitability and the ability to occasionally spread that activity to neighboring regions and thereby cause a seizure. The enhanced excitability (epileptiform activity) may result from many different factors such as altered cellular properties, glial dysfunction, or altered synaptic connections caused by a local scar, blood clot, or tumor. The development of a focal onset seizure can be arbitrarily divided into four phases: (1) the interictal period between seizures followed by (2) synchronization of activity within the seizure focus, (3) seizure spread, and finally, (4) secondary generalization. Phases 2 to 4 represent the ictal phase of the seizure. Different factors contribute to each phase.

Much of our knowledge about the electrical events during seizures comes from studies of animal models of focal onset seizures. A seizure is induced in an animal by focal electrical stimulation or by acute injection of a convulsant agent. This approach along with in vitro studies of tissue from these animal models has provided a good understanding of electrical events within the focus during a seizure as well as during the onset of the interictal period.

Neurons in a Seizure Focus Have Abnormal Bursting Activity

How does electrical activity in a single neuron or group of neurons lead to a focal onset seizure? Each neuron

within a seizure focus has a stereotypic and synchronized electrical response, the paroxysmal depolarizing shift, a depolarization that is sudden, large (20–40 mV), and long-lasting (50–200 ms), and that triggers a train of action potentials at its peak. The paroxysmal depolarizing shift is followed by an afterhyperpolarization (Figure 58–5A).

The paroxysmal depolarizing shift and afterhyperpolarization are shaped by the intrinsic membrane properties of the neuron (eg, voltage-gated Na^+, K^+, and Ca^{2+} channels) and by synaptic inputs from excitatory and inhibitory neurons (primarily glutamatergic and GABAergic, respectively). The depolarizing phase results primarily from activation of α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA)- and *N*-methyl-D-aspartate (NMDA)-type glutamate receptor-channels (Figure 58–5A), as well as voltage-gated Na^+ and Ca^{2+} channels. NMDA-type receptor-channels are particularly effective in enhancing excitability because depolarization relieves Mg^{2+} blockage of the channel. Removal of the blockage increases current through the channel, thus enhancing the depolarization and allowing additional Ca^{2+} to enter the neuron (Chapter 13).

The normal response of a cortical pyramidal neuron to excitatory input consists of an excitatory postsynaptic potential (EPSP) followed by an inhibitory postsynaptic potential (IPSP) (Figure 58–5B). Thus, the paroxysmal depolarizing shift can be viewed as a massive enhancement of these depolarizing and hyperpolarizing synaptic components. The afterhyperpolarization is generated by voltage-dependent and Ca^{2+}-dependent K^+ channels as well as by a γ-aminobutyric acid (GABA)-mediated Cl^- conductance (ionotropic $GABA_A$ receptors) and K^+conductance (metabotropic $GABA_B$ receptors) (Figure 58–5A). The Ca^{2+} influx through voltage-dependent Ca^{2+} channels and NMDA-type receptor-channels triggers the opening of calcium-activated channels, particularly K^+ channels. The afterhyperpolarization limits the duration of the paroxysmal depolarizing shift, and its gradual disappearance is the most important factor in the onset of a focal onset seizure, as discussed later.

Thus, it is not surprising that many convulsants act by enhancing excitation or blocking inhibition. Conversely, anticonvulsants can act by blocking excitation or enhancing inhibition. For example, the benzodiazepines diazepam (Valium) and lorazepam (Ativan) enhance $GABA_A$-mediated inhibition and are used in the emergency treatment of prolonged repetitive seizures. The anticonvulsants phenytoin (Dilantin) and carbamazepine (Tegretol) and several others reduce the opening of voltage-gated Na^+ channels that underlie the action potential. Molecular models of the Na^+ channel indicate that these drugs are more effective when the channel is in the open or activated state.

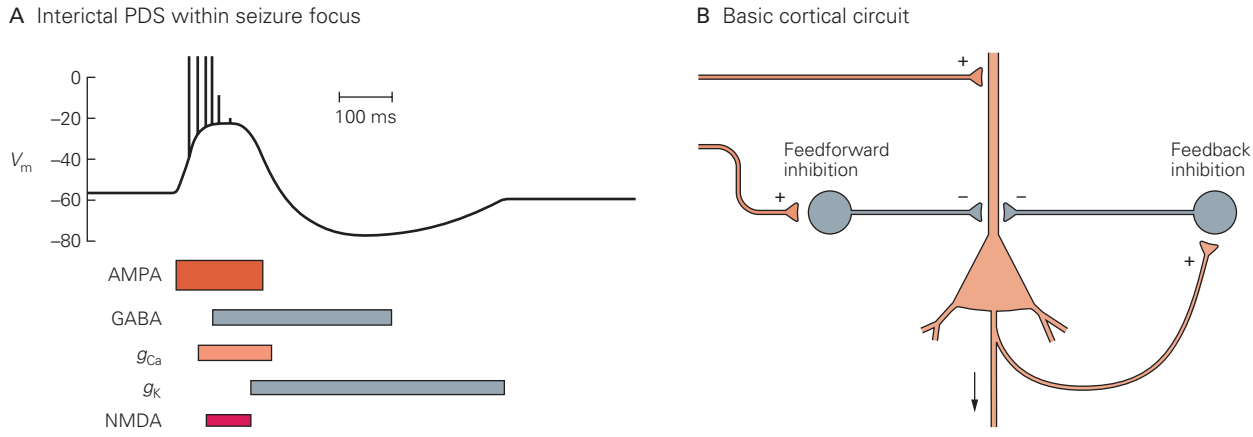

Figure 58–5 The conductances that underlie the paroxysmal depolarizing shift of a neuron in a seizure focus.

A. The paroxysmal depolarizing shift (**PDS**) is largely dependent on α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (**AMPA**)- and *N*-methyl-D-aspartate (**NMDA**)-type glutamate receptor-channels whose effectiveness is enhanced by the opening of voltage-gated Ca^{2+} channels (g_{Ca}). Following the depolarization, the cell is hyperpolarized by activation of γ-aminobutyric acid (**GABA**) receptors (both ionotropic $GABA_A$ and metabotropic $GABA_B$) as well as by voltage-gated and calcium-activated K^+ channels (g_K). (Adapted, with permission, from Lothman 1993a.)

B. Recurrent axon branches activate inhibitory neurons and cause feedback inhibition of the pyramidal neuron. Extrinsic excitatory inputs can also activate feedforward inhibition. The PDS represents exaggerated excitation in a seizure focus, whereas the inhibitory circuitry forms the basis of surround inhibition, important in restricting interictal activity to the seizure focus.

Thus, fittingly, the ability of these drugs to block Na^+ channels is enhanced by repetitive activity associated with seizures; that is, the greatest effect is in those neurons that need to be silenced the most.

The Breakdown of Surround Inhibition Leads to Synchronization

As long as the abnormal electrical activity is restricted to a small group of neurons, there are no clinical manifestations. The synchronization of neurons in a seizure focus is dependent not only on the intrinsic properties of each individual cell but also on the number and strength of connections between neurons. During the interictal period, the abnormal activity is confined to the seizure focus by inhibition of the surrounding tissue.

This "inhibitory surround," initially described by David Prince, is particularly dependent on feedforward and feedback inhibition by GABAergic inhibitory interneurons (Figure 58–6A). Although inhibitory circuits in the cerebral cortex are often represented by simple diagrams (Figure 58–6B), the morphology and connectivity of cortical inhibitory neurons are actually quite complex and a topic of continuing investigation with many new methods such as cell type–specific viral labeling and optogenetic stimulation.

During the development of a focal seizure, the excitation in the circuit overcomes the inhibitory

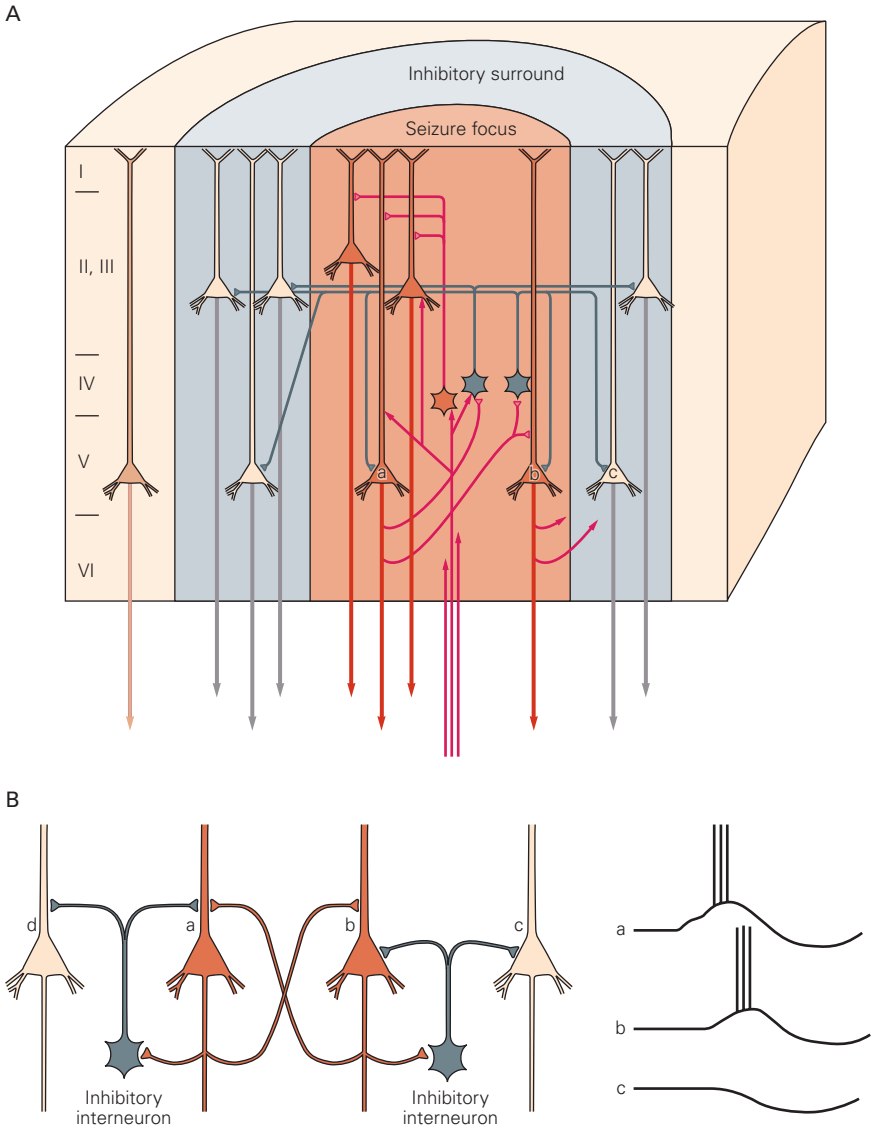

Figure 58–6 The spatial and temporal organization of a seizure focus depends on the interplay between excitation and inhibition of neurons in the focus.

A. The pyramidal cell *a* shows the typical electrical properties of neurons in a seizure focus (see part **B**). Excitation in cell *a* activates another pyramidal cell (*b*), and when many such cells fire synchronously, a spike is recorded on the electroencephalogram. However, cell *a* also activates γ-aminobutyric acid (GABA)-ergic inhibitory interneurons (**gray**). These interneurons can reduce the activity of cells *a* and *b* through feedback inhibition, thus limiting the seizure focus temporally, as well as prevent the firing of cells outside the focus, represented here by cell *c*. This latter phenomenon creates an inhibitory surround that acts to contain the hyperexcitability to the seizure focus during interictal periods. When extrinsic or intrinsic factors alter this balance of excitation and inhibition, the inhibitory surround begins to break down and the seizure activity spreads, leading to seizure generation. (Adapted, with permission, from Lothman and Collins 1990.)

B. The synaptic connections and activity patterns for cells *a*, *b*, and *c* shown in part **A**. Cells *a* and *b* (within the seizure focus) undergo a paroxysmal depolarizing shift, whereas cell *c* (in the inhibitory surround) is hyperpolarized due to input from GABAergic inhibitory interneurons.

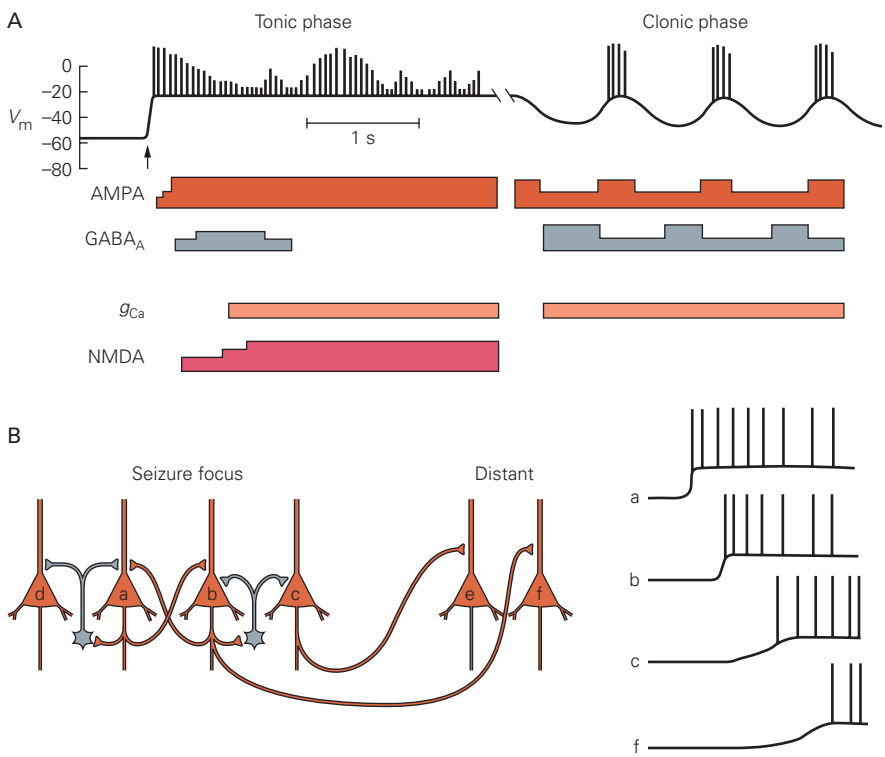

Figure 58–7 A focal onset seizure begins with the loss of the afterhyperpolarization and surround inhibition. (Adapted, with permission, from Lothman 1993a.)

A. With the onset of a seizure (**arrow**), neurons in the seizure focus depolarize as in the first phase of a paroxysmal depolarizing shift. However, unlike the interictal period, the depolarization persists for seconds or minutes. The γ-aminobutyric acid (**GABA**)-mediated inhibition fails, whereas excitatory activity in the α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (**AMPA**)- and *N*-methyl-D-aspartate (**NMDA**)-type glutamate receptors is functionally enhanced. This activity corresponds to the tonic phase of a secondarily generalized tonic-clonic seizure. As the GABA-mediated inhibition gradually returns, the neurons in the seizure focus enter a period of oscillation corresponding to the clonic phase.

B. As the surround inhibition breaks down, neurons in the seizure focus become synchronously excited and send trains of action potentials to distant neurons, thus spreading the abnormal activity from the focus. Compare this pattern of activity in cells *a* to *c* with that during the interictal period (Figure 58–6B).

surround, and the afterhyperpolarization in the neurons of the original focus gradually disappears. As a result, a nearly continuous high-frequency train of action potentials is generated, and the seizure begins to spread beyond the original focus (Figure 58–7).

An important factor in the spread of focal onset seizures appears to be that the intense firing of the pyramidal neurons results in a relative decrease in synaptic transmission from the inhibitory GABAergic interneurons, although the interneurons remain viable. Whether this decrease results from a presynaptic change in the release of GABA or a postsynaptic change in GABA receptors is still not understood and may not be the same in all cases. Other factors that may contribute to the loss of the inhibitory surround over time include changes in dendritic morphology, the density of receptors or channels, or a depolarizing shift in E_K caused by extracellular K^+ ion accumulation. Prolonged firing also transmits action potentials to distant sites in the brain, which in turn may trigger trains of action potentials in neurons that project back to neurons in the seizure focus (backpropagation). Reciprocal connections between the neocortex and thalamus may be particularly important in this regard.

Despite our understanding of such mechanisms, we still do not know what causes a seizure to occur at any particular moment. The inability to predict when a seizure will occur is perhaps the most debilitating aspect of epilepsy. New approaches to this dilemma are discussed in Box 58–2. Some patients learn to recognize the triggers most critical for them, such as sleep deprivation or stress, and thus adjust their lifestyle to avoid these circumstances. But in many individuals, seizures do not follow a predictable pattern.

In a few patients, sensory stimuli such as flashing lights can trigger seizures, suggesting that repeated excitation of some circuits causes a change in excitability. For example, NMDA-type glutamate receptor activity and GABAergic inhibition can undergo changes dependent on the frequency of firing of the presynaptic neuron. This provides one possible molecular mechanism for such changes in network excitability. On a longer time scale, circadian rhythms and hormonal patterns may also influence the likelihood

Box 58–2 New Approaches to Real-Time Seizure Detection and Prevention

Perhaps the most disabling aspect of seizures and epilepsy is the uncertainty of it all—when will the next seizure occur? As you can imagine, this impacts employment, driving, and recreation and often prevents the development of an individual's full potential. Patients with epilepsy sometimes have a brief warning or aura, but rarely do they have enough time to institute a therapeutic intervention such as a pill or an injection in order to abort the seizure.

Clinicians and epilepsy researchers have long recognized the importance of real-time seizure *detection* and real-time seizure *prevention* as a goal of therapy. Of course, acute detection must precede an acute treatment. However, in general, this approach has only been possible in patients undergoing EEG monitoring either with surface EEG electrodes or implanted electrodes. Several technologies are now emerging that allow new hope for detection, and thus enable efforts to abort or prevent an imminent seizure. Most are still in the experimental phase in animal models, but a few have reached clinical trials and even, in the case of vagal nerve stimulators, clinical practice. Seizure prevention can be imagined in two general ways: either altering the excitability of large regions of brain or somehow interrupting activity within a seizure focus. These two approaches can also be considered in engineering terms as open-loop or closed-loop strategies, respectively.

The first approach led to the development in 1997 of the vagal nerve stimulator, implanted in the neck and powered by a pacemaker-style battery (Figure 58–8). The

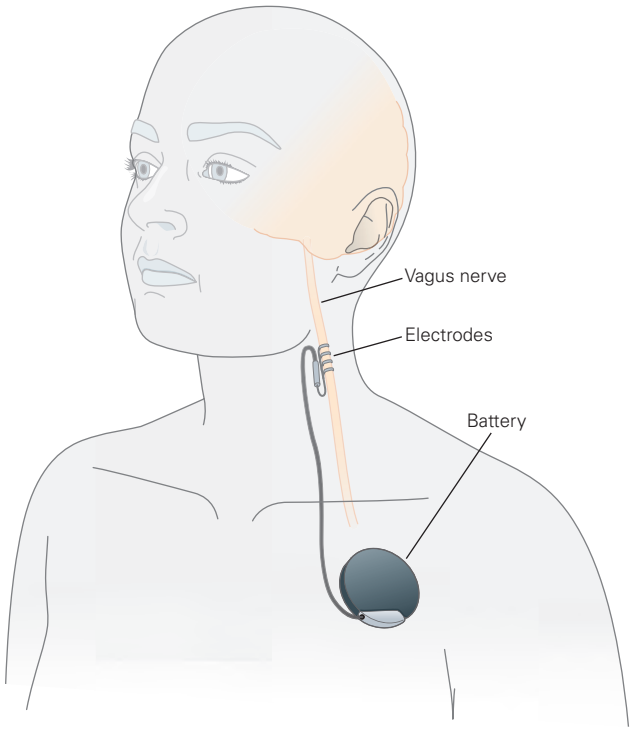

Figure 58–8 Vagal nerve stimulation. Schematic of placement of electrodes on the left vagus nerve powered by a battery implanted subcutaneously in the chest wall. The stimulation can be programmed at regular intervals (eg, every 30 seconds) and can also be activated on demand by placing a magnet over the chest. (Adapted from Stacey and Litt 2008.)

resulting chronic, intermittent stimulation of the vagus nerve has been effective in reducing seizure frequency in some patients. The patient can also activate the stimulator with a hand-held magnet during an aura to see if acute stimulation can prevent a seizure. The exact mechanism of seizure reduction by vagal nerve stimulation is still unclear, but presumably involves activation of the autonomic nervous system, and thus, this form of stimulation has limited specificity to particular brain regions.

Because many patients with intractable epilepsy have seizures that originate from one or more discrete foci in the brain, it would obviously be ideal to be able to detect abnormal activity within a seizure focus, and thus through some sort of feedback mechanism deliver a stimulus that would abort the spread of epileptiform activity from that focus. This goal has been an active area of investigation over the past decade, leading to a clinical trial the results of which were recently published. The device tested was a chronically implanted neurostimulator (RNS System, Neuropace) that directly stimulates the seizure focus when epileptiform activity is detected (Figure 58–9).

In this multicenter double-blinded trial, the device was implanted in patients with intractable focal onset seizures with one or two seizure foci. The patients were monitored for an average of 5 years. The device can be programmed by the clinician to match characteristics for each patient. The patients were randomized into two groups, responsive stimulation or sham stimulation groups, for the first 5 months, and then followed for up to 2 years. There was a 44% reduction in seizure frequency after 1 year and a 53% reduction after 2 years, suggestive of a progressive effect. The device was generally well tolerated. Thus, this approach has therapeutic potential for some patients and provides proof-of-concept evidence for closed-loop seizure detection and stimulation.

The RNS System uses electrical stimulation, but other strategies being studied in animals promise to refine methods of seizure prevention. These include neuronal stimulation or silencing using viral-mediated delivery of opto- or chemogenetic probes. In general, a replication-defective virus can be targeted to a specific cell type within a brain region. In the optogenetic approach, the virus is engineered to express ion channels or pumps that reduce neuron excitability when exposed to light. In the chemogenetic approach, a chemical is delivered systemically. This strategy has now been successfully employed in animal models of epilepsy.

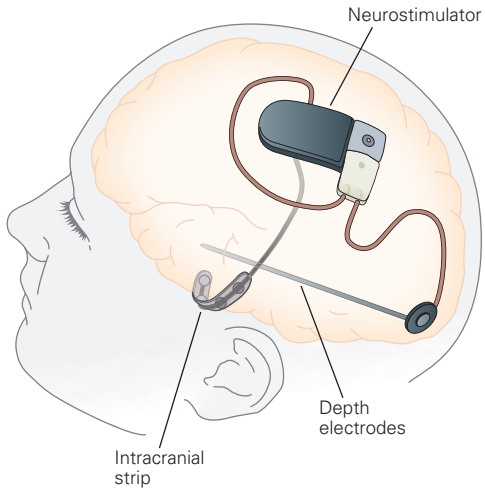

Figure 58–9 Closed-loop seizure detection and prevention. This schematic diagram of the closed-loop RNS System shows the intracranial strip and depth electrodes that detect seizure activity and subsequently deliver programmed stimulation to the seizure focus. (Adapted, with permission, from Heck et al. 2014.)

The optogenetic strategy is similar to the neurostimulator except that stimulation is delivered through a fiber optic light guide implanted near the seizure focus. The advantage of this approach is that the virus is engineered to deliver stimulation to a specific population of neurons. The chemogenetic approach has the advantage of noninvasive delivery of the chemical, but lacks the speed that can be achieved with optical or electrical stimulation. Even when optimized and tested in clinical trials, these invasive approaches are likely to be useful only in a subset of focal onset epilepsies that have stable and well-defined seizure foci. Thus, continuing and complementary efforts to understand the genetic mechanisms of epileptogenesis, as well as new technologies such as stem cell therapies, remain essential.

of seizures, as demonstrated by patients who have seizures only while sleeping (nocturnal epilepsy) or during their menstrual period (catamenial epilepsy). If we could develop continuous monitoring methods to predict the timing of seizure generation (Box 58–2), acute intervention to deliver a drug or change neural activity patterns to prevent seizures might become a therapeutic option. However, EEG studies reveal great variability between patients in pre-ictal patterns. Continuous chronic stimulation of neural circuits is another method of modifying the excitability of epileptic circuits. As an example of this approach, implanted vagal nerve stimulators have been modestly successful in treating pharmaco-resistant epilepsy that does not respond to other treatments.

The Spread of Seizure Activity Involves Normal Cortical Circuitry

If activity in the seizure focus is sufficiently intense, the electrical activity begins to spread to other brain regions. Spread of seizure activity from a focus generally follows the same axonal pathways as does normal cortical activity. Thus, thalamocortical, subcortical, and transcallosal pathways can all become involved in seizure spread. Seizure activity can propagate from a seizure focus to other areas of the same hemisphere or across the corpus callosum to involve the contralateral hemisphere (Figure 58–10). Once both hemispheres become involved, a focal onset seizure has become secondarily generalized. At this point, the patient generally experiences loss of consciousness. The spread of a partial seizure usually occurs rapidly over a few seconds, but can also evolve over many minutes. Rapid generalization is more likely if a focal onset seizure begins in the neocortex than if it begins in the limbic system (in particular, the hippocampus and amygdala).

An interesting unanswered question is what terminates a seizure. Remarkably, few mechanisms for the self-limiting return to the interictal state have been defined with certainty. One definite conclusion at this point is that termination is not due to cellular metabolic exhaustion, because under severe conditions clinical seizures may continue for hours (see below). During the initial 30 seconds or so of a focal onset seizure that secondarily generalizes, neurons in the involved areas undergo prolonged depolarization and fire continuously (due to loss of the afterhyperpolarization that normally follows a paroxysmal depolarizing shift). As the seizure evolves, the neurons begin to repolarize and the afterhyperpolarization reappears. The cycles of depolarization and repolarization correspond to the clonic phase of the seizure (Figure 58–7A).

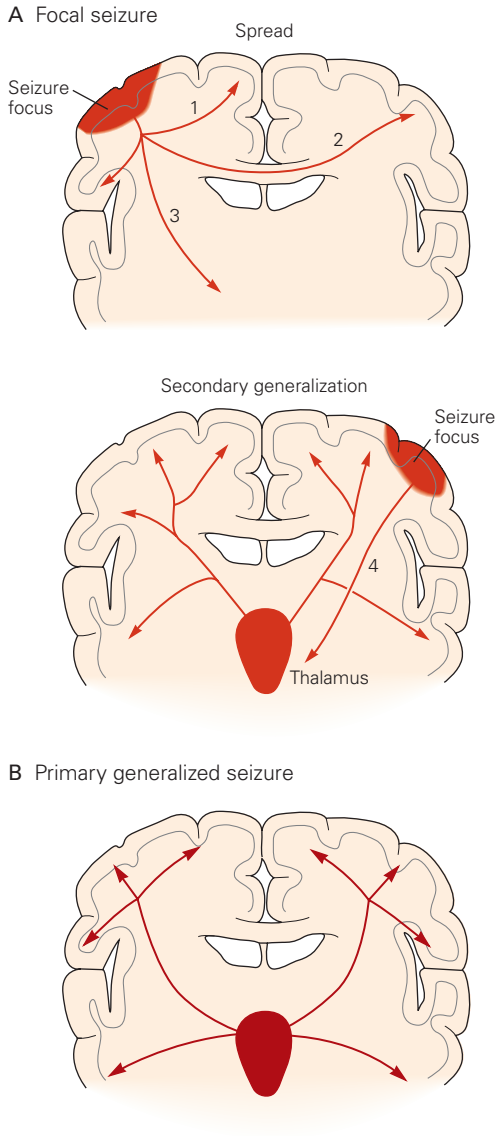

Figure 58–10 Focal and generalized onset seizures propagate via several pathways. (Adapted, with permission, from Lothman 1993b.)

A. Focal onset seizures can spread locally from a focus via intrahemispheric fibers (**1**) and more remotely to homotopic contralateral cortex (**2**) and subcortical centers (**3**). The secondary generalization of a focal onset seizure spreads to subcortical centers via projections to the thalamus (**4**). Widespread thalamocortical interconnections then contribute to rapid activation of both hemispheres.

B. In a generalized onset seizure, such as a typical absence seizure, interconnections between the thalamus and cortex are a major route of seizure propagation.

The seizure is often followed by a period of decreased electrical activity, the postictal period, which may be accompanied by symptoms of confusion, drowsiness, or even focal neurological deficits such as a hemiparesis (Todd paralysis). A neurological exam in the postictal period can lead to insights about the locus of the seizure focus when there is prolonged depression of one brain region or function, once other brain regions have regained normal function.

Generalized Onset Seizures Are Driven by Thalamocortical Circuits

Unlike the typical focal onset seizure, a generalized onset seizure abruptly disrupts normal brain activity in both cerebral hemispheres simultaneously. Generalized onset seizures and their associated epilepsies vary both in their manifestations and etiologies. Although the cellular mechanisms of generalized onset seizures differ in a number of interesting respects from those of focal onset or secondarily generalized seizures, a generalized onset seizure can be difficult to distinguish clinically or by EEG from a focal onset seizure that rapidly generalizes.

The most studied type of generalized onset seizure is the typical absence seizure (petit mal), whose characteristic EEG pattern (the 3-Hz spike-and-wave pattern in Figure 58–11A) was first recognized by Hans Berger in 1933. F. A. Gibbs recognized the relationship of this EEG pattern to typical absence seizures (he aptly described the pattern as "dart and dome") and attributed the mechanism to generalized cortical disturbance. The distinctive clinical features of typical absence seizures have a clear correlation with the EEG activity.

The typical absence seizure begins suddenly, lasts 10 to 30 seconds, and produces impaired awareness with only minor motor manifestations such as blinking or lip smacking. Unlike a focal onset seizure that secondarily generalizes, generalized onset seizures are not preceded by an aura or followed by postictal symptoms. The spike-wave EEG pattern can be seen in all cerebral areas abruptly and simultaneously and is immediately preceded and followed by normal background activity. Very brief (1–5 seconds) runs of 3-Hz EEG activity without apparent clinical symptoms are common in patients with absence seizures, but if frequent, they can affect their ability to carry out normal activities such as school performance.

In contrast to Gibbs's hypothesis of diffuse cortical hyperexcitability, Penfield and Jasper noted that the EEG in typical absence seizures is similar to rhythmic EEG activity in sleep, so-called sleep spindles (Chapter 44). They proposed a "centrencephalic" hypothesis in which generalization was attributed to rhythmic activity (pacing) by neuronal aggregates in the upper brain stem or thalamus that project diffusely to the cortex.

Research on animal models of generalized onset seizures and studies of the genetics of generalized epilepsy suggest that elements of both hypotheses are correct. In cats, parenteral injections of penicillin, a weak $GABA_A$ antagonist, produce behavioral unresponsiveness associated with an EEG pattern of bilateral synchronous slow waves (generalized penicillin epilepsy). During such a seizure, thalamic and cortical cells become synchronized through the same reciprocal thalamocortical connections that contribute to normal sleep spindles during slow-wave sleep.

Such seizures could in theory represent a form of diffuse hyperexcitability in the cortex. Recordings from individual cortical neurons show an increase in the rate of firing during a depolarizing burst that in turn produces a powerful GABAergic inhibitory feedback that hyperpolarizes the cell for approximately 200 ms after each burst (Figure 58–11C). This depolarization followed by inhibition differs fundamentally from the paroxysmal depolarizing shift in focal onset seizures in that GABAergic inhibition is preserved. In the typical absence seizure, the summated activity of the bursts produces the spike while the summated inhibition produces the wave of the spike-wave EEG pattern.

What are the properties of cells and networks that facilitate this generalized and synchronous activity? An early clue came from studies of the intrinsic bursting of thalamic relay neurons. Henrik Jahnsen and Rodolfo Llinas found that these neurons robustly express the T-type voltage-gated Ca^{2+} channel that is inactivated at the resting membrane potential but becomes available for activation when the cell is hyperpolarized (Chapter 10). A subsequent depolarization then transiently opens the Ca^{2+} channel (thus its name, T-type), and the Ca^{2+} influx generates low-threshold Ca^{2+} spikes. Consistent with the hypothesis that T-type channels contribute to absence seizures, certain anticonvulsant agents that block absence seizures, such as ethosuximide (Zarontin) and valproic acid (Depakote), also block T-type channels. T-type channels are encoded by three related genes (*Cav3.1*–*Cav3.3*), with *Cav3.1* the predominant type in the thalamus.

The circuitry of the thalamus seems ideally suited to the generation of generalized onset seizures. The pattern of thalamic neuron activity during sleep spindles suggests a reciprocal interaction between thalamic relay neurons and GABAergic interneurons in the thalamic reticular nucleus and perigeniculate nucleus (Figure 58–11B). Studies of thalamic brain slices by David McCormick and his colleagues indicate that

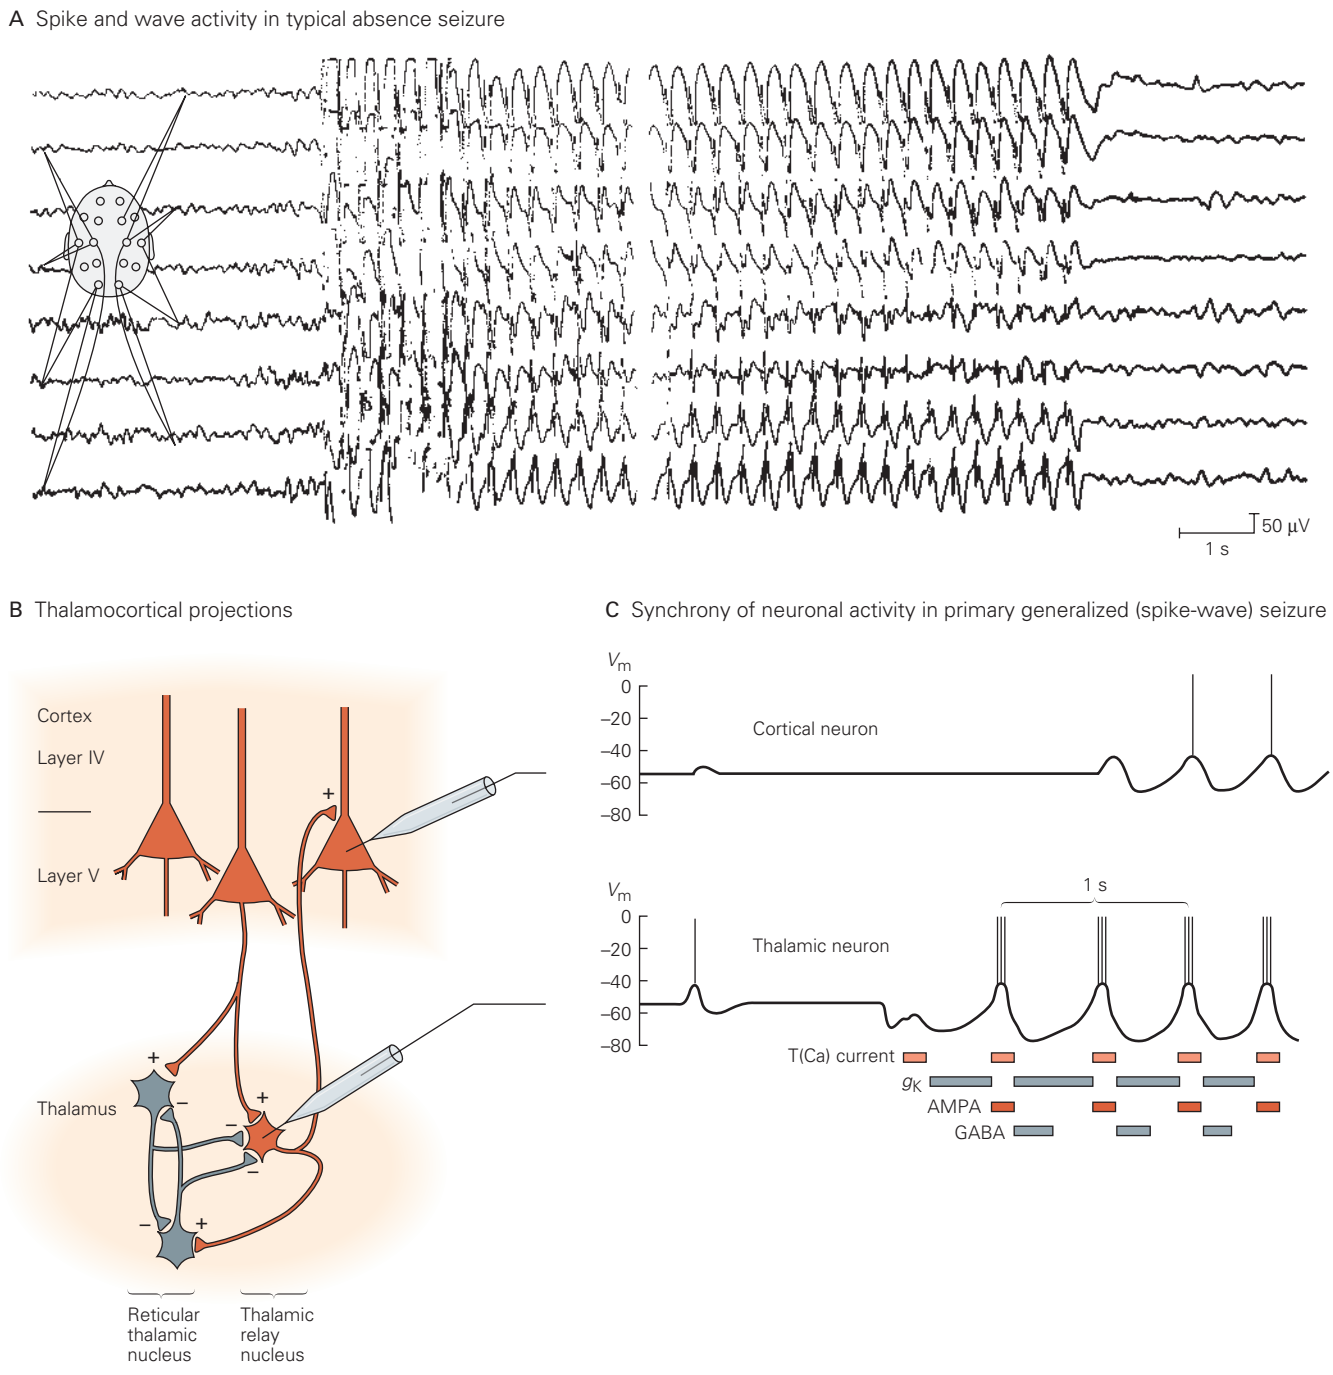

Figure 58–11 Generalized onset seizures have distinctive electroencephalogram (EEG) and single-neuron patterns.

A. This EEG from a 12-year-old patient with typical absence (petit mal) seizures shows the sudden onset of synchronous spikes at a frequency of 3 per second and wave activity lasting approximately 14 seconds. The seizure clinically manifested as a staring spell with occasional eye blinks. Unlike a focal onset seizure, there is no buildup of activity preceding the seizure and the electrical activity returns abruptly to the normal background level following the seizure. The discontinuity in the trace is due to removal of a 3-second period of recording. (Reproduced, with permission, from Lothman and Collins 1990.)

B. Thalamocortical connections that participate in the generation of sleep spindles (Chapter 44) are thought to be essential for the generation of generalized onset seizures. Pyramidal cells in the cortex are reciprocally connected by excitatory synapses with thalamic relay neurons. GABAergic inhibitory interneurons in the reticular thalamic nucleus are excited by pyramidal cells in the cortex and by thalamic relay neurons and inhibit the thalamic relay cells. The interneurons are also reciprocally connected.

C. Neuronal activity of cortical and thalamic neurons becomes synchronized during a generalized onset seizure. The depolarization is dependent on conductances in α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (**AMPA**)-type glutamate receptor-channels and T-type voltage-gated Ca^{2+} channels. The repolarization is due to γ-aminobutyric acid (**GABA**)-mediated inhibition as well as voltage- and calcium-dependent K^+ conductances (g_K). (Adapted, with permission, from Lothman 1993a.)

the interneurons hyperpolarize the relay neurons, thus removing the inactivation of T-type Ca^{2+} channels. This action leads to an oscillatory response: A rebound burst of action potentials following each IPSP to which the T-type Ca^{2+} channels contribute stimulates the GABAergic interneurons, resulting in another round of relay neuron rebound firing. The relay neurons also excite cortical neurons, manifested in the EEG by a "spindle." Both the T-type Ca^{2+} channel and the $GABA_B$ receptor-channel play an important role in the generation of this activity, which resembles human absence seizures (Chapter 44).

Mutations in voltage-gated Ca^{2+} channels have produced several mouse models of generalized epilepsy, including the so-called *totterer* mouse, which bears a mutation in the P/Q-type calcium channels involved in neurotransmitter release. Studies of these mutants by Jeffrey Noebels and his colleagues have revealed that the animals develop generalized onset seizures when they reach adolescence. EEGs in these animals show a paroxysmal spike-wave discharge and seizures that are characterized by an arrest of behavior and blockade by ethosuximide, similar to typical absence seizures in children. Thalamic neurons in these mice have elevated T-type Ca^{2+} channels that favor rebound bursting. Mutations of over 20 different genes for this phenotype have now been described in mice. Remarkably, many encode ion channel subunits or proteins involved in presynaptic transmitter release.

Locating the Seizure Focus Is Critical to the Surgical Treatment of Epilepsy

The pioneering studies of Wilder Penfield in Montreal in the early 1950s led to the recognition that removal of the temporal lobe in certain patients with focal onset seizures of hippocampal origin could reduce the number of seizures or even cure epilepsy. As surgical treatment for such patients became more common, it became clear that the surgical outcome is directly related to the adequacy of the resection. Thus, precise localization of the seizure focus in cases of focal onset seizures is essential. Electrical mapping of seizure foci originally relied on the surface EEG, which we have seen is biased toward particular sets of neurons in the cortex immediately adjacent to the skull. However, seizures intractable to conventional medical management often begin in deep structures that show little or no abnormality on the surface EEG at the onset of the seizure. Thus, the surface EEG is somewhat limited in identifying the location of the seizure focus.

The development of magnetic resonance imaging (MRI) markedly improved the noninvasive anatomical mapping of seizure foci. This technique is now routine in the evaluation of epilepsies involving the temporal lobe, but also shows increasing promise for identifying seizure foci in other locations. The scientific basis of anatomical mapping of seizure foci by MRI was the observation that a majority of patients with intractable focal onset seizures with impaired awareness have atrophy and cell loss in the mesial portions of the hippocampal formation. There is a dramatic loss of neurons within the hippocampus (mesial temporal sclerosis), changes in dendritic morphology of surviving cells, and collateral sprouting of some axons. The anatomical resolution of modern MRI machines has allowed a noninvasive, quantitative assessment of the size of the hippocampus in epilepsy patients. Loss of volume of the hippocampus on one or another side of the brain generally correlates well with the localization of seizure foci in the hippocampus as determined by functional criteria using implanted depth electrodes.

The typical patient with mesial temporal epilepsy has unilateral disease, which leads to shrinkage of the hippocampus on one side that can be associated with apparent dilatation of the temporal horn of the lateral ventricle. Such a case is illustrated in Box 58–3. However, in many patients, abnormalities cannot be detected using anatomical MRI; thus, nonanatomical (functional) imaging techniques (fMRI) are used as well (Chapter 6).

Functional neuroimaging takes advantage of the changes in cerebral metabolism and blood flow that occur in the seizure focus during the ictal and interictal periods. The electrical activity associated with a seizure places a large metabolic demand on brain tissue. During a focal onset seizure, there is an approximately three-fold increase in glucose and oxygen utilization. Between seizures, the seizure focus often shows decreased metabolism. Despite the increased metabolic demands, the brain is able to maintain normal adenosine triphosphate (ATP) levels during a focal onset seizure. On the other hand, the transient interruption of breathing during a generalized motor seizure causes a decrease in oxygen levels in the blood. This results in a drop in ATP concentration and an increase in anaerobic metabolism as indicated by rising lactate levels. This oxygen debt is quickly replenished in the postictal period, and no permanent damage to brain tissue results from a single generalized seizure.

Positron emission tomography (PET) scans of patients with focal onset seizures originating in the mesial temporal lobe frequently show interictal hypometabolism, with metabolic changes extending to the lateral temporal lobe, ipsilateral thalamus, basal ganglia, and frontal cortex. PET scans using nonhydrolyzable glucose analogs have been particularly helpful

Box 58–3 Surgical Treatment of Temporal Lobe Epilepsy

A 27-year-old woman had episodes of decreased responsiveness beginning at age 19. At first, she would stare off and appear confused during the episodes. Later, she developed an aura consisting of a feeling of fear. This fear was followed by altered consciousness, a wide-eyed stare, tightening of the left arm, and a scream that lasted for 14 to 20 seconds (Figure 58–12).

These spells were diagnosed as complex partial seizures. The seizures occurred several times a week despite treatment with several antiepileptic drugs. She was unable to work or drive due to frequent seizures. She had a history of meningitis at age 6 months, and throughout childhood she had experienced brief episodes of altered perception described as "like someone threw a switch."

Based on an evaluation summarized in Figures 58–13 and 58–14, a right amygdalohippocampectomy was performed. The patient was seizure-free following the operation and returned to full-time employment.

Figure 58–12 The patient is shown reading quietly in the period preceding the seizure (A), during the period when she reported a feeling of fear (B), and during the period when there was alteration of consciousness and an audible scream (C). (Reproduced, with permission, from Dr. Martin Salinsky.)

in identifying seizure foci in patients with normal MRI scans and in some early childhood epilepsies. Unfortunately, for unclear reasons, PET has been less reliable in localizing seizure foci in extratemporal areas such as the frontal lobe. An additional limitation is the expense of the PET scan and the short half-life of the isotopes (a nearby cyclotron is required). PET scanning can also be used to look for functional changes in neurotransmitter receptor binding and transport related to seizure activity.

A related technique that measures cerebral blood flow, single-photon emission computed tomography (SPECT), has been used more frequently than PET. SPECT does not have the resolution of PET but can be performed in the nuclear medicine department of many large hospitals. Injection of radioisotopes and SPECT imaging at the time of a seizure (ictal SPECT) reveal a pattern of hypermetabolism followed by hypometabolism in the seizure focus and surrounding tissue. Magnetoencephalography and functional MRI also offer further advantages in the mapping of seizure foci.

With rigorous selection of patients for epilepsy surgery, the cure rate for epilepsy with a well-defined

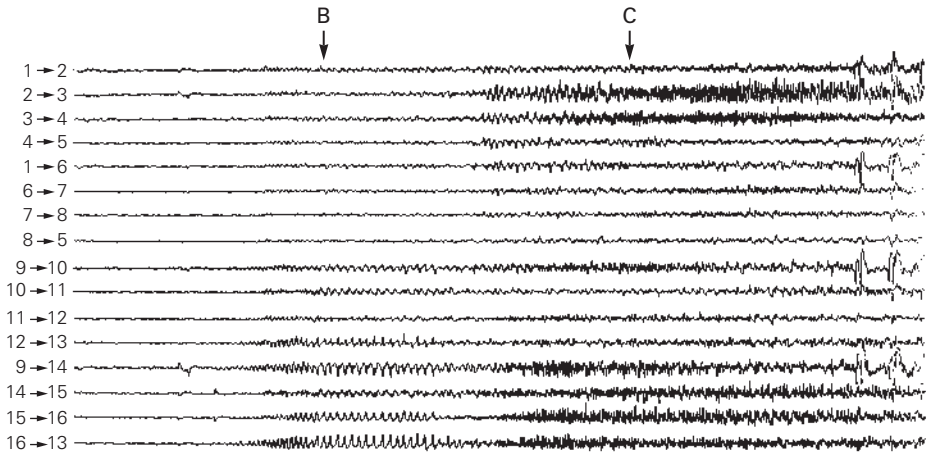

Figure 58–13 The electroencephalogram (EEG) at the time of the photographs in Figure 58–12. Low-amplitude background rhythms occur in the beginning (*left*). At the point when the patient reported fear (**B**), there is a buildup of EEG activity at the onset of a focal onset seizure with impaired awareness, but this activity is confined to the EEG electrodes over the right hemisphere (electrodes 9–16). At the point awareness is altered (**C**), the seizure activity has spread to the left hemisphere (electrodes 1–8). EEG spike-waves are particularly prominent in lead 9 over the right anterior temporal region. (Reproduced, with permission, from Dr. Martin Salinsky.)

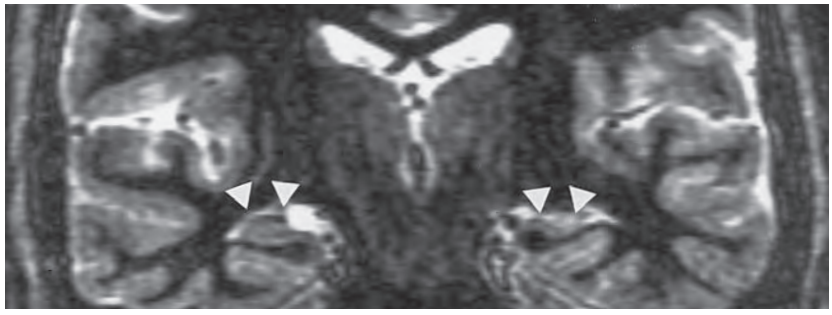

Figure 58–14 Enhanced magnetic resonance imaging reveals atrophy of the right hippocampus (arrows on the right) and a normal left hippocampus (arrows on the left). (Reproduced, with permission, from Dr. Martin Salinsky.)

seizure focus in the temporal lobe can approach 80%. Patients with complicating factors (eg, multiple foci) have lower success rates. However, even among these patients, the number and severity of seizures are usually reduced. Patients who have been "cured" of seizures may still experience cognitive problems such as memory loss and social problems such as adjustments to more independent living and limited employment opportunities. These factors emphasize the need for treatment as early in life as feasible.

Prolonged Seizures Can Cause Brain Damage

Repeated Convulsive Seizures Are a Medical Emergency

As noted above, brain tissue can compensate for the metabolic stress of a focal onset seizure or the transient decrease in oxygen delivery during a single generalized tonic-clonic seizure. In a generalized seizure, stimulation of the hypothalamus leads to massive

activation of the "stress" response of the sympathetic nervous system. The increased systemic blood pressure and serum glucose initially compensate for increased metabolic demand, but these homeostatic mechanisms fail during prolonged seizures. The resulting systemic metabolic derangements, including hypoxia, hypotension, hypoglycemia, and acidemia, lead to a reduction in high-energy phosphates (ATP and phosphocreatine) in the brain and thus can be devastating to brain tissue.

Systemic complications such as cardiac arrhythmias, pulmonary edema, hyperthermia, and muscle breakdown can also occur. The occurrence of repeated generalized seizures without return to full consciousness between seizures, called *status epilepticus*, is a true medical emergency. This condition requires aggressive seizure management and general medical support because 30 or more minutes of continuous convulsive seizures leads to brain injury or even death. Status epilepticus can involve nonconvulsive seizures for which the metabolic consequences are much less severe.

In addition to the dangers of status epilepticus, patients with poorly controlled seizures are also at risk for sudden death (sudden unexpected death in epilepsy [SUDEP]), the leading cause of death in patients with uncontrolled seizures. The underlying mechanisms for SUDEP are not completely understood, but recent studies by Richard Bagnall and colleagues as well as others suggest that cases of SUDEP have clinically relevant mutations in the genes implicated in cardiac arrhythmia and epilepsy. Such data support an association between SUDEP and cardiac arrhythmias or interruption of brain stem circuits involved in respiratory control. This topic is appropriately the focus of intense current investigation.

Excitotoxicity Underlies Seizure-Related Brain Damage

Repeated seizures can damage the brain independently of cardiopulmonary or systemic metabolic changes, suggesting that local factors in the brain can result in neuronal death. The immature brain appears particularly vulnerable to such damage, perhaps because of greater electrotonic coupling between neurons in the developing brain, less effective potassium buffering by immature glia, and decreased glucose transport across the blood–brain barrier.

In 1880, Wilhelm Sommer first noted the vulnerability of the hippocampus to such insults, with preferential loss of the pyramidal neurons in the CA1 and CA3 regions. This pattern has been duplicated in experimental animals by electrical stimulation of afferents to the hippocampus or by injection of excitatory amino acid analogs such as kainic acid. Interestingly, kainic acid causes local damage at the site of injection and also at the site of termination of afferents originating at the injection site.

These observations suggest that release of the excitatory transmitter glutamate during excessive stimulation such as a seizure can itself cause neuronal damage, a condition termed *excitotoxicity*. Because it has been difficult to detect increases in extracellular glutamate during status epilepticus, it appears that excitotoxicity results more from excessive stimulation of glutamate receptors than from tonic increases in extracellular glutamate. The histological appearance of acute excitotoxicity includes massive swelling of cell bodies and dendrites, the predominant locations of glutamate receptors and excitatory synapses.

Although the cellular and molecular mechanisms of excitotoxicity are still not fully understood, several features are clear. Overactivation of glutamate receptors leads to an excessive increase in intracellular Ca^{2+} that can activate a self-destructive cellular cascade involving calcium-dependent enzymes, such as phosphatases, proteases, and lipases. Lipid peroxidation can also cause production of free radicals that damage vital cellular proteins and lead to cell death. The role of mitochondria in Ca^{2+} homeostasis and in control of free radicals may also be important. The pattern of cell death was first thought to reflect necrosis due to the autolysis of critical cellular proteins. However, the activation of "death genes," characteristic of programmed cell death (apoptosis), may also be involved.

Seizure-related brain damage or excitotoxicity can be specific to certain types of cells in particular brain regions, perhaps due to protective factors, such as calcium-binding proteins in some cells and sensitizing factors, such as the expression of calcium-permeable glutamate receptors in other cells. For example, excitotoxicity induced in vitro by excessive activation of AMPA-type glutamate receptors preferentially affects interneurons that express AMPA-type receptors that have high Ca^{2+} permeability, providing a possible mechanism for their selective vulnerability.

Several outbreaks of "amnestic" shellfish poisoning provide a vivid example of the consequences of overactivation of glutamate receptors. Domoic acid, a glutamate analog not present in the brain, is a natural product of certain species of marine algae that flourish during appropriate ocean conditions. Domoic acid can be concentrated by filter feeders such as shellfish. Ingestion of domoic-contaminated shellfish sporadically causes outbreaks of neurological damage, including severe seizures and memory loss (amnesia).

The area most sensitive to damage is the hippocampus, providing further support for the excitotoxicity hypothesis and the critical role of the hippocampus in learning and memory.

The Factors Leading to Development of Epilepsy Are Poorly Understood

A single seizure does not warrant a diagnosis of epilepsy. Normal people can have a seizure under extenuating circumstances such as after drug ingestion or extreme sleep deprivation. Clinicians look for possible causes of seizures in such patients but usually do not begin treatment with anticonvulsants following a single seizure. Unfortunately, our understanding of what factors contribute to susceptibility to epilepsy is still rudimentary. However, progress on this front is increasing rapidly with the advent of experimental mutagenesis in animal models and clinical neurogenetics in patients including whole-exome sequencing.

Some forms of epilepsy have long been considered to result in part from a genetic predisposition. For example, infants with febrile seizures often have a family history of similar seizures. The role of genetics in epilepsy is supported by the existence of familial epileptic syndromes in humans as well as seizure-prone animal models with such exotic names as *Papio papio* (a baboon with photosensitive seizures), audiogenic mice (in which loud sounds induce seizures), and spontaneous single-locus mutations such as *reeler* and *totterer* mice (names alluding to the clinical manifestations of cerebellar mutations in these animals). Even with a genetic predisposition or a structural lesion, the evolution of the epileptic phenotype often involves maladaptive changes in brain structure and function.

Mutations in Ion Channels Are Among the Genetic Causes of Epilepsy

Recent studies have provided a wealth of new information concerning the molecular genetics of epilepsy. At present, more than 120 genes have been linked to an epileptic phenotype; approximately half of these were discovered in humans and the others in animals, mostly mice. The affected proteins include ion channel subunits, proteins involved in synaptic transmission such as transporters, vesicle proteins, synaptic receptors, and molecules involved in Ca^{2+} signaling. For example, seizures in the *totterer* mutant mouse are due to a spontaneous mutation in the gene that encodes the $Ca_V2.1$ or α_{1A}-subunit of the P/Q-type voltage-gated Ca^{2+} channel. That a mutation in these classes of proteins can cause epilepsy is perhaps not unexpected given the dependence of seizures on synaptic transmission and neuronal excitability.

Some of the other genes linked to epilepsy in mice have been more surprising, such as the genes for centromere BP-B, a DNA binding protein, and the sodium/hydrogen exchanger, which is affected in the slow-wave epilepsy mouse. A wide variety of human genes cause neurological disorders, of which epilepsy is only one manifestation. For example, Rett syndrome, a disease associated with intellectual disability, autism, and seizures, is caused by mutations in *MECP2* (methyl-CpG-binding protein-2), a regulator of gene transcription. Although the exact links are not known, it is clear that mutations in many different genes may result in epilepsy.

In most cases, genetic epilepsy syndromes in humans have complex rather than simple (Mendelian) inheritance patterns, suggesting the involvement of many, rather than single, genes. Nevertheless, a number of monogenic epilepsies have been identified in studies of families with epilepsy. Ortrud Steinlein and colleagues reported in 1995 that a mutation in the α4-subunit of the nicotinic acetylcholine receptor-channel is responsible for autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE), the first example of an autosomal gene defect in human epilepsy. Subsequently, other voltage- and ligand-gated channel proteins have been identified as critical genes for epilepsy. Mutations in ion channel genes (channelopathies) constitute a major cause of known monogenic epilepsies (Figure 58–15). Many more genes are being discovered by clinical exome analysis for de novo mutations. The large number of genes for K^+ channels and the critical role of these channels in balancing excitation and inhibition are important reasons for the expanding epilepsy genome.

In voltage-gated channels, mutations largely involve the main pore-forming subunit(s), but there are also examples of epilepsy-causing mutations in regulatory subunits. When examined in vitro, the mutant channel proteins are most commonly associated with either reductions in the expression of the channel on the surface of the plasma membrane (due to reduced targeting to the membrane or premature degradation) or altered kinetics of the channels. It is straightforward to consider how changes in ion channel gating might affect the excitability of neurons and their synchronization during seizure generation. However, ion channel mutations may also affect neuronal development and thus exert their epileptogenic effects through a

	Channel	Subunits affected	Epilepsy
a	Voltage-gated Na^+	Na_V 1.1, Na_V 1.2, β1	Generalized epilepsy with febrile seizures plus (GEFS+) Severe myoclonic epilepsy of infancy Benign infantile epilepsy
	Voltage-gated K^+	K_V 1.1	Temporal lobe epilepsy
	Ca^{2+}-activated K^+	Ca_V 1.1	Absence epilepsy
b	$GABA_A$ receptor	α1, β3, γ2	GEFS+ Juvenile myoclonic epilepsy Childhood absence epilepsy
	M-type K^+	KCNQ2/3	Benign neonatal epilepsy
	Voltage-gated Ca^{2+}	Ca_V 2.1	Absence epilepsy
	Cl^-	CLCN2	Juvenile myoclonic epilepsy

Figure 58–15 **Channelopathies are a major, but not the only, cause of monogenic human epilepsies.** The human epilepsy genes discovered so far can affect multiple phases of synaptic transmission including the migration of interneurons (**1**), upstream activation of interneurons (**2**), γ-aminobutyric acid (GABA) levels within interneurons (**3**), the excitability of excitatory and inhibitory neurons (**4**), the release of neurotransmitters (**5**), and the postsynaptic response to neurotransmitters (**6**). The inset shows that the impact of mutations in these genes on neuronal excitability can affect the shape of the action potential as well as the afterpotentials and synaptic events that follow. Mutations indicated near the spike (**a**) affect the repolarization of the action potential. Other mutations shown in (**b**) affect the afterhyperpolarization, synaptic conductances, or interspike interval.

secondary action on cell migration, network formation, or patterns of gene expression.

In the early days of research on epilepsy genes, it was widely expected that the genes would mostly underlie generalized epilepsies, based on the idea that a gene mutation (eg, in an ion channel) would be expected to affect most neurons. However, the very first autosomal dominant epilepsy gene discovered by Steinlein and colleagues caused a focal onset (frontal lobe) epilepsy, and another gives rise to seizures originating in the temporal lobe with an auditory aura. In retrospect, this should not be so surprising because channel subunits are rarely expressed uniformly in the brain, and some brain regions are more likely to generate seizures than other regions.

Timing of gene expression is also important. For example, *totterer* mice with mutations in the pore-forming $Ca_V2.1$ subunit of P/Q-type Ca^{2+} channels show spike-wave–type seizures that begin in the third postnatal week, presumably because N-type Ca^{2+} channels are the predominant functional isoform earlier in development, whereas P/Q-type Ca^{2+} channels predominate later. The neurological phenotype begins once the mutant channel is functionally required during development.

Moreover, one mutation can give rise to different epilepsy phenotypes, or different mutant genes can cause the same epilepsy phenotype. As an example of the latter, the ADNFLE syndrome, first discovered as a mutation in the α4-subunit of the nicotinic

ACh receptor, can also be caused by a mutation in the α2-subunit. But not all family members who carry this autosomal dominant mutation have epilepsy, indicating that even in this form of monogenic epilepsy other genes as well as nongenetic factors can influence the phenotype. The GEFS+ syndrome (generalized epilepsy with febrile seizures plus) is a good example of this heterogeneity. It is a childhood syndrome and can involve different seizure types in different family members. GEFS+ is seen in families with mutations in the genes for one of three different Na^+ channel subunits or one of two $GABA_A$ receptors. Family studies of generalized onset epilepsy suggest that seizure types may be heritable within families. These findings indicate that even monogenic epilepsies are likely modified by other genes, environmental influences, and even experience-dependent changes in synapses.

Altered cortical development may be a common cause of epilepsy. The increased resolution of MRI scans has revealed an unexpectedly large number of cortical malformations and localized areas of abnormal cortical folding in patients with epilepsy. Thus, mutations that disturb the normal formation of the cortex or network wiring are candidate genes for epilepsy. This idea is supported by the mapping of two X-linked cortical malformations with epileptic phenotypes: familial periventricular heterotopia and familial subcortical band heterotopia. The genes responsible for these two disorders that encode filamin A and doublecortin, respectively, are presumably important in neuronal migration. Small focal cortical dysplasias can function as seizure foci that give rise to partial and secondarily generalized seizures, whereas more extensive cortical malformations can cause a variety of seizure types and usually are associated with other neurological problems.

Another X-linked gene, *aristaless related homeobox* (*ARX*), is an example of a cell type–specific transcription factor altering migration, because it is expressed only in interneuron precursors. A particularly instructive example is the association of epilepsy with tuberous sclerosis complex (TSC), an autosomal dominant genetic disorder that results from the lack of the functional Tsc1-Tsc2 complex, leading to hyperactivity of the mammalian target of rapamycin (mTOR) complex 1 (mTORC1) signaling pathway. Early clinical trials of mTOR inhibitors as treatment for refractory epilepsy in these patients have been promising. Such examples provide hope for linking the underlying biology of epilepsy syndromes to clinically relevant treatments.

The epilepsy genome is rapidly expanding, driven by clinical exome sequencing and an appreciation of the biological pathways leading to neural network instability. Unfortunately, the vast majority of cases of epilepsy cannot yet be explained by even the recent surge in the identification of epilepsy genes. The identification of large numbers of patients through online registries may provide the population samples needed to evaluate susceptibility genes that underlie complex inheritance patterns.

The Genesis of Acquired Epilepsies Is a Maladaptive Response to Injury

Epilepsy often develops following a discrete cortical injury such as a penetrating head wound. This injury serves as the nidus for a seizure focus, leading at some later point to seizures. This has led to the idea that the early insult triggers a set of progressive physiological or anatomical changes that lead to chronic seizures. That is, the characteristic "silent" interval (usually months or years) between the insult and the onset of recurrent seizures may reflect progressive maladaptive molecular and cellular changes that might be amenable to therapeutic manipulation. Although an attractive hypothesis, a unified picture of this process has yet to emerge. The most promising evidence has come from studies of tissue removed from patients undergoing temporal lobectomy and rodent models of limbic seizures.

In one experimental model, hyperexcitability is induced by repeated stimulation of limbic structures, such as the amygdala or hippocampus. The initial stimulus is followed by an electrical response (the afterdischarge) that becomes more extensive and prolonged with repeated stimuli until a generalized seizure occurs. This process, called *kindling*, can be induced by electrical or chemical stimuli. Many investigators believe that kindling may contribute to the development of epilepsy in humans.

Kindling is thought to involve synaptic changes in the hippocampal formation that resemble those important in learning and memory (Chapters 53 and 54). These include short-term changes in excitability and persistent morphological changes, including generation of adult-born neurons, axonal sprouting, and synaptic reorganization. Rearrangements of synaptic connections have been observed in the dentate gyrus of patients with long-standing temporal lobe seizures as well as following kindling in experimental animals. In addition to axonal sprouting (Figure 58–16), changes include alterations in dendritic structure, control of transmitter release, and novel expression and alterations in subunit stoichiometry of ion channels and pumps.

The long-term changes that lead to epilepsy also are likely to involve specific patterns of gene

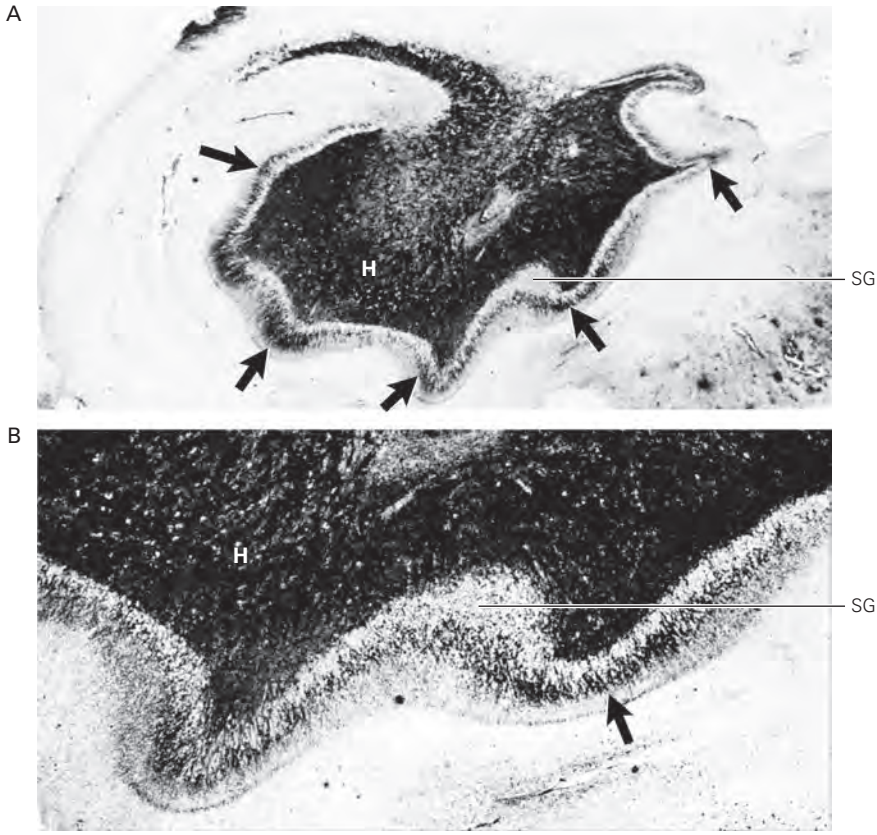

Figure 58–16 Mossy fiber synaptic reorganization (sprouting) in the human temporal lobe may cause hyperexcitability. (Reproduced, with permission, from Sutula et al. 1989. Copyright © 1989 American Neurological Association.)

A. Timm stain of a transverse section of hippocampus removed from a patient with epilepsy at the time of temporal lobectomy for control of epilepsy. The stain appears black in the axons of the dentate granule cells (mossy fibers) due to the presence of zinc in these axons. The mossy fibers normally pass through the dentate hilus (**H**) on their way to synapse on CA3 pyramidal cells. In the epileptic tissue shown here, stained fibers appear in the supragranular layer of the dentate gyrus (**SG, arrowheads**), which now contains not only the granule cell dendrites but also newly sprouted mossy fibers. These aberrant sprouts of mossy fibers form new recurrent excitatory synapses on dentate granule cells.

B. This high magnification of a segment of the supragranular layer shows the Timm-stained mossy fibers in greater detail.

expression. For example, the proto-oncogene c-*fos* and other immediate early genes as well as growth factors can be activated by seizures. Because many immediate early genes encode transcription factors that control other genes, the gene products that result from epileptiform activity could initiate changes that contribute to or suppress the development of epilepsy by altering such mechanisms as cell fate, axon targeting, dendritic outgrowth, and synapse formation.

Highlights

1. Seizures are one of the most dramatic examples of the collective electrical behavior of the mammalian brain. The distinctive clinical pattern of partial seizures and generalized seizures can be attributed to the distinctly different patterns of activity of cortical neurons.
2. Studies of focal onset seizures in animals reveal a series of events—from the activity of neurons in the seizure focus to synchronization and subsequent spread of epileptiform activity throughout the cortex. The gradual loss of GABAergic surround inhibition is critical to the early steps in this progression. In contrast, generalized onset seizures are thought to arise from activity in thalamocortical circuits, perhaps combined with a general abnormality in the membrane excitability of all cortical neurons.
3. The electroencephalogram (EEG) has long provided a window on the electrical activity of the cortex, both in normal phases of arousal and during abnormal activities such as seizures. The EEG

can be used to identify certain electrical activity patterns associated with seizures, but it provides limited insight into the pathophysiology of seizures. Several much more powerful and noninvasive approaches are now available to locate the focus of a partial seizure. This has led to the widespread and successful use of epilepsy surgery for selected patients, particularly those with complex partial seizures of hippocampal onset. The promise of invasive approaches to seizure detection and seizure prevention provides additional hope for improved control of seizures.

4. The increasing power of genetic, molecular, and modern cell-physiological approaches applied to the study of seizures and epilepsy also gives new hope that an understanding of these disruptions of normal brain activity will provide new therapeutic options for patients afflicted with epilepsy, as well as new insights into the function of the mammalian brain.
5. Further neurobiological studies of the progression from an acute seizure to the development of epilepsy should provide alternative strategies for treatment beyond the standard options of anticonvulsants or epilepsy surgery.

Disorders of Conscious and Unconscious Mental Processes

Although cognitive neuroscience emerged at the end of the 20th century as a major new discipline, a precise meaning of the term *cognition* remains elusive. The term is used in different ways in different contexts. At one extreme, the term *cognitive* in cognitive neuroscience connotes what was meant by the older term *information processing*. In this sense, cognition is simply what the brain does. When cognitive neuroscientists say that visual features or motor acts are *represented* by neural activity, they are using concepts from information processing. From this point of view, the language of cognition provides a bridge between descriptions of neural activity and behavior because the same terms can be applied in both domains.

At the other extreme, the term *cognition* refers to those higher-level processes fundamental to the formation of conscious experience. This is what is meant by the term *cognitive therapy*, an approach to treatment pioneered by Aaron Beck and Albert Ellis and developed from behavior therapy. Rather than trying to change a patient's behavior directly, cognitive therapy has the aim of changing the patient's attitudes and beliefs (Box 59–1).

In common parlance, the term *cognition* means thinking and reasoning, a usage closer to its Latin root *cognoscere* (getting to know or perceiving). Thus, the *Oxford English Dictionary* defines it as "the action or faculty of knowing." Indeed, we know the world by applying thinking and reasoning to the raw data of our senses.

This idea is implicit in our characterization of many kinds of disorders of cognition. After brain damage, some patients can no longer process the input supplied by the senses. This type of disorder was first delineated by Sigmund Freud, who called it agnosia, or loss of knowledge (Chapter 17). Agnosias can take many forms. A patient with visual agnosia can see perfectly well but is no longer able to recognize or make sense of what he sees. A patient with prosopagnosia has a specific problem recognizing faces. A patient with auditory agnosia might hear perfectly well but is unable to recognize spoken words.

Cognition is sometimes impaired from birth so that a person has difficulty in acquiring knowledge. This might lead to general mental retardation or, if the problem is more localized, to specific learning difficulties such as dyslexia (difficulty learning about written

Box 59–1 Cognitive Therapy

Dissatisfaction with psychological treatments based on Freud's theories of unconscious motivation intensified in the middle of the 20th century. Not only did these theories have no relevance to experimental psychology, but there was no empirical evidence that psychodynamic treatments actually worked.

The first form of alternative psychological therapy to emerge from laboratory studies is known as *behavior therapy*. The fundamental assumption of this approach is that maladaptive behavior is learned and can therefore be eliminated by applying the Pavlovian and Skinnerian principles of stimulus-response learning. So, for example, a child who has been attacked by a dog can become fearful of all dogs, but this fearful response can be extinguished if the child learns that the conditioned stimulus (the sight of a dog) is not followed by the unconditioned stimulus (being bitten).

Behavior therapy was shown to be quick and effective for phobias, but many mental disorders are better characterized in terms of maladaptive thinking rather than maladaptive behavior. In the 1960s, Aaron Beck and Albert Ellis initiated a new kind of therapy in which the principles of learning are used to change thoughts rather than behavior. This is known as *cognitive therapy* or *cognitive behavior therapy*.

This form of therapy has been particularly successful in the treatment of depression. Depression is typically associated with negative thoughts (eg, a person remembering only the bad things that have happened to him/her) and negative attitudes (eg, a person believing that he/she will never achieve his/her goals). Cognitive therapists teach their clients methods for reducing the frequency of negative thoughts and changing their negative attitudes into positive ones.

language) or autism (difficulty in learning about other minds). Finally, cognition can become dysfunctional so that the knowledge acquired about the world is false. These disorders of thinking lead to the sort of false perceptions (hallucinations) and false beliefs (delusions) associated with major mental illnesses such as schizophrenia.

Conscious and Unconscious Cognitive Processes Have Distinct Neural Correlates

Cognition—deriving knowledge through thinking and reasoning—is one of three components of consciousness (see Chapter 42 for discussion of the conscious aspects of emotions, often called feelings). The other two are emotion and will. It used to be taken for granted that thinking and reasoning were under conscious voluntary control and that cognition was not possible without consciousness. By the end of the 19th century, however, Freud developed a theory of unconscious mental processes and suggested that much human behavior is guided by internal processes of which we are not aware.

Of more direct importance for neuroscience was the idea of *unconscious inference*, originally proposed by Helmholtz. Helmholtz was the first to carry out quantitative psychophysical experiments and to measure the speed with which afferent signals in peripheral nerves are conducted. Prior to these experiments, sensory signals were assumed to arrive in the brain immediately (with the speed of light), but Helmholtz showed that nerve conduction was actually quite slow. He also noted that reaction times were even slower. These observations implied that a great deal of brain work intervened between sensory stimuli and conscious perception of an object. Helmholtz concluded that much of what goes on in the brain is not conscious and that what does enter consciousness (ie, what is perceived) depends on unconscious inferences. In other words, the brain uses evidence from the senses to decide on the most likely identity of the object that is causing activity in the sensory organs but does this without our awareness.

This view was extremely unpopular with Helmholtz's contemporaries and, indeed, still is today. Most people believe that consciousness is necessary for making inferences and that moral responsibility can be assigned only to decisions that are based on conscious inference. If inferences could be made without consciousness, there could be no ethical basis for praise or blame. Helmholtz's ideas about unconscious inferences were largely ignored.

Nevertheless, by the middle of the 20th century, evidence began to accumulate in favor of the idea that most cognitive processing never enters consciousness. After the development of electronic computers and the emergence of the study of artificial intelligence, researchers began to study how, and to what extent, machines could perceive the world beyond themselves.

It rapidly became clear that many perceptual processes that at first seem simple are actually very complex when defined as a set of computations.

Visual perception is the prime example. In the 1960s, almost no one realized how difficult it would be to build machines that could recognize the shape and appearance of objects, because it seems so easy for us. I look out of the window and I see buildings, trees, flowers, and people. I am not aware of any mental processes behind this perception; my awareness of all these objects seems instantaneous and direct. It turns out that teaching a machine how to work out which edges go with which object in a typical cluttered visual scene containing many overlapping objects is exceptionally difficult. The computational approach to vision revealed the underlying neural processes on which our seemingly effortless perception of the world depends. Similar processes underlie all sensory perception and especially the perception of sounds as speech. Most neuroscientists now believe that we are not conscious of cognitive processes, only our perceptions.

The evidence for unconscious cognitive processes comes not only from artificial intelligence studies but also studies of cognition in people with brain damage. The effects of unconscious processes on behavior can be demonstrated most strikingly in certain patients with "blind sight," a disorder first delineated in the 1970s by Lawrence Weiskrantz. These patients have lesions in the primary visual cortex and claim to see nothing in the part of the visual field served by the damaged area. Nevertheless, when asked to guess, they are able to detect simple visual properties such as movement or color far better than is expected by chance. Despite having no sensory-based perception of objects in the blind parts of the visual field, these patients do possess unconscious information about the objects, and this information is available to guide their behavior.

Another example is unilateral neglect caused by lesions in the right parietal lobe (Chapter 17). Patients with this disorder have normal vision, but they seem unware of objects on the left side of the space in front of them. Some patients even ignore the left side of individual objects. In one experiment by John Marshall and Peter Halligan, patients were shown two drawings of a house. The left side of one house was on fire (Figure 59–1). When asked if there were any differences between the houses, patients replied "no." But when asked which house they would prefer to live in, they chose the house that was not burning. This choice was thus made based on information that was not represented in consciousness. Blind sight and unilateral neglect are just two examples of the abundant empirical evidence for the existence of unconscious cognitive processes, evidence not available to us through introspection.

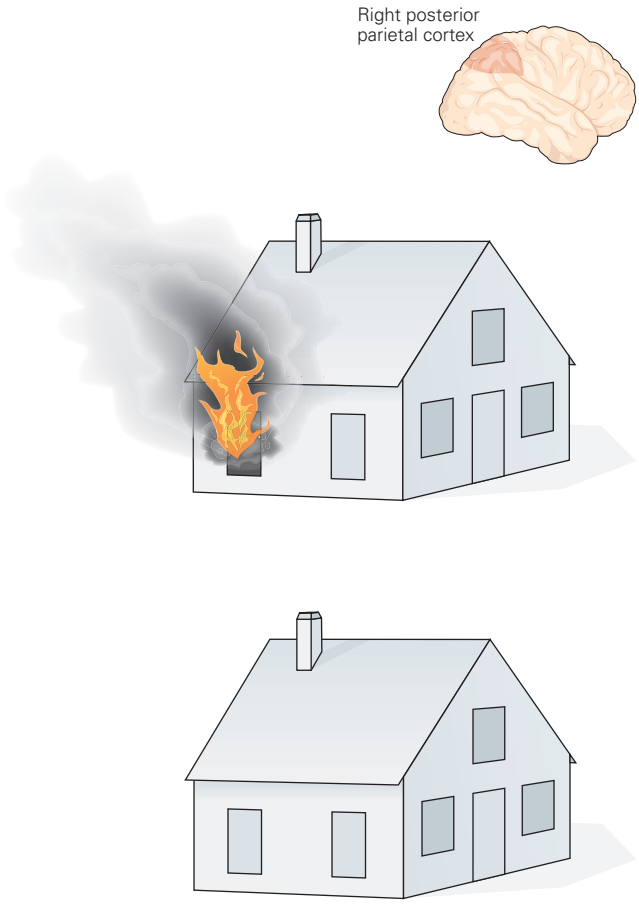

Figure 59–1 Unconscious processing in cases of spatial neglect. After damage to the right parietal lobe, many patients seem to be unaware of the left side of space (unilateral neglect syndrome). When such patients are shown the two drawings reproduced here, they say that the two houses look the same. However, they also say that they would prefer to live in the lower house, indicating that they have unconsciously processed the image of the fire in the other house. (Adapted from Marshall and Halligan 1988.)

Currently, one of the most exciting areas of investigation in neuroscience concerns the search for the *neural correlates of consciousness* initiated by Francis Crick and Christopher Koch. The aim is to demonstrate qualitative differences between the neural activity associated with conscious and unconscious cognitive processes. This research is important not only because it may give us answers to the difficult question of the function of consciousness but also because it is relevant to our understanding of many neurological and psychiatric disorders. The weird experiences

and delusional beliefs of patients with certain cognitive disorders were once dismissed as beyond understanding. Cognitive neuroscience provides us with a framework for understanding how these experiences and beliefs can arise from specific alterations in normal cognitive mechanisms.

Differences Between Conscious and Unconscious Processes in Perception Can Be Seen in Exaggerated Form After Brain Damage

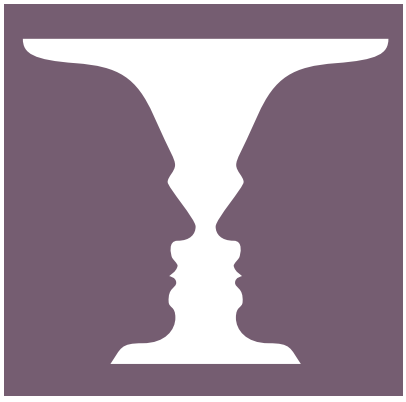
The relationship between sensory stimulation and perception is far from direct. Perception can change without any change in sensory stimulation, as illustrated by ambiguous figures such as the Rubin figure and the Necker cube (Figure 59–2). Conversely, a big change in sensory stimulation can occur without the observer being aware of this change—the perception remains constant. A compelling example of this is change blindness.

To demonstrate change blindness, two versions of a complex scene are constructed. In one well-known example developed by Ron Rensink, the picture consists of a military transport plane standing on an airport runway. In one of the two versions, an engine is missing. If these two pictures are shown in alternation on a computer screen, but critically interspersed with a blank screen, it can take minutes to notice the difference even though it is immediately obvious when pointed out. (See Figure 25-8 for another example.)

In light of these phenomena, we can explore the neural activity associated with changes in perception when there is no change in sensory stimulation. Likewise, we can discover whether changes in sensory input are registered in the brain even if not represented in consciousness. We can ask whether there is some qualitative difference between the neural activity associated with conscious as opposed to unconscious processes.

Two important results have emerged from studies of the neural activity associated with specific types of conscious percepts. First, certain kinds of percepts are related to neural activity in specific areas of the brain. Those brain areas that are specialized for recognition of certain kinds of objects (eg, faces, words, landscapes) or for certain visual features (eg, color, motion) are more active when the object or the feature is consciously perceived (Figure 59–3). For example, when we perceive the faces in the Rubin figure, there is more activity in the area of the fusiform gyrus, which is specialized for the processing of faces.

This observation also applies to deviant perception (hallucinations). After degeneration of the peripheral visual system leading to blindness, some patients experience intermittent visual hallucinations (Charles Bonnet syndrome). These hallucinations vary from one patient to another: Some patients see colored patches, others see grid-like patterns, and some even see faces. Dominic ffytche found that these hallucinations are associated with increased activity in the secondary visual cortex, and the content of the hallucination is related to the specific locus of activity (Figure 59–4). Schizophrenic patients frequently experience complex auditory hallucinations, which usually have the form of voices talking to or about the patient. These



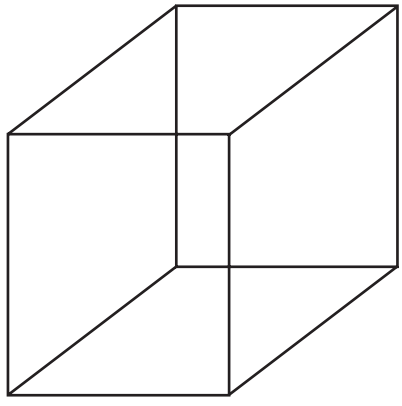


Figure 59–2 Ambiguous figures. If you stare at the figure on the left (the Rubin figure), you sometimes see a vase and sometimes two faces looking at each other. If you stare at the figure on the right (the Necker cube), you see a three-dimensional cube, but the front face of the cube is sometimes seen at the bottom left and sometimes at the top right. In each figure, the brain finds two equally good, but mutually exclusive, interpretations of what is there. Our conscious perception spontaneously alternates between these two interpretations.

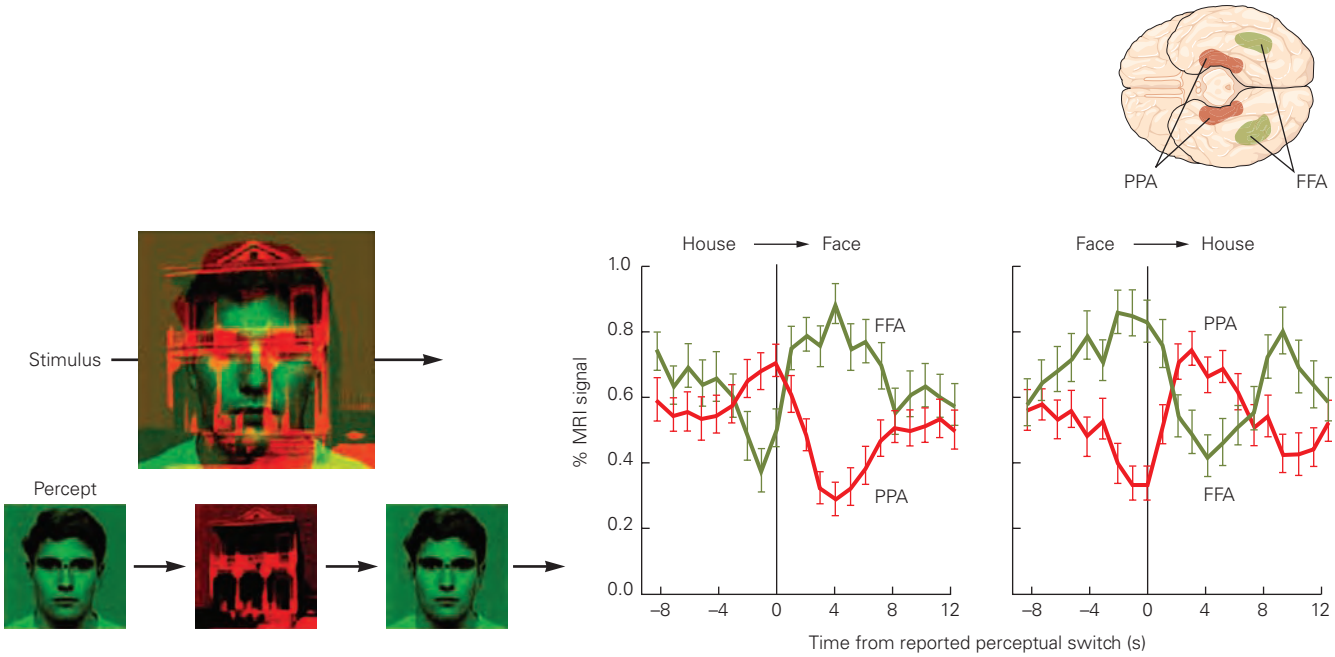

Figure 59–3 Neural activity associated with ambiguous visual information. An ambiguous stimulus was created by simultaneously presenting a face to one eye and a house to the other eye. Brain activity was measured while subjects observed these images. Subjects were instructed to press a button whenever a spontaneous switch in perception occurred (because of binocular rivalry). When the face is perceived (*left*), activity increases in the fusiform face area (**FFA**); when the house is perceived (*right*), activity increases in the parahippocampal place area (**PPA**). (Abbreviation: **MRI**, magnetic resonance imaging.) (Reproduced, with permission, from Tong et al. 1998. Copyright © 1998 by Cell Press.)

hallucinations are associated with activity in the auditory cortex.

These observations suggest that conscious experience may result from activity in certain cortical regions. This idea is difficult to test experimentally, but in the 1950s, the neurosurgeon Wilder Penfield found that electrical stimulation of the cortex in patients undergoing neurosurgery can generate a conscious experience. More recently, it has been found that transcranial magnetic stimulation of the cortex in the region of V5/MT can lead to seeing moving light flashes.

The second important conclusion drawn from studies that seek to correlate neural activity and specific percepts is that activity in a specialized area is necessary but not sufficient to yield conscious experience. For example, in the change blindness paradigm, subjects are often unaware of large changes in the picture they are viewing. If the change involves a face, activity is elicited in the fusiform gyrus whether or not the subject is aware of the change. But when the sensory change is also perceived consciously, there is, in addition, activity in the parietal and frontal cortices (Figure 59–5).

These observations are relevant to our understanding of unilateral neglect. Since objects on the left side still elicit neural activity in the visual cortex, it may be that the damage in the right parietal cortex simply prevents the formation of *conscious* representations of objects on the left side of space. Nevertheless, this sensory activity can support an unconscious inference in patients that they would not want to live in the house that is burning on the left side.

Stimuli that do not enter awareness can also elicit overt responses. A face with a fearful expression elicits a fear response in the autonomic nervous system, measured as an increase in skin conductance (galvanic response) because of sweating. This response occurs even if the face is immediately followed by another visual stimulus, such that the face is not consciously perceived. There may be an advantage to having a rapid but low-resolution system for recognizing dangerous things. We jump first; only later, on the basis of a slow, high-resolution system, are we able to identity the object that made us jump (Chapter 48). Damage in one or the other of these two recognition systems can explain certain otherwise puzzling neurological and psychiatric disorders.

Prosopagnosia is a perceptual disorder in which faces are no longer recognizable. The patient knows

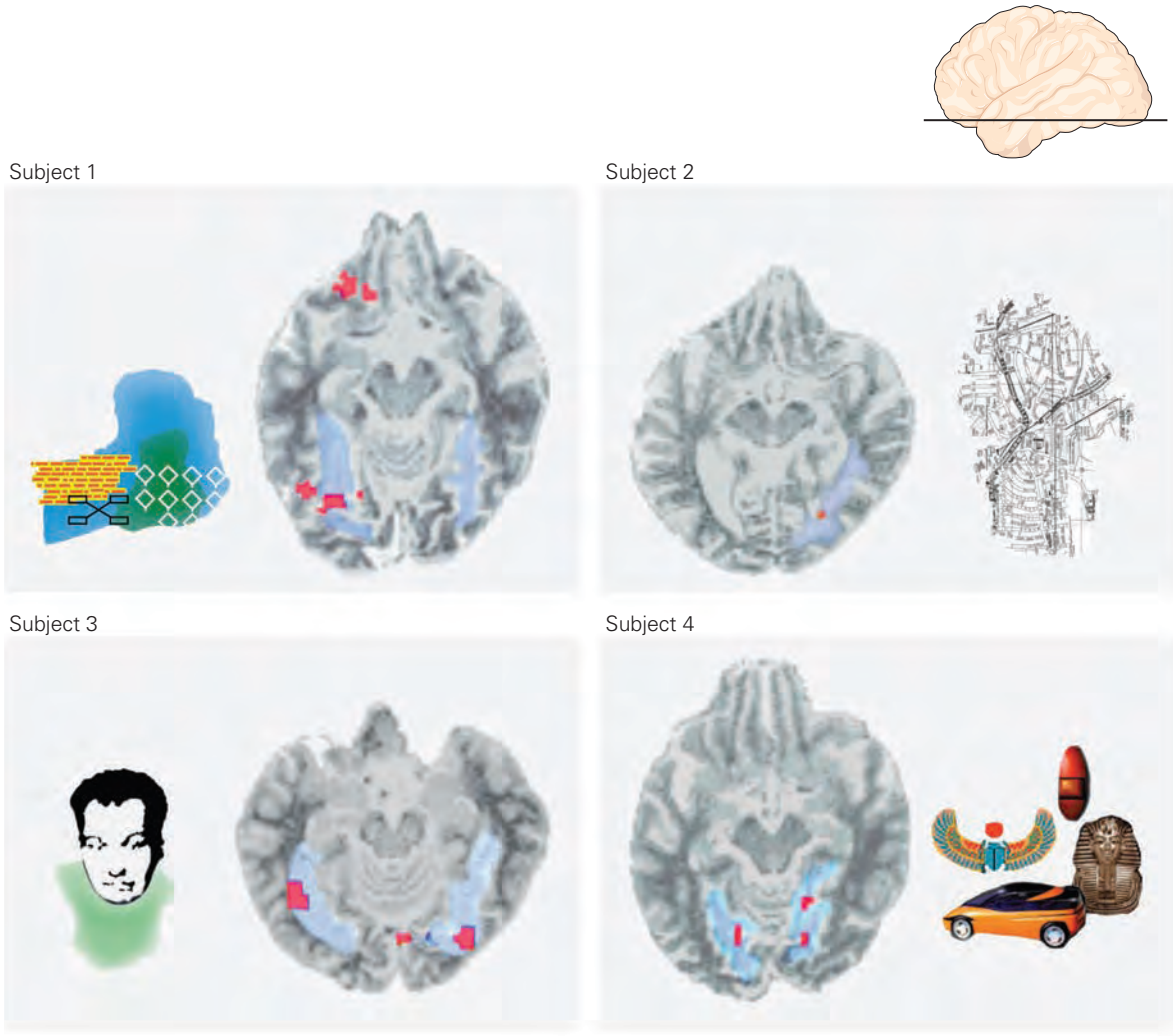

Figure 59–4 Neural activity associated with visual hallucinations. Some patients with damage to the retina experience visual hallucinations. The location of the neural activity and the content of the hallucination are related. The experience of colors, patterns, objects, or faces is associated with heightened activity (**red**) in specific regions of inferior temporal cortex. The **blue** area is the fusiform gyrus. (Reproduced, with permission, from ffytche et al. 1998. Copyright © 1998 Springer Nature.)

he is looking at a face but cannot recognize the face, even a beloved face known for years. The problem is specific to faces, since the patient may still be able to recognize the person from their clothes, gait, and voice. However, patients with prosopagnosia are able to identify faces unconsciously. They show autonomic responses to familiar faces and do better than chance when asked to guess whether or not a face shown to them belongs to a person who is familiar. In fact, their awareness of the autonomic (emotional) responses elicited by a face may enable them to judge familiarity.

Capgras syndrome, a delusion that is occasionally observed in schizophrenic patients and in some patients suffering from brain injury or dementia, produces a more unsettling experience. These patients firmly believe that someone close to them, usually a husband or wife, has been replaced by an impostor. They claim that the person, although similar if not identical in appearance, is in fact someone else. Often, this delusion is acted on with the demand that the impostor leave the house.

Hadyn Ellis and Andy Young have suggested that this bizarre delusion is the mirror phenomenon of prosopagnosia. According to this view, the circuitry for face recognition is intact, but the circuitry that mediates the emotional response to the face is not. As a result, patients recognize the person in front of them but, because the emotional response is lacking,

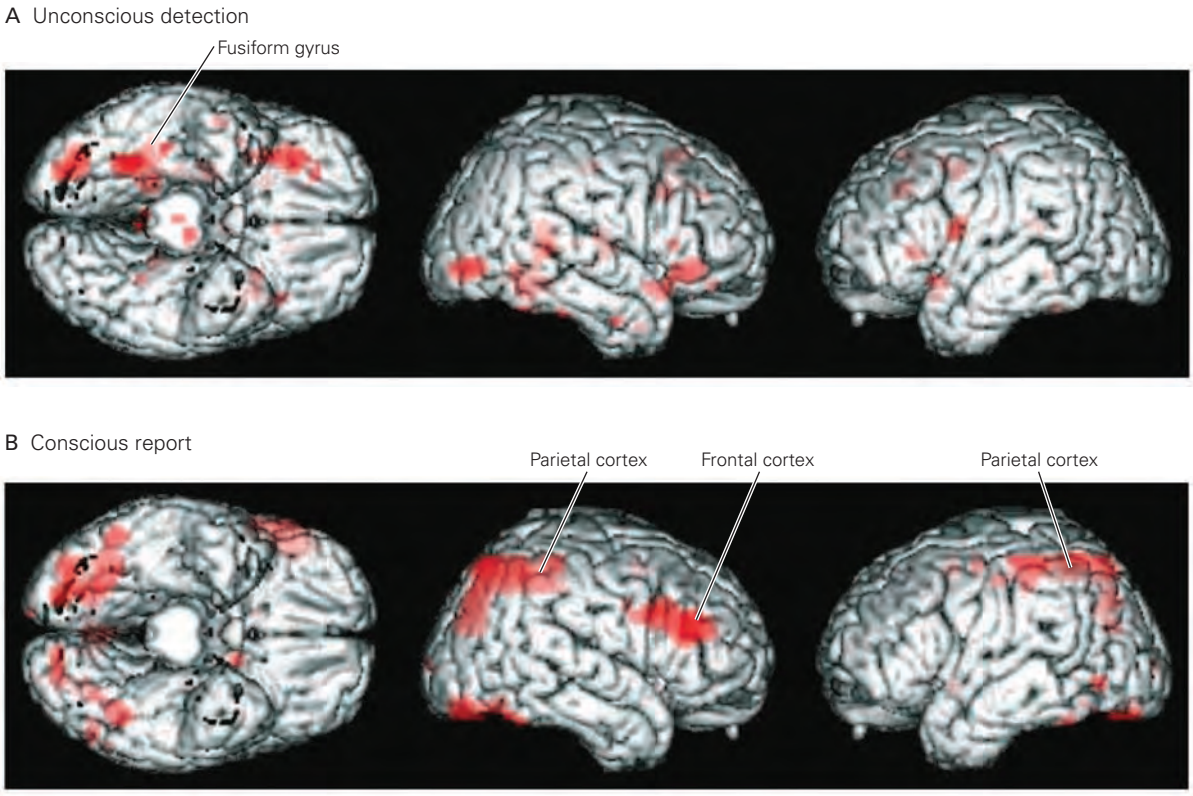

Figure 59–5 Brain activity with and without awareness. Activity in the fusiform face area increases when the face viewed by subjects changes, whether subjects are unaware of the change or conscious of it. When subjects are aware of the change, activity in parietal and frontal cortex also increases. (Reproduced, with permission, from Beck et al. 2001.)

feel that there is something fundamentally wrong. This account has been partially confirmed by the observation that these patients do not have normal autonomic responses to familiar faces.

This explanation implies that Capgras delusions are not the consequence of disordered thinking but of disordered experience. A patient sees the face of his wife without having the normal emotional response. The conclusion that this is not his wife but an impostor is a cognitive response to this abnormal experience, the mind's attempt to explain the experience.

The Control of Action Is Largely Unconscious

The sense that we are in control of our own actions is a major component of consciousness. But are we aware of all aspects of our own actions? David Milner and Mel Goodale studied a patient known as D.F. who demonstrates a striking lack of awareness of certain aspects of her own actions. As a result of damage to her inferior temporal lobe caused by carbon monoxide poisoning, D.F. suffers from *form agnosia*—she is unable to identify the shapes of things. She cannot distinguish a square from an oblong card and cannot describe the orientation of a slot. Yet when she picks up the oblong card to place it through the slot, she orients her hand and forms her grasp appropriately because of the unconscious operation of visuomotor circuits (Figure 59–6).

This sort of unconscious guidance is not unique to patients with brain damage. It is simply revealed more starkly in the case of D.F. because the system that normally brings visual information about shape into consciousness is impaired. Indeed, we can all make rapid and accurate grasping movements without being aware of the perceptual and motor information that is being used to control these movements. Sometimes, we are not even aware of having made the movement. This largely unconscious system for visually guided reaching and grasping is analogous to, and probably overlaps with, the rapid but poor-resolution system associated with fear responses.

Although we may not be aware of the perceptual and motor details of actions like reaching and grasping,

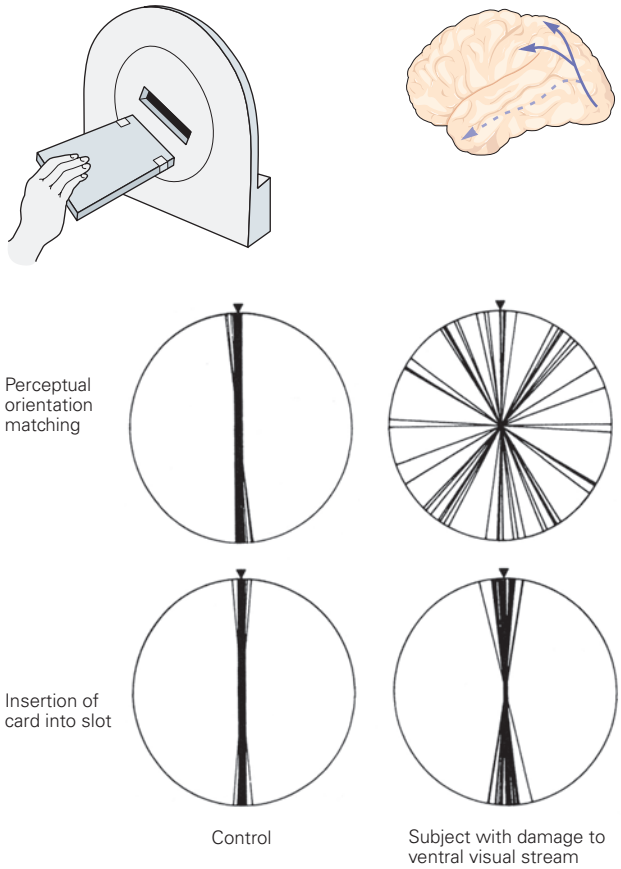

Figure 59–6 Action can be controlled by unconscious stimuli. A patient, D.F., with damage to the inferior temporal cortex, is unable to recognize objects based on their shape (form agnosia). She cannot align the tablet with the orientation of the slot (perceptual matching) because she is not consciously aware of the orientation of either the tablet or the slot. However, when she is asked to put the tablet through the slot in a quick movement, she orients her hand rapidly and accurately. Presumably, the movement is driven by visuomotor computations of which the subject is unaware. (Adapted, with permission, from Milner and Goodale 1995.)

we are vividly aware of being in control of some of our actions—we are aware of a difference between actions that we cause and those that happen involuntarily. Benjamin Libet studied the phenomenon of voluntary action in controlled experiments. He asked his subjects to lift a finger "whenever they felt the urge to do so" and to report the time at which they had this urge. His subjects had no difficulty in reliably reporting the time of this subjective experience. At the same time, Libet used electroencephalography to measure the "readiness potential," a change in brain activity that occurs up to 1 second before a subject makes any voluntary movement. The time at which subjects reported feeling the urge to lift a finger occurred hundreds of milliseconds *after* the beginning of this readiness potential. This result has generated much discussion among philosophers as well as neuroscientists concerning the existence of free will. If brain activity can *predict* an action before a person is aware of having the urge to perform that action, does this mean that our experience of freely willing actions is an illusion?

Although Libet's result has been widely replicated, the relevance of his experimental protocol for our understanding of free will remains controversial. Lifting one finger is not an action that we often perform. Actions usually have goals. For example, we might press a button in order to ring a bell. When our actions are followed by the goal we expect, we feel that we are in control of our actions. It is this subjective experience that gives us a sense of agency, of being the cause of events. Applying Libet's paradigm to such actions, Patrick Haggard discovered the phenomenon of "intentional binding." When a deliberate movement (pressing a button) is followed by its intended goal (hearing a tone), these events are experienced subjectively as bound together in time (Figure 59–7).

This temporal binding of our actions to their goals provides an empirical marker of our sense of agency, since a stronger sense of agency is associated with a greater degree of binding. If a movement occurs passively, caused for example by magnetic stimulation to the brain, then intentional binding is decreased; we actually perceive the time between movement and outcome as longer than the actual physical time.

Our sense of agency is closely linked to our belief in free will and to the idea that people can be held

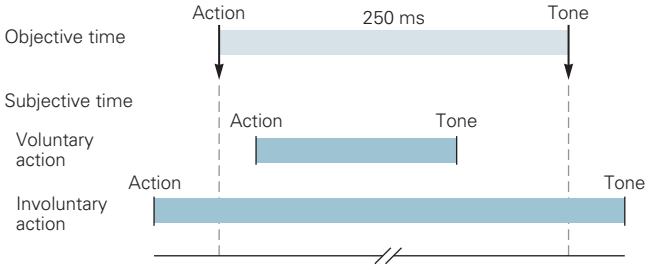

Figure 59–7 We experience our actions and their effects as bound together in time. When subjects are asked to press a button that triggers a sound 250 ms later, they experience their action and the sound as occurring closer together (subjective time) than they actually are (objective time). In contrast, when their finger moves involuntarily through trans cranial magnetic stimulation (TMS) of motor cortex, the movements and the sound are experienced as further apart compared to objective time. Temporal binding occurs only when the movement is intended and deliberate and thus is a marker of the experience of agency. (Based on Haggard, Clark, and Kalogeras 2002.)

responsible for their actions when these are performed deliberately. Intentional binding is increased when associated with outcomes that have moral consequences. It is reduced for actions that have been commanded by others, rather than performed freely. These results do not address the question of whether or not free will exists, but they suggest that our conscious experience of acting freely has a major role in creating social norms of responsibility. Such norms are critical for maintaining social cohesion.

Unconscious inference occurs in the motor domain as well as the sensory domain. Our experience of agency is created from two components: our prior expectations and the sensory consequences of the outcome of the action. We are surprised if the actual sensations do not match what we expect, as when we pick up an object that is much lighter than anticipated (Chapter 30). If the outcome confirms our expectations, however, we pay little attention to the actual sensory evidence—we experience what we expected to happen rather than what actually happened.

Pierre Fourneret and Marc Jeannerod asked subjects to draw a vertical line using a computer's mouse. The subjects could not see their hand and so could not see that the computer created a distortion in the line displayed on the screen. The striking result was that subjects were not aware that they had moved their hand at an angle of 10° to the left to produce the vertical line on the screen (Figure 59–8). This lack of awareness occurred for deviations of up to 15°. When subjects were instructed not to look at the screen but simply repeat the movement they had just made, they did not reproduce the deviant movement they had made but instead drew the straight-ahead movement that they believed they had made. It would seem that as long as the goal is realized (drawing a straightforward line), we experience the expected sensory feedback, not the actual sensory feedback.

This phenomenon helps us understand some otherwise bizarre experiences. For example, after the amputation of a limb, some patients may experience a phantom limb. They still experience the urge to move the missing limb, and they can select specific movements they want the missing limb to make. Their sensorimotor systems predict the proprioceptive sensations they would feel if they were to move an intact limb, and it is these predicted sensations that underlie the sensation of a moving phantom limb.

After a limb has been paralyzed due to stroke, some patients believe that they are still able to move the limb (anosognosia for hemiplegia). Here, again, such patients can select the movements they want to make and are aware of their expectations about the movement. Despite the lack of sensory evidence that follows their attempt to initiate the movement, they believe that the movement did occur.

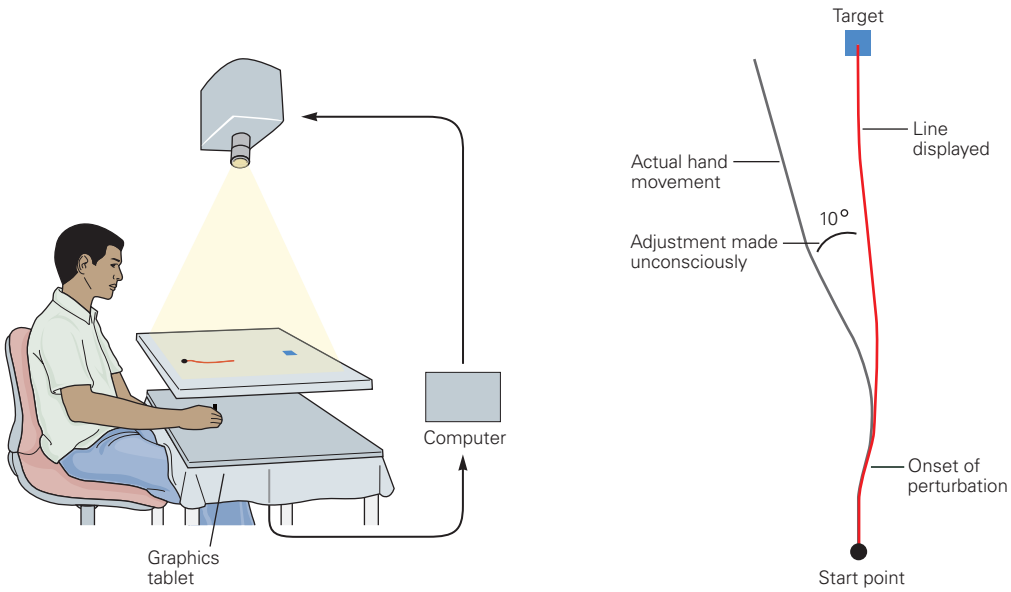

Figure 59–8 Actions can be modified unconsciously. Subjects are asked to draw a straight line with a computer mouse. They can see the line on the screen but not their hand movement. The computer is programmed to systematically distort the line displayed on the screen. In the result shown here, the subject had to move his hand 10° to the left to produce a vertical line on the screen. Subjects are not aware of making such adjustments. The Conscious Recall of Memories Is a Creative Process

For most of us, memory is the conscious imaginative reliving of a past experience. If we take no account of subjective experience (the behaviorist stance), however, memory is a process by which our past experience alters future behavior. Our behavior is often affected by past experience, but without conscious recall of the memory or awareness of the influence it is having on us. Once again, this type of experience is seen most strikingly in patients with damage to specific areas of the brain.

Some patients become densely amnesic after damage to the medial regions of the temporal lobe. They show no decline in intellect as measured by IQ tests but cannot remember anything for more than a few minutes. Although devastating, this memory impairment is actually rather circumscribed. The problem is largely manifested in *declarative memory*, and most severely in a type of declarative memory called *episodic memory*, the ability to recollect events in one's life (Chapter 54). *Procedural memory*, in which consciousness has a minor role (Chapter 53), remains intact. Thus, patients can still remember motor skills such as riding a bicycle and can often learn new motor skills at a normal rate. This selective effect of brain damage can lead to dramatic dissociations. A patient who has been learning some new skill every day for a week will deny ever having performed the task before. He is then surprised to find how skillful he has become.

A widely used protocol tests subjects' ability to recall lists of words they have memorized, a task that taps a form of declarative memory. In the recall phase, a subject is presented with a list of the words that were on the study list plus new words. An amnesic patient has great difficulty with this type of task and may misclassify most of the previously seen words as new since she cannot recall seeing them before. Nevertheless, the brain activity elicited by reading old words is different from that elicited by the new words: There is unconscious recognition of a difference, equivalent to that shown by patients with unilateral neglect or prosopagnosia. Normal subjects usually find this task easy, but they too will occasionally misclassify old words as new; as with amnesiacs, evoked brain responses in normal subjects register the distinction lost to conscious recall (Figure 59–9).

Occasionally, a subject misclassifies a new word as an old one. This misclassification amounts to a false memory. Such misclassifications are most likely to occur when the new word is semantically related to one or more of the old words. If the list of old words contained *big*, *great*, *huge*, then the new word *large* is likely to be identified as old. One explanation for this is that the perception of the new word *large* has been unconsciously primed by the previous presentation of the old words. Thus, the new word *large* is processed easily and quickly, and because the subject is aware of this, he concludes the word must be familiar and classifies it as old.

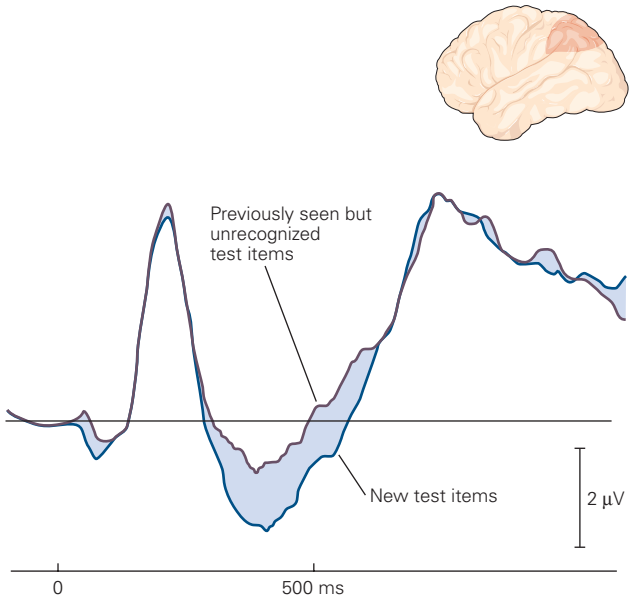

Figure 59–9 Brain activity shows the imprint of forgotten memories. Subjects were presented with a list of words, including some that had been presented earlier and some that were new. When asked to identify the words presented earlier, subjects correctly identified some of the old words but forgot others. Immediately after the visual presentation of a word, there is a brief fluctuation in the evoked potential in the brain. Evoked responses in the parietal region of the brain reflect whether or not the words had been seen before, even when subjects did not consciously recognize the words. The pattern produced by old words, whether recognized or not, is different from that produced by the new words. (Reproduced, with permission, from Rugg et al. 1998. Copyright © 1998 Springer Nature.)

This observation emphasizes that memory is a creative process. Our conscious memories are constructed from both conscious recall and unconscious knowledge. To guard against false memories, as with false percepts, we use our knowledge about the world to determine which memories are plausible.

In some patients, the process by which memories are screened can become dramatically disturbed. If asked what happened yesterday, most patients with amnesia will say that they cannot remember, but a few will give elaborate accounts that do not correspond to reality. Such false memories are called confabulations and can sometimes be extremely implausible. For example, one patient said that he had met Harold Wilson

(a former British Prime Minister) and discussed a building job they were both working on.

The creative mechanisms needed to reconstruct memories of past episodes are also involved when imagining events that might happen in the future. In amnesic patients with damage to the hippocampus, the ability to imagine new events is markedly impaired.

Behavioral Observation Needs to Be Supplemented With Subjective Reports

By the middle of the 20th century, it had become clear that the classic behaviorist approach was inadequate for the exploration of many psychological processes. Language acquisition, selective attention, and working memory cannot be understood in terms of relations between stimuli and responses, however complex the relationships postulated.

The demonstration that some cognitive processes are unconscious requires that we move even further from behaviorism. If we want to explore the whole range of conscious and unconscious cognitive processes, we will not be able to do so by focusing on overt behavior alone. We cannot assume that a subject making purposeful, goal-directed actions is necessarily aware of the stimuli eliciting the action or even of the action itself. We must supplement behavioral observations with subjective reports. We have to ask the subject, "Did you see the stimulus? Did you move your hand?"

One hundred years ago, introspection was the major method for obtaining data in psychology. How else could one study consciousness? But different schools of psychology obtained different results and, as John B. Watson emphasized, there seemed to be no objective way of deciding who was right. How can you independently confirm subjective experience? Thus, the method fell into disrepute. During the decades in which psychology was dominated by behaviorism, subjective reports were not considered an appropriate source of data. As a result, methods for recording subjective reports lag far behind methods for recording overt behavior. Regrettably, many studies of cognitive processes still do not require reports of subjective experience from subjects because of the long tradition of excluding such reports.

The one domain of psychology in which subjective reports continued to be used was psychophysics, the study of the relationship between sensation (physical energy) and perception (psychological experience) introduced by Fechner in 1860. Such studies give robust and reliable results and have created some of the few laws in psychology, such as Weber's law (the just-noticeable difference between two stimuli is proportional to the magnitude of the stimuli). In these studies, subjects are typically asked "Did you see the stimulus?" or "How confident are you that you saw the stimulus?"

Signal detection theory, developed in the 1950s, provides a robust methodology for measuring the ability to detect a stimulus (discriminability, d') independently of any reporting biases (Chapter 17). If your discriminability is high, then you will successfully detect small changes in the stimuli. More recently, there has been increasing interest in the second question, "How confident are you that you saw the stimulus?" Reporting one's confidence requires *metacognition*, the ability to reflect on our cognitive processes. This ability has an important role in the control of behavior. For example, if we realize that we are not performing some task very well, we might slow down and pay more attention to what we are doing.

The ability to reflect on our perception can be measured objectively. Likewise, the ability to reflect on the quality of our cognitive processes can also be assessed quantitatively. If your metacognitive accuracy is high, then you will successfully discriminate between your right and wrong answers. In other words, a correct detection will usually be associated with a high degree of confidence, whereas an incorrect detection will be associated with a low degree of confidence. However, your metacognitive accuracy need not be related to your signal detection ability. You could be good at detecting signals while at the same time poor at knowing whether your answers are likely to be right or wrong. In fact, patients with damage to anterior prefrontal cortex retain the ability to detect visual signals but show a marked deficit in metacognitive accuracy.

Verbal reports cannot, of course, be used in signal detection experiments with laboratory animals or preverbal infants. One alternative is to identify aspects of behaviors that reflect confidence. For example, if we are confident that we left our keys somewhere in the living room, we will spend more time looking there before we switch to the hall. Louise Goupil and Sid Kouider applied this insight to the study of metacognition in preverbal infants. The infants had to remember which of two boxes had contained a toy that was later removed without their knowledge. They spent more time searching inside the correct box. The infants were also more likely to ask an adult for help to open the correct box. These effects did not occur after long intervals. This behavior suggests that the infants had some insight into their current state of knowledge. They knew when they could no longer remember which was

the correct box. Similar experiments suggest that rats and monkeys also have some metacognitive abilities.

Verification of Subjective Reports Is Challenging

Reports of subjective experience, such as confidence, serve like a meter. Just as an electrical meter converts electrical resistance into the position of a pointer on a dial (reading 100 ohms), so a subject converts a light stimulus into the report of a color ("I see red"). But there is a critical way in which the meter is not like a person. The meter does not experience red and cannot communicate meaning. And, although the meter might be faulty, it can never pretend to see red when it is really seeing blue. Most of the time, we presume that subjective reports are true, that is, the subject is trying as far as possible to give an accurate description of his experience. But how can we be sure that we can rely on these subjective reports?

The problem of verifying subjective reports can partially be addressed with the use of brain imaging. Brain imaging studies have shown that neural activity occurs in localized areas of the brain during mental activity that is not associated with any overt behavior. The content of such mental activity, such as imagining or daydreaming, can be known only from the subject's reports.

If we scan a subject while he says he is imagining moving his hand, activity will be detected in many parts of the motor system. In most motor regions, this activity is less intense than the activity associated with an actual movement, but it is well above resting levels. Similarly, if a subject reports that she is imagining a face she has recently seen, activity can be detected in the fusiform gyrus, the "face recognition area" (Figure 59–10). In these examples, the location of the observed neural activity detected by the scanner

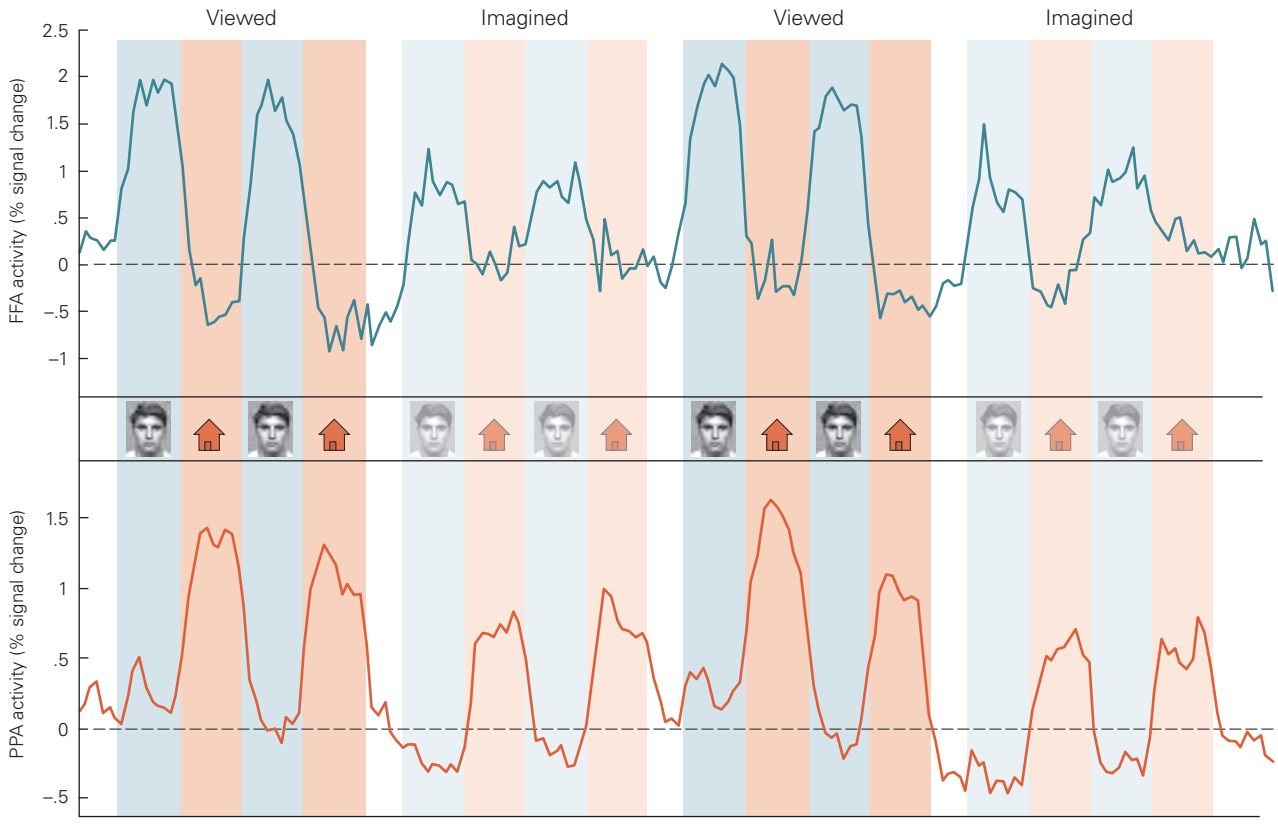

Figure 59–10 Imagining a face or a place correlates with activity in specific areas of the brain. Subjects were scanned while they viewed or imagined faces and houses. In the first block of trials, subjects alternately viewed a face or a house. When viewing a face, brain activity increases in the fusiform face area of the inferior temporal lobe (**FFA**). When viewing a house, brain activity increases in the parahippocampal place area of the inferior temporal cortex (**PPA**). In the next block of trials, subjects alternately *imagined* a face and a house. The same brain regions are active during both the imagining and direct viewing of faces and houses, although the activity is less pronounced during the imagined viewing. (Reproduced, with permission, from O'Craven and Kanwisher 2000. Copyright © 2000 MIT.)

provides independent confirmation of the content of the experience reported by the subject. The content of consciousness can, in certain limited cases, be inferred from patterns of neural activity.

Malingering and Hysteria Can Lead to Unreliable Subjective Reports

What if a subject reports seeing "blue" even though what they experienced was red? How could this arise, and what is the status of the subjective report in such cases?

Consider a patient who has become amnesic as a result of extensive damage to the medial temporal cortex. Shown a photograph of someone whom he sees every day on the ward, the patient denies ever having seen this person, even while physiological measurements (electroencephalogram or skin conductance) show a response to this photo (but not to photos of people he has not seen before). We conclude that conscious memory processes have been damaged while unconscious processes remain intact. This patient's subjective report is an accurate account of what he knows *consciously*, but it excludes those things he "knows" that have not entered consciousness.

Another patient, found wandering on the street, shows no evidence of brain damage but reports he cannot remember anything about himself or his history. When shown photographs of people from his past, he denies any knowledge of them, but at the same time, he shows physiological responses to the photos. In this case, because of the lack of detectable brain damage (and other features of the memory loss), we begin to wonder about the truthfulness of his statements. Perhaps the physiological responses indicate that he does consciously recognize people. Subsequently, the patient is identified by the police, and we discover that he is wanted for a serious crime committed in the neighboring county. Our doubts about the reliability of his reports increase. Finally, our suspicions are confirmed when he foolishly tells a fellow patient, "It's so easy to fool those clinical psychologists."

In this case, we have direct evidence that the patient was deliberately misleading others about himself. To deceive others, we must be conscious not only of our own mental state but also that of others. Is there some way we can test for deceit? One approach is to use a memory test of the kind discussed earlier. The patient studies a list of words. He is then shown a new list consisting of the words he has just studied and new words, and he must decide whether each word is old or new. A genuine amnesic would not recognize any of the words; he would have to guess, but through unconscious priming effects, he would perform better than chance. The malingering patient can recognize the old words but will have a strong tendency to deny that he has seen them before. Unless he is very sophisticated, he may perform worse than chance. It seems we should be able to distinguish between the genuine amnesic and the malingerer.

A third kind of patient also simulates amnesia (or some other disorder) but does so unconsciously and thus is not a malingerer. Such a case would be called hysterical or psychogenic amnesia. Like the malingerer, his performance on the recognition test is worse than chance. Nonetheless, he is not aware of his simulation. The same mechanism occurs in normal people who have been hypnotized and then told that they will have no memory for what has just happened. This phenomenon is sometimes referred to as a dissociated state: That part of the mind that records experiences and makes verbal reports has become dissociated from the part that is creating the simulation. Hysterical simulations can also create sensory loss, such as hysterical blindness, and motor disorders, such as hysterical paralysis or hysterical dystonia.

We are still a long way from understanding the cognitive processes or underlying physiology of these disorders. A key problem is how to distinguish hysteria from malingering. From the standpoint of conscious experience, the two disorders are quite different: The malingerer is aware that he is simulating, whereas the hysterical patient is not. Yet the patients' subjective reports and overt behavior in the two cases are very similar. Is there no measure that can distinguish between these different disorders? Perhaps the only way to demonstrate the critical distinction between these different states of consciousness is through neuroimaging studies.

Highlights

1. The study of mental disorders forces us to confront the conceptual gap between the mental and the physical. It is no longer possible to maintain that mental disorders have mental causes, whereas physical disorders have physical causes.
2. Cognitive neuroscience has had a major impact on our attempts to bridge this gap because its descriptive language, the language of information processing, can be applied simultaneously to psychological and neural processes. Information theory and the development of the computer hint at how science can address the question of how subjective experience can emerge from activity in a physical brain.

3. It is now clear that perception, action, and memory are the result of many parallel processes and that, although some of these processes support conscious experience, the majority occur below the level of awareness.
4. Striking abnormalities occur when some of these processes are damaged while others remain intact. One patient, D.F., with damage to the inferior temporal cortex, is no longer consciously aware of the shape of an object and hence cannot describe it or recognize what it is. She can nevertheless form her hand into the appropriate shape to pick up the object.
5. We have very little awareness of the details of our actions, but we are vividly aware of being in control (the sense of agency). In extreme cases, this sense of agency can become detached from the control of action. After limb amputation, many people experience having a phantom limb that they can move, and after a limb has been paralyzed due to a stroke, some patients believe that they can still move the limb.
6. Recollection of the past is not like replaying a video. Memory is a creative process based on imperfect recall filled out with general knowledge. Through loss of this creativity, patients with amnesia have difficulty with imagining the future as well as remembering the past.
7. Subjective experience is an important part of human life. When we make a decision, our choice is indicated by our behavior, but our confidence in that choice is a subjective experience. We can study such experiences through verbal report. Confidence in our choices is an example of *metacognition* (ie, the ability to reflect on our cognitive processes). Damage to the frontal cortex can impair metacognition, while leaving decision-making intact.
8. Verbal reports are not always reliable. People can fake memory loss in order to escape justice. Malingering of this kind is very difficult to detect, since it closely resembles disorders such as hysterical amnesia, in which the patient is not aware that he is simulating the disorder. The challenge for cognitive neuroscience is to distinguish these cases.

Disorders of Thought and Volition in Schizophrenia

In this chapter and the next, we examine disorders that affect perception, thought, mood, emotion, and motivation: schizophrenia, depression, bipolar disorder, and anxiety disorders. These have been challenging to understand, but recent progress in genetic analysis has begun to yield significant clues to their pathogenesis.

Mental illness has damaging effects on individuals, families, and society. The World Health Organization reports that mental illnesses, in the aggregate, constitute the leading cause of disability worldwide and are the leading risk factors for the 800,000 annual suicides reported by the World Health Organization. In addition, depression and anxiety disorders frequently co-occur with and worsen the outcomes of diabetes mellitus, coronary artery disease, stroke, and several other illnesses.

Medications such as antipsychotic drugs, lithium, and antidepressant drugs discovered during the mid-20th century made it possible to close large and often substandard mental hospitals; however, halfway houses and other less restrictive treatment settings did not materialize in sufficient numbers. As a result, many people with schizophrenia and severe bipolar disorder become homeless at some time in their lives, and in many countries, individuals with severe mental disorders compose a large fraction of prison populations.

In addition, although antipsychotic drugs, lithium, and antidepressant drugs have played important roles in controlling symptoms of mental disorders, significant limitations in treatment efficacy remain. For example, there are no effective treatments for the highly disabling cognitive impairments and deficit symptoms of schizophrenia. Even for symptoms that benefit from existing medications, such as hallucinations and delusions, residual symptoms remain and relapses are the rule. Because of significant scientific challenges posed by the human brain and limitations in animal models of mental disorders, there has been little advance in the efficacy of psychiatric drugs for more than 50 years. However, recent progress in human genetics and neural science has created significant opportunities to improve upon this unfortunate state of affairs.

Schizophrenia Is Characterized by Cognitive Impairments, Deficit Symptoms, and Psychotic Symptoms

In medicine, the understanding of a disease, and therefore its diagnosis, is ultimately based on identification of two features: (1) etiological factors (eg, microbes, toxins, or genetic risks) and (2) mechanism of pathogenesis (the processes by which etiologic agents produce disease). While human genetics and neural science are beginning to provide insights into the etiology and pathogenesis of disorders such as schizophrenia, bipolar disorder, and autism spectrum disorders, this research has not yet yielded objective diagnostic tests or biomarkers. As a result, psychiatric diagnoses still rely on a description of the patient's symptoms, the examiner's observations, and the course of the illness over time.

Schizophrenia is a very severe illness. Its symptoms can be divided into three clusters: (1) cognitive symptoms; (2) deficit, or negative, symptoms; and (3) psychotic symptoms. These symptom clusters exhibit different temporal patterns of onset—with cognitive impairments and deficit symptoms typically the earliest. The different timing of onset and the precise symptoms of each cluster are thought to result from the effects of developmental pathogenic mechanisms on different neural circuits and brain regions. As a result, existing treatments such as antipsychotic drugs, which act on one "downstream" aspect of the disease process, exert no beneficial effects on cognitive impairments or deficit symptoms.

At the beginning of the 20th century, Emil Kraepelin in Germany recognized that cognitive decline was a distinguishing feature of schizophrenia, because psychotic symptoms occur in a variety of psychiatric conditions. Indeed, Kraepelin's term for what later came to be called schizophrenia was *dementia praecox*, a term that highlighted the early onset of cognitive loss. Cognitive impairments in schizophrenia target working memory and executive function, declarative memory, verbal fluency, the ability to identify the emotions conveyed by facial expressions, and other aspects of social cognition. These impairments do not significantly improve with existing medications, but ongoing research shows promising, albeit still modest, benefits from psychological therapies aimed at cognitive remediation.

Deficit symptoms include blunted emotional responses, withdrawal from social interaction, impoverished content of thought and speech, and loss of motivation. Psychotic symptoms include hallucinations, delusions, and disordered thought such as loosening of association (Box 60–1). Psychotic symptoms of schizophrenia are responsive to antipsychotic drugs. These drugs also reduce psychotic symptoms that

Box 60–1 Thought Disorder

The structure of a psychotic person's speech may range from wandering to incoherence, a symptom commonly referred to as loosening of association. Other examples of schizophrenic speech include neologisms (idiosyncratically invented words), blocking (sudden spontaneous interruptions), or clanging (associations based on the sounds rather than the meanings of words, such as, "If you can make sense out of nonsense, well, have fun. I'm trying to make cents out of sense. I'm not making cents anymore. I have to make dollars.")

Examples of loosening of associations are:

"I'm supposed to be making a film but I don't know what is going to be the end of it. Jesus Christ is writing a book about me."

"I don't think they care for me because two million camels . . . 10 million taxis . . . Father Christmas on the rebound."

Question: "How does your head feel?" Answer: "My head, well that's the hardest part of the job. My memory is just as good as the next working man's. I tell you what my trouble is, I can't read. You can't learn anything if you can't read or write properly. You can't pick up a nice book, I don't just mean a sex book, a book about literature or about history or something like that. You can't pick up and read it and find things out for yourself."

Several types of loosening of association have been described (eg, derailment, incoherence, tangentiality, or loss of goal). However, it remains unclear whether these reflect disturbances in fundamentally different mechanisms or different manifestations of a common underlying disturbance, such as the inability to represent a "speech plan" to guide coherent speech. A disturbance of such a mechanism would be consistent with, and may parallel, impairment of control of other cognitive functions in schizophrenia, such as deficits in working memory.

occur in other neuropsychiatric disorders, including bipolar disorder, severe depression, and neurodegenerative disorders such as Parkinson disease, Huntington disease, and Alzheimer disease.

Schizophrenia Has a Characteristic Course of Illness With Onset During the Second and Third Decades of Life

Schizophrenia affects 0.25% to 0.75% of the population worldwide, with only modest regional differences. Males are more commonly affected than females, with the sex ratio estimated to be 3:2, and onset is often earlier in males. Schizophrenia typically begins during the late teen years or the early to mid-twenties. Enduring cognitive and deficit symptoms generally begin months and sometimes years prior to the onset of psychotic symptoms. This period is referred to as the ultra-high-risk state by some researchers and as the schizophrenia prodrome by others.

Individuals in this risk state generally have measurable declines in cognitive functioning accompanied by such symptoms as social isolation, suspiciousness, and decreased motivation to engage in school work or other tasks. Attenuated psychotic symptoms often follow, including transient and mild hallucinations. Not every teen with such symptoms progresses to develop the full spectrum of symptoms warranting a diagnosis of schizophrenia. A small fraction recovers; others develop serious psychiatric conditions other than schizophrenia. Antipsychotic medications do not appear to benefit individuals in the risk state, nor do they delay the onset of schizophrenia. However, talk therapies and therapies delivered via computer-based approaches aimed at cognitive remediation show promise in delaying the onset of psychosis.

The Psychotic Symptoms of Schizophrenia Tend to Be Episodic

Psychotic symptoms, including hallucinations and delusions, are the most dramatic manifestations of schizophrenia. Hallucinations are percepts that occur in the absence of appropriate sensory stimuli, and they may occur in any sensory modality. In schizophrenia, the most common hallucinations are auditory. Typically, an affected person hears voices, but noises and music are also common. Sometimes, the voices will carry on a dialog and frequently are experienced as derogatory or bullying. Occasionally, voices will issue commands to the affected individual that can create a high risk of harm to self or others.

Delusions are firm beliefs that have no realistic basis and are not explained by the patient's culture, nor are they amenable to change by argument or evidence. Delusions may be quite varied in form. For some affected individuals, reality is significantly distorted: The world is full of hidden signs meant only for the affected person (ideas of reference), or the person believes that he is being closely watched, followed, or persecuted (paranoid delusions). Others may experience bizarre delusions; for example, they may believe that someone is inserting thoughts into or extracting thoughts from their minds or that their close relatives have been replaced by aliens from another planet. In addition to the person's enduring cognitive impairments, psychotic episodes are frequently accompanied by disordered thought and odd patterns of speech (Box 60–1).

Psychotic symptoms may also occur in other neuropsychiatric disorders, such as bipolar disorder, major (unipolar) depression, various neurodegenerative disorders, and drug-induced states. However, these other conditions can usually be distinguished from schizophrenia by associated symptoms and age of onset. Once schizophrenia has become fully manifest, psychotic symptoms tend to be episodic. Periods of florid psychosis accompanied by markedly disordered thinking, emotion, and behavior are interspersed with periods in which psychotic symptoms are milder or even absent. Psychotic episodes typically require hospitalization; the severity and duration of such episodes are markedly shortened by antipsychotic drugs. First and second episodes of psychosis often respond fully to antipsychotic drugs, but cognitive impairments and deficit symptoms typically persist. After the first few psychotic relapses, people with schizophrenia typically suffer residual psychotic symptoms even between their acute relapses and suffer these symptoms despite treatment with antipsychotic drugs. Cognitive and social functioning typically continue to deteriorate over several years until they reach a plateau well below the person's premorbid level of functioning.

The Risk of Schizophrenia Is Highly Influenced by Genes

As early as 1930, Franz Kalman in Germany studied familial patterns of schizophrenia and concluded that genes contribute significantly. To separate genetic from environmental influences more clearly, Seymour Kety, David Rosenthal, and Paul Wender examined children who were adopted at or shortly after birth in Denmark. They found that the rate of schizophrenia in the biological family of the adoptee was much more strongly

predictive of schizophrenia than the rate of schizophrenia in the adoptive family.

Kety and his colleagues also observed that some of the biological relatives of adoptees with schizophrenia exhibited milder symptoms related to schizophrenia, such as social isolation, suspiciousness, eccentric beliefs, and magical thinking, but not frank hallucinations or delusions. Since Kety's time, it has been observed that such relatives may also exhibit cognitive impairments that are intermediate between unaffected individuals and those with schizophrenia. They also may exhibit thinning of the cerebral cortex observed by magnetic resonance imaging (MRI) that is also intermediate between healthy individuals and those with schizophrenia. (Cortical thinning in schizophrenia is discussed below.) Such individuals are now diagnosed with schizotypal disorder, which appears to be the milder end of the schizophrenia spectrum of psychotic disorders. The severity and nature of symptoms appear to be influenced by the individual's overall burden of risk-associated genetic variants as well as exposure to environmental risk factors.

Irving Gottesman's studies of extended pedigrees of Danish patients with schizophrenia supported the importance of genes. Gottesman noted the correlations between the risk of schizophrenia in relatives and the degree to which they shared DNA sequences with an affected person. He found a greater lifetime risk of schizophrenia among first-degree relatives (including parents, siblings, and children, who share 50% of DNA sequences with the patient) than among second-degree relatives (including aunts, uncles, nieces, nephews, and grandchildren, who share 25% of their DNA sequences). Even third-degree relatives (who share only 12.5% of the patient's DNA sequences) were at higher risk for schizophrenia than the approximately 1% of the general population at risk for this disease (Figure 60–1).

Based on the differences in levels of risk Gottesman measured in these pedigrees, he recognized that schizophrenia risk was not transmitted within families as Mendelian dominant or recessive traits (ie, it was not caused by a single genetic locus). He predicted correctly that schizophrenia is a polygenic trait, involving a large number of loci throughout the human genome. This genetic architecture underlies many human phenotypes, including disease phenotypes, and may involve many hundreds of loci within the genome. In polygenic traits, variants at each disease-associated locus contribute small, additive effects to the phenotype. Genetic risk variants act together with environmental factors to produce the schizophrenia phenotype.

In 2014, a large global consortium reported on a genome-wide association study of more than 35,000 individuals with schizophrenia. The study identified 108 genome-wide significant loci associated with schizophrenia that were distributed across the genome. The research continues, and the number of known loci is already greater than 250. Each of these loci represents a segment of DNA identified by a single

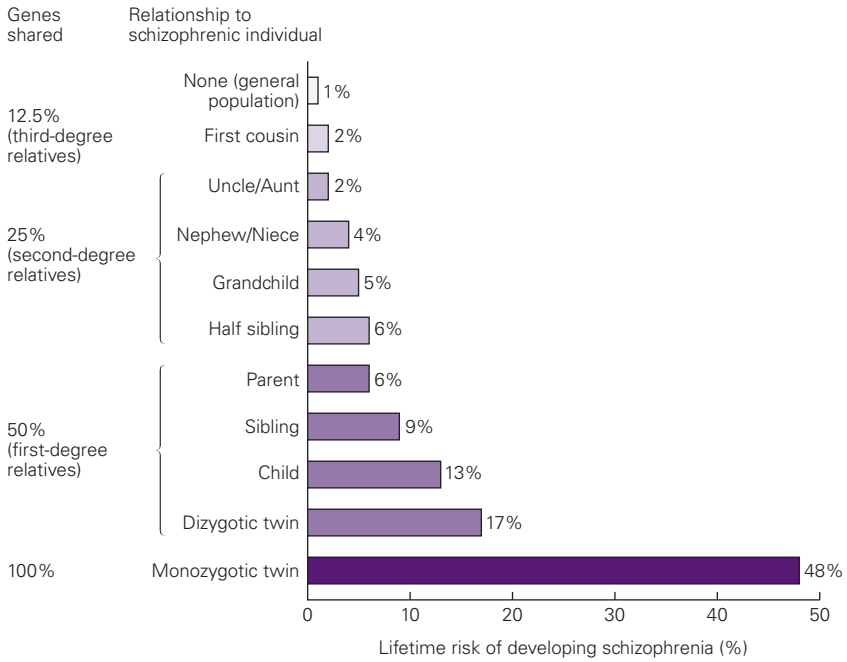

Figure 60–1 **The lifetime risk of schizophrenia increases as a function of genetic relatedness to a person with schizophrenia.** The risk of schizophrenia rises with genetic relatedness to an affected individual and, therefore, with increased sharing of DNA sequences. However, the pattern of segregation in families does not follow simple Mendelian ratios; rather, inheritance reflects genetic complexity. In addition, risk varies within categories of relatedness (first- and second-degree relatives), suggesting a role for unshared developmental or environmental effects. (Reproduced, with permission, from Gottesman 1991.)

nucleotide polymorphism that confers a small increment in risk (typically 5%–10%) for schizophrenia. The value of such allelic variants is as a tool to identify genes that play a role in the molecular mechanism of disease. In turn, the implicated genes help identify molecular pathways that can potentially be exploited in the development of therapeutic drugs.

In addition to the utility of genetics for discovering biological processes involved in disease, it can also contribute to the stratification of study populations in epidemiological and clinical studies. A person's risk of schizophrenia or other disorders can be estimated by calculating his or her total burden of common risk alleles for the condition. The result is a polygenic risk score, a measure that is increasingly being used to stratify populations by genetic susceptibility to schizophrenia in both clinical studies and in epidemiologic studies of environmental risk factors.

Environmental risk factors for schizophrenia that have been replicated across studies include nutrient deprivation in utero (notably in studies following famines), season of birth (winter and early spring birth), urban birth, and migration. The analysis of causal factors within such broad categories of exposure is likely to benefit from knowing who is susceptible. Moreover, clues to environmentally induced causal pathways may be found in the risk genotypes of those with schizophrenia who have had a particular exposure.

Given the lack of objective diagnostic tests, current diagnostic criteria, such as those within the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders*, are based on clinical observation and course of illness. As a result, individuals currently diagnosed with schizophrenia are highly heterogeneous. Polygenic risk scores can explain only a portion of the variance in schizophrenia cohorts, and the scores provide only probabilistic information. However, they represent the first objective tool that permits stratification of subjects diagnosed with schizophrenia. As such, the application of such scores may begin to diminish heterogeneity in clinical studies ranging from neuroimaging to neurophysiological studies to treatment trials.

Although almost all cases of schizophrenia reflect polygenic risks, as predicted by Gottesman, a small percentage of cases are highly influenced by the presence of a penetrant mutation that typically exerts pleiotropic effects, including intellectual disability, resulting in what is often called syndromic schizophrenia. Most of these penetrant mutations are copy number variants: deletions, duplications, or sometimes triplications of a particular segment of a chromosome.

The most common and best studied cause of syndromic schizophrenia is the 22q11.2 microdeletion, which accounts for approximately 1% of patients diagnosed with schizophrenia. The microdeletion typically occurs de novo and results in loss of one of two copies of 38 to 44 genes. As is typical for such copy number variations, those affected suffer from a complex of symptoms. The syndrome accompanying the 22q11.2 microdeletion, sometimes called velocardiofacial or DiGeorge syndrome, includes cognitive disability, cardiovascular defects, and facial dysmorphology. The penetrance of each of these symptoms and signs is independent of the others; thus, affected individuals have different combinations of phenotypes. Individuals with the 22q.11.2 microdeletion have a 25% to 40% risk of schizophrenia and a 20% risk of autism. Other syndromic forms of psychosis are similarly variable.

Syndromic forms of schizophrenia can provide important windows into the biology of psychosis, even if their similarities to common polygenic types of schizophrenia are still a matter of study. One powerful advantage of penetrant mutations is the ability to generate cellular and animal models in order to characterize their effects on brain structure and function. A second advantage is the ability to prospectively study individuals carrying these mutations. Studying syndromic schizophrenia, therefore, has the potential to reveal much about basic pathophysiological mechanisms. One important area of investigation is how copy number variations and other high-penetrance mutations that lead to psychosis manifest based on a person's genetic background, specifically the many common DNA variants that influence risk. To this point, recent findings suggest that the propensity in individuals carrying a copy number variation to develop psychotic symptoms may result from a strong interaction of the copy number variation with the person's polygenic background risk for schizophrenia, suggesting significant shared mechanisms between schizophrenia associated with single genetic mutations and that associated only with polygenic variants.

Schizophrenia Is Characterized by Abnormalities in Brain Structure and Function

Abnormalities in the structure and function of the brain have been identified in schizophrenia both by postmortem examination and by a variety of noninvasive technologies in living patients. The best replicated finding, both by postmortem study and by structural MRI, is loss of gray matter in prefrontal, temporal, and parietal regions of cerebral cortex (Figure 60–2) with counterbalancing increases in the size of the cerebral ventricles (Figure 60–3). Thinning of the cerebral cortex

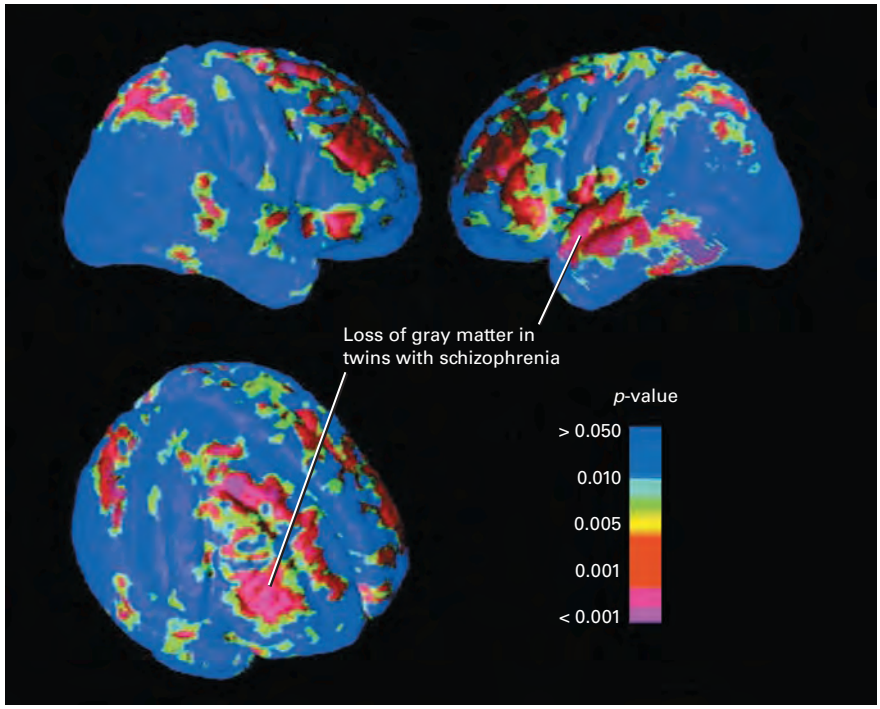

Figure 60–2 Gray matter loss in schizophrenia. Gray matter loss is well documented in schizophrenia. First-degree relatives who do not have a diagnosis of schizophrenia still often exhibit cortical gray matter loss intermediate between healthy individuals and those diagnosed with schizophrenia. Consistent with this, a study that examined losses of cortical gray matter in monozygotic and dizygotic twin pairs discordant for schizophrenia compared to healthy matched control twins found significant losses in those at genetic risk for schizophrenia but without the disease. Those members of twin pairs diagnosed with schizophrenia demonstrated additional, disease-specific cortical thinning in dorsolateral prefrontal, superior temporal, and superior parietal association areas. These additional defects appear to reflect the influence of nongenetic factors involved in pathogenesis (eg, developmental or environmental factors). The disease-specific gray matter loss correlates with the degree of cognitive impairment rather than with duration of illness or drug treatment. The images here show regional deficits in gray matter in monozygotic twins with schizophrenia relative to their healthy co-twins (n = 10 pairs) viewed from the right, left, and right oblique perspectives. Differences in twins are illustrated by the pseudocolor scale superimposed on cortical surface maps, with **pink** and **red** indicating the greatest statistical significance. (Reproduced, with permission, from Cannon et al. 2002.)

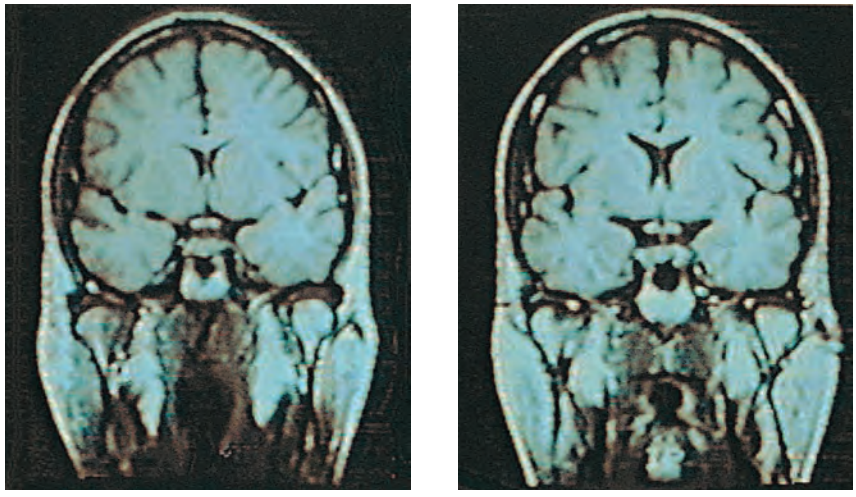

Unaffected twin | Schizophrenic twin

Figure 60–3 Enlargement of lateral ventricles in schizophrenia. Magnetic resonance imaging comparison of monozygotic twins discordant for schizophrenia. The affected member of the twin pair has the enlarged ventricles characteristic of schizophrenia. Because there is a wide range of normal ventricular volumes in the population, an unaffected monozygotic twin serves as a particularly appropriate control subject. Because monozygotic twins have identical genomes, this comparison also illustrates the role of nongenetic factors in schizophrenia.

is most pronounced in the dorsolateral prefrontal cortex, a brain region critical for working memory and thus cognitive control of thought, emotion, and behavior.

Loss of gray matter in the superior temporal gyrus, temporal pole, amygdala, and hippocampus in schizophrenia has also been correlated with impairments in cognition, recognition of emotions in others, and regulation of emotion in the affected person. Functional neuroimaging using positron emission tomography and functional MRI (fMRI) has demonstrated that patients' deficits in performing working memory tasks while being imaged are associated with decrements in the activation of dorsolateral prefrontal cortex, a brain region known to play a critical role in working memory (Figure 60–4).

There is also growing recognition that schizophrenia is characterized by disruptions in connectivity between brain regions (Figure 60–5). Anatomical connectivity can be measured by diffusion tensor imaging, which identifies major axon tracts as they course between brain regions. Functional connectivity between brain regions can be estimated physiologically by measuring the degree to which activity patterns in different brain regions correlate with each other, using such approaches as resting state fMRI and electrophysiology. Both imaging and physiological methods reveal that individuals with schizophrenia have deficits in the connections between brain regions. Weaker connections would likely impair cognition and complex behaviors.

Loss of Gray Matter in the Cerebral Cortex Appears to Result From Loss of Synaptic Contacts Rather Than Loss of Cells

Postmortem studies have examined the cellular abnormalities that underlie the gross anatomical findings and functional deficits in schizophrenia. These studies have revealed that gray matter loss in the prefrontal and temporal cortical regions is not the result of cell death but rather a reduction in dendritic processes. As a consequence, the packing density of cells in the cerebral cortex increases. More cells per unit volume and less total gray matter contribute to enlargement of the ventricular spaces.

A reduction in dendrites and dendritic spines on pyramidal neurons, the most common type of excitatory neuron in the neocortex (Figure 60–6), would likely signify a loss of synaptic contacts in affected brain regions in individuals with schizophrenia. The loss of synaptic connections could underlie abnormalities in long-range functional connectivity and failures to recruit prefrontal cortical regions during tasks that require working memory (Figures 60–4 and 60–5).

Abnormalities in Brain Development During Adolescence May Be Responsible for Schizophrenia

Schizophrenia exhibits a stereotypic onset between late adolescence and early adulthood, with cognitive decline and negative symptoms occurring months or years before the onset of psychosis. This timing suggests the pathogenesis of schizophrenia might involve abnormalities in the late stages of brain development during adolescence, when cognitive function, emotion regulation, and executive function normally mature.

Throughout development, neurons elaborate an excessively large number of synaptic connections. Generally, synapses are strengthened and preserved when they are utilized, while weak or inefficient synapses are eliminated through a process called pruning. The process of synaptic refinement, which involves both synaptogenesis and pruning, results in neural computations that are efficient and adapted to the environment. Experience-dependent synaptic refinement was first described in the visual cortex, where pruning of weak connections is necessary for the emergence of binocular vision (see Chapter 49). Synaptogenesis and pruning continue throughout life, making possible new learning and updating of older memories. However, superimposed on such local events are significant waves of synaptic pruning that are spatially specific and developmentally timed. The last such wave in human brain maturation occurs during adolescence and early adulthood, with pruning in the temporal and prefrontal association cortex. This late wave of pruning is followed by myelination of many axons in these areas of cortex.

In the early 1980s, Irwin Feinberg hypothesized that schizophrenia might result from abnormal and excessive synaptic pruning during adolescence. Postmortem examination of the brains of persons with schizophrenia subsequently demonstrated a reduction of dendritic spines, and of synapses, in prefrontal and temporal cortices. Studies in nonhuman primates, taken together with human postmortem and neuroimaging studies, suggest that loss of dendritic arbors does not result from antipsychotic medications taken by many individuals with schizophrenia. The onset of cognitive impairment and negative symptoms during this period is consistent with the idea that synaptic pruning somehow goes haywire, damaging the ability of the cerebral cortex to process information. When the overpruning hypothesis was first enunciated in the

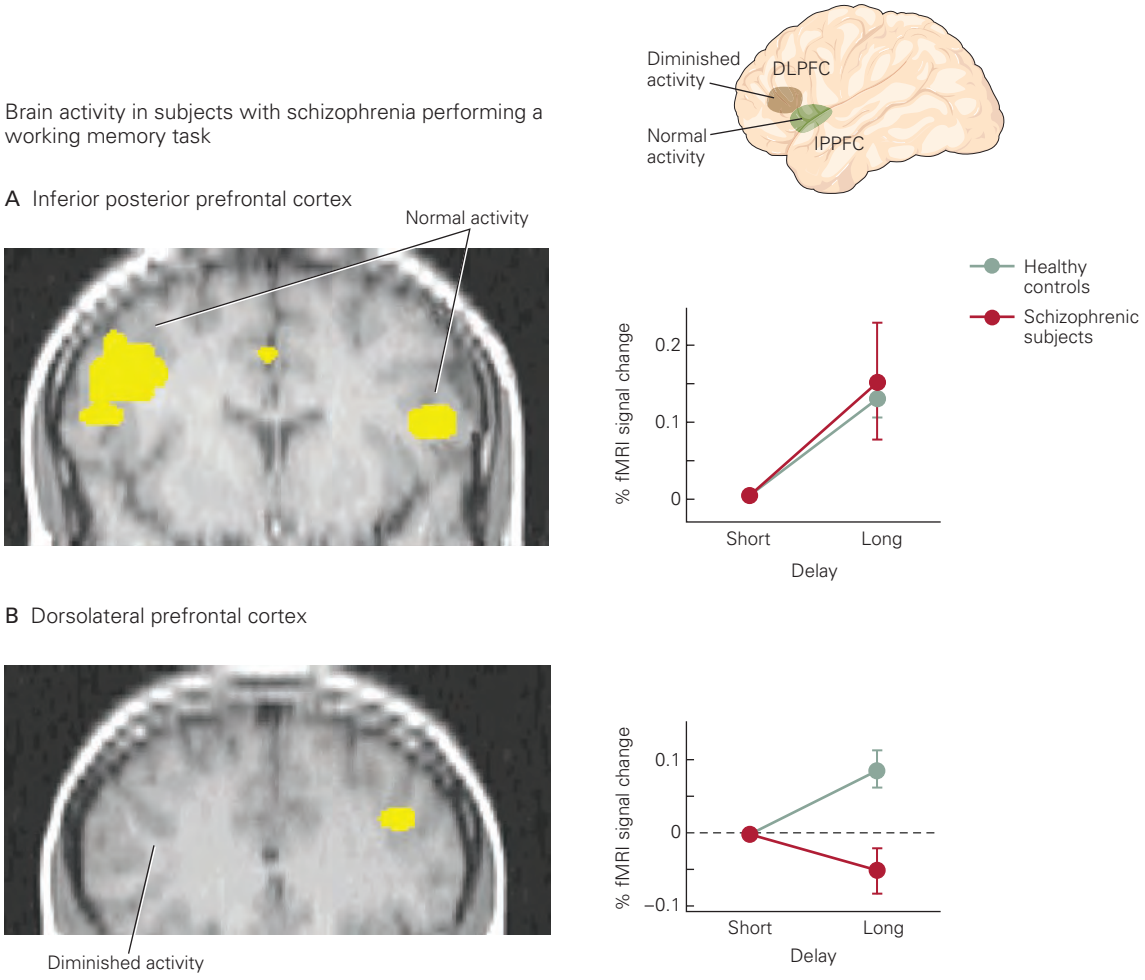

Figure 60–4 Deficits in the function of prefrontal cortex in schizophrenia. Functional magnetic resonance imaging (**fMRI**) was used to test the hypothesis that in patients with schizophrenia working memory engages circuits in the prefrontal cortex differently than in controls. Activity in the prefrontal cortex of two groups—patients with schizophrenia (first-episode patients who had never been given antipsychotic drugs) and healthy controls—was examined while subjects performed a working memory task. Subjects were presented with a sequence of letters and instructed to respond to a particular letter (the "probe" letter) only if it immediately followed another specified letter (the "contextual cue" letter). Demands on working memory were increased by increasing the delay between the cue and the probe letters. The greater demand on working memory requires greater activation of prefrontal cortical circuits. (Adapted, with permission, from Barch et al. 2001.)

A. In both patients with schizophrenia and controls, normal increases in activation within inferior posterior regions of prefrontal cortex (**IPPFC**; Brodmann's area 44/46) as a function of demand on working memory suggest that the function of these regions remains intact in schizophrenia. The plot shows the fMRI signal change that occurs in the right side of the prefrontal cortex in the long-delay and short-delay conditions in healthy controls and in patients with schizophrenia. Similar effects were observed for the left side.

B. There is less activity in Brodmann's area 46/49, a region of dorsolateral prefrontal cortex (**DLPFC**), in patients with schizophrenia relative to healthy controls. Unlike Brodmann's area 44/49 (shown in part **A**), Brodmann's area 46/49 is not activated normally in subjects with schizophrenia, consistent with the deficit in working memory seen in patients with schizophrenia. Selective impairment of one region of prefrontal cortex alongside other regions that appear to have normal function suggests that the impairment is due to a regionally specific process rather than a diffuse and nonspecific pathological process.

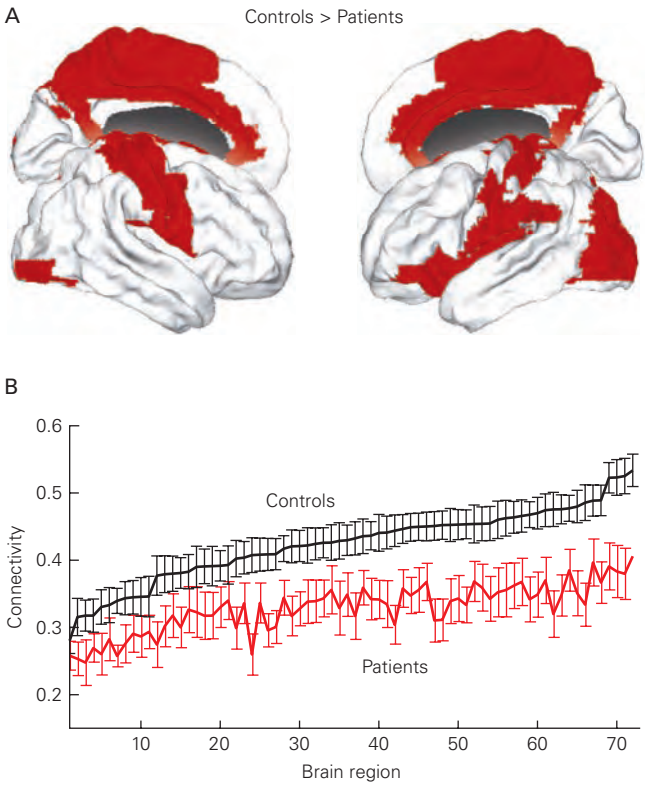

Figure 60–5 Decreased functional connectivity in schizophrenia. Correlations in neural activity between 72 defined brain regions were measured in patients with schizophrenia and in control subjects by resting state functional magnetic resonance imaging. (Reproduced, with permission, from Lynall et al. 2010.)

A. Brain regions that showed statistically significant reductions in functional connectivity in patients compared to controls are highlighted in **red**.

B. Mean (+/– standard error of the mean) functional connectivity between each brain region and the rest of the brain for patients and healthy controls.

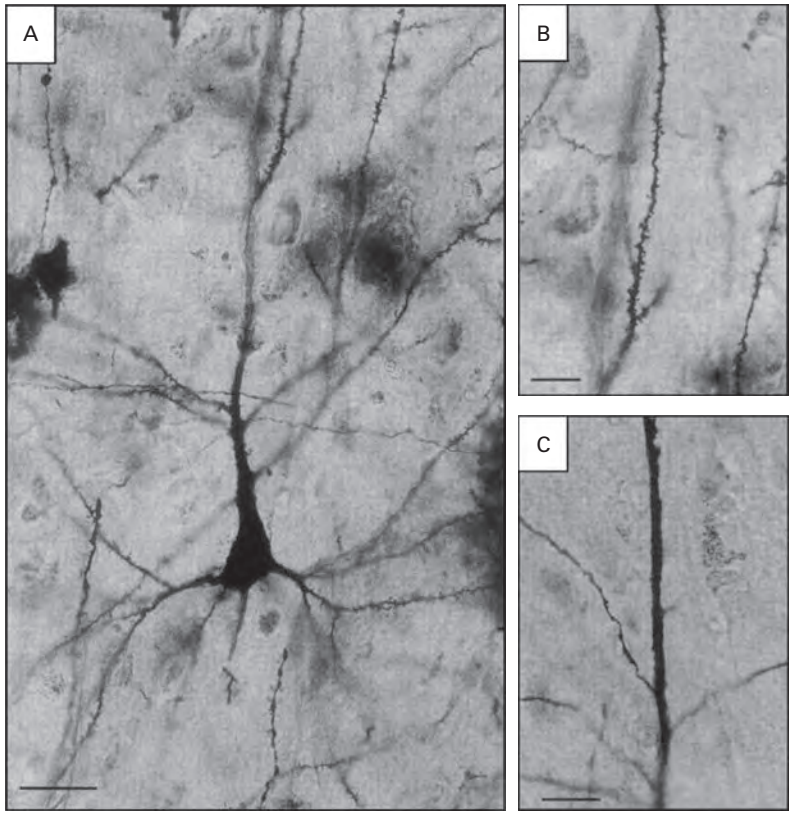

Figure 60–6 Photomicrographs of pyramidal neurons from the cerebral cortex from human brains stained by the Golgi method.

A. A layer III pyramidal neuron from a control brain, showing its morphology and its dendrites which are studded with spines.

B. A higher power view showing spines on a dendrite of a pyramidal neuron from a control brain.

C. A segment of a dendrite devoid of spines from the cerebral cortex of a person who had schizophrenia. (Scale: **A:** 30 µm; **B:** 20 µm; **C:** 15 µm.) Spine numbers are a rough proxy for the number of synaptic contacts onto the dendrite from other neurons; thus the paucity of spines in schizophrenia is consistent with fewer synaptic contacts than are found in the cerebral cortex of healthy brains.

(Reproduced, with permission, Garey et al. 1998. With permission from BMJ Publishing Group Ltd.)

1980s, it lacked a plausible molecular or cellular mechanism that might explain how synaptic pruning might go awry in schizophrenia. Recent genetic analysis may have provided a solution.

Unbiased, large-scale genetic studies have found that the strongest association with risk for schizophrenia lies within the major histocompatibility (MHC) locus on chromosome 6. The MHC locus encodes many proteins involved in immune function. Fine mapping of the locus pinpointed the largest genetic association signal to the genes encoding complement factor C4, a component of the classic complement cascade that, outside the brain, is involved in tagging microbes and damaged cells for engulfment and destruction by phagocytic cells. Subsequent analysis showed that the risk for schizophrenia is elevated as a function of increased expression in the brain of C4A (one of two isoforms). This finding adds support to the overpruning hypothesis because one function of the complement system in brain is to tag weak or inefficient synapses for removal by microglia (Figure 60–7).

Elevated expression of the complement factor C4A involved in synaptic pruning is certainly not the only mechanism leading to schizophrenia. As with any polygenic disorder, no one gene is necessary or sufficient for the disease phenotype. Thus, not everyone with schizophrenia has a high-risk C4A genotype, and not everyone with a high-risk C4A genotype develops schizophrenia. Many other genes are implicated in the risk for schizophrenia. Several such risk factors other than C4 are involved in regulation of the complement cascade, but the vast majority are not. Many of the genes associated with schizophrenia that have been identified to date are involved in various aspects of the structure and function of synapses; several encode ion channels. Thus, it seems likely that the genetic risk for schizophrenia involves, at least in part, synaptic function, synaptic plasticity, and synaptic pruning, and overpruning of synapses during adolescence is one plausible mechanism that should be explored further in studies of youth at high risk for schizophrenia. Nevertheless, other pathways, as yet less well characterized, may also turn out to be important. We have a long way to go in understanding the pathogenesis of schizophrenia.

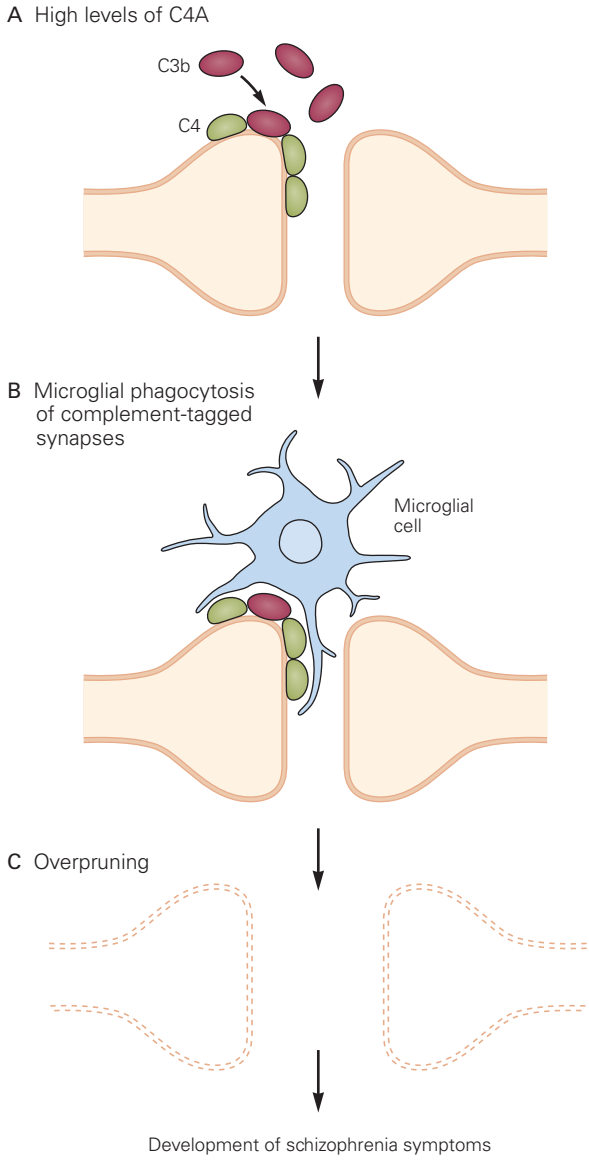

Figure 60–7 Complement factors and microglia have a role in synapse elimination. Maturation and plasticity of the nervous system involve both synaptogenesis and elimination of weak synapses. Complement factor 3b (**C3b**) is thought to serve as a "punishment signal" that identifies weak synapses for phagocytosis by microglia. Complement factor 4 (**C4**), a component of the complement cascade, is synthesized by neurons and astrocytes and recruits C3b to weak synapses. In humans, a complex genomic locus on chromosome 6 contains varying numbers of copies of the genes that encode the complement factor C4 proteins, C4A and C4B. Variants within this locus that give rise to high levels of C4A expression in brain increase schizophrenia risk. (Reproduced, with permission, from Christina Usher and Beth Stevens.)

Antipsychotic Drugs Act on Dopaminergic Systems in the Brain

All current antipsychotic drugs produce their therapeutic effects by blocking D_2 dopamine receptors in the forebrain. These drugs have many other effects at

various neurotransmitter receptors and intracellular signaling pathways, but these other actions primarily influence their side effects, not their main therapeutic mechanisms (Figure 60–8).

The first effective antipsychotic drug, chlorpromazine, was developed for its antihistaminic and sedating effects and was first investigated as a surgical preanesthetic by Henry Laborit in 1952. Based on its sedating effects, it was tested in psychotic patients soon thereafter. These tests showed, surprisingly, reduced hallucinations and delusions; indeed, the sedative effect of chlorpromazine is now considered a side effect. The success of chlorpromazine led to attempts to discover other antipsychotic drugs. Although many chemically diverse antipsychotic drugs are now in use, all share the same initial action of chlorpromazine in the brain, the ability to block the D_2 dopamine receptor. As a class, these drugs ameliorate psychotic symptoms not only in schizophrenia, but also in bipolar disorder, severe depression, and various neurodegenerative disorders. None of the antipsychotic drugs provide effective treatment for the cognitive impairments or deficit symptoms of schizophrenia.

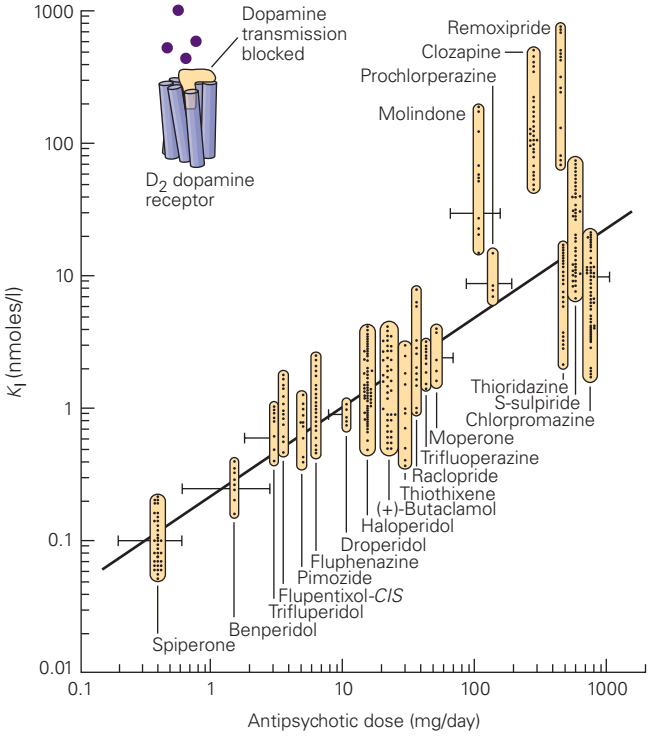

Figure 60–8 The potency of first-generation antipsychotic drugs in treating psychotic symptoms correlates strongly with their affinity for D_2 dopamine receptors. On the horizontal axis is the average daily dose required to achieve similar levels of clinical efficacy. On the vertical axis is K_i, the concentration of drug required to bind 50% of D_2 receptors in vitro. The higher the drug concentration required, the lower is the affinity of the drug for the receptor. One caveat is that the measurements on the two axes were not entirely independent of each other, as the ability of a drug to block D_2 receptors in vitro was often used to help determine doses used in clinical trials. Clozapine, which does not fall on the line, has significantly greater efficacy than the others. The mechanism of its greater efficacy is not understood. (Adapted, with permission, from Seeman et al. 1976.)

Among their side effects, chlorpromazine and related drugs caused Parkinson-like motor symptoms. Because Parkinson disease is caused by the loss of dopaminergic neurons in the midbrain, the occurrence of Parkinson-like side effects suggested to Arvid Carlsson that these drugs acted by decreasing dopaminergic transmission. Following up on this idea, Carlsson established that the antipsychotic drugs block dopamine receptors. Two families of dopamine receptors are known. The D_1 family, which in humans includes D_1 and D_5, are coupled to stimulatory G proteins that activate adenylyl cyclase. The D_2 family, which includes D_2, D_3, and D_4, are coupled to the inhibitory G protein (G_i) that inhibits the cyclase and activates a hyperpolarizing K^+ channel. A second signaling pathway for D_2 receptors is mediated by β-arrestin. The D_1 receptor is expressed in the striatum and is the major class of dopamine receptor in the cerebral cortex and hippocampus. The D_2 receptor is expressed most densely in the striatum, cerebral cortex, amygdala, and hippocampus. Correlations between receptor binding studies and clinical efficacy on psychotic symptoms indicated that the D_2 family is the molecular target for the therapeutic actions of antipsychotic drugs.

Clozapine, an antipsychotic drug discovered in 1959, had a low liability for causing Parkinson-like motor side effects. However, because it had some severe side effects, including a small chance of causing a potentially lethal loss of blood granulocytes, its use was discontinued until a clinical trial in the late 1980s clearly showed that it had greater efficacy than other antipsychotic drugs. Clozapine caused improvement in some individuals who had not responded to other antipsychotic drugs. It was reintroduced in conjunction with weekly monitoring of white cell counts; attempts to equal the efficacy of clozapine also motivated the development of second-generation antipsychotic drugs that mimicked some of its receptor binding properties, notably the ability to block serotonin 5-HT_{2A} receptors, an action that appears to diminish motor side effects. Large-scale clinical trials of the second-generation antipsychotic drugs have shown that their efficacy is no greater than the first-generation drugs, with none

having efficacy equal to clozapine. The liability of second-generation drugs for causing Parkinson-like motor side effects is lower than that of the first generation, but they typically cause more severe weight gain and other metabolic problems.

Because drugs that reduce psychotic symptoms do so by blocking D_2 receptors, investigators have asked: What is the role of dopamine in the symptoms of schizophrenia? Although some drugs that block D_2 receptors reduce psychotic symptoms, other drugs that increase dopamine at synapses, such as amphetamine and cocaine, can produce psychotic symptoms when taken chronically at high doses. Thus, Carlsson suggested that dopaminergic systems are hyperactive in schizophrenia. Evidence for this hypothesis has been difficult to obtain. The most direct evidence for this idea comes from studies begun in the mid-1990s that found that amphetamine-induced increases in dopamine release were greater in patients with schizophrenia than in healthy subjects. These studies suggest that abnormalities in amphetamine-sensitive processes—such as dopamine storage, vesicular transport, dopamine release, or dopamine reuptake by presynaptic neurons—may lead to hyperactivity in the subcortical dopaminergic systems and could contribute to the psychotic symptoms of schizophrenia, the symptoms that respond to antipsychotic drugs.

Although dopamine activity may increase in subcortical regions of the brain in schizophrenia, it may decrease in cortical regions; such a decrease might contribute to the cognitive impairments seen in schizophrenia. In particular, there may be fewer D_1 receptors in the prefrontal cortex in schizophrenia, which would be consistent with the observation that D_1 receptors in the prefrontal cortex normally play a role in working memory and in executive functions.

Highlights

1. Schizophrenia is a chronic, profoundly disabling disorder characterized by dramatic psychotic symptoms as well as deficits in emotion, motivation, and cognition.
2. Risk for schizophrenia is an inherited, polygenic trait.
3. Antipsychotic drugs are effective in reducing hallucinations, delusions, and thought disorder but do not benefit the cognitive and deficit symptoms of schizophrenia.
4. Cognitive impairments reduce the ability of people with schizophrenia to regulate their behavior in accordance with their goals. As a result, people with schizophrenia are frequently unable to succeed in school or to hold down jobs, even at times when antipsychotic drugs effectively control their hallucinations and delusions.
5. Postmortem and neuroimaging studies document loss of gray matter in the prefrontal and temporal cerebral cortex in a pattern that is consistent with cognitive impairments, such as deficits in working memory.
6. The gray matter loss results from decreased dendritic arborization and decreased dendritic spines, which implies that synaptic connections are also reduced. One hypothesis consistent with these anatomic findings and with the typical age of onset in adolescence is that schizophrenia is triggered by excessive and inappropriate synaptic pruning in the prefrontal and temporal cerebral cortices during adolescence and young adulthood.
7. Progress in the genetic analysis of schizophrenia combined with the use of new tools to study systems-level neuroscience promises to help attain the much needed advances in understanding disease mechanisms and in discovering new therapeutics.

Disorders of Mood and Anxiety

Depression, bipolar disorder, and anxiety disorders have been well documented in medical writings since ancient times. In the fifth century BC, Hippocrates taught that moods depended on the balance of four humors—blood, phlegm, yellow bile, and black bile. An excess of black bile (*melancholia* is the ancient Greek term for black bile) was believed to cause a state dominated by fear and despondency. Robert Burton's *Anatomy of Melancholy* (1621) was not only an important medical text but also viewed literature and the arts through the lens of melancholia. Such texts describe symptoms that remain familiar today; they also recognized that symptoms of depression and of anxiety often occur together.

In this chapter, we discuss mood and anxiety disorders together, not only because they frequently cooccur but also because of overlapping genetic and environmental risk factors and some shared neural structures, including regions of the amygdala, hippocampus, prefrontal cortex, and insular cortex.

Mood Disorders Can Be Divided Into Two General Classes: Unipolar Depression and Bipolar Disorder

There are no objective medical tests for mood and anxiety disorders. Thus, diagnosis depends on observation of symptoms, behavior, cognition, functional

impairments, and natural history (including age of onset, course, and outcome). Patterns of familial transmission and response to treatment can also inform diagnostic classification. Based on such factors, it is possible to distinguish between two major groupings of mood disorders: unipolar depression and bipolar disorder. Unipolar depression, when severe and pervasive, is classified as major depression or major depressive disorder. Major depression is diagnosed when people suffer from depressive episodes alone. Bipolar disorder is diagnosed when episodes of mania also occur.

The lifetime risk of major depressive disorder in the United States is approximately 19%. Within any 1-year period, 8.3% of the population suffers major depression. The prevalence of depression differs in different countries and cultures; however, in the absence of objective medical tests, such epidemiologic data are subject to diagnostic and reporting biases, and thus, it is difficult to draw comparative conclusions. The World Health Organization reports that depression is a leading cause of disability worldwide, and other studies find it to be a leading cause of economic loss from noncommunicable disease. These dire social and economic consequences occur because depression is common, often begins early in life, and interferes with cognition, energy, and motivation, which are all necessary to learn in school and to work effectively.

Bipolar disorder is less common than unipolar depression, with a prevalence of approximately 1% worldwide. Its symptoms are relatively constant across countries and cultures. The incidence of bipolar disorder is equivalent in males and females.

Major Depressive Disorder Differs Significantly From Normal Sadness

Several factors distinguish major depression from transient periods of sadness that may occur in everyday life and from the grief that often follows a personal loss. These include the life context in which symptoms occur, their duration and pervasiveness, and their association with physiological, behavioral, and cognitive symptoms (Table 61–1). In healthy people, mood alternates between low and high, with timing and intensity phased appropriately with interpersonal interactions and life events. Mood states that are contextually inappropriate, extreme in amplitude, rigid, or prolonged are suggestive of either depression or mania, depending on their valence.

Depressive episodes, whether associated with unipolar or bipolar illness, are characterized by negative mood states such as sadness, anxiety, loss of interests, or irritability lasting for most of the day, day in and day out, and unrelieved by events that were previously enjoyable. This loss of interest is well expressed

Table 61–1 Symptoms of Mood Disorders

Five or more of the following symptoms have been present during the same 2-week period and represent a change from previous functioning. At least one of the symptoms is either (1) depressed mood or (2) loss of interest or pleasure.

1. Depressed mood most of the day, nearly every day, as indicated by either subjective report (eg, feels sad, empty, hopeless) or observations made by others (eg, appears tearful).
2. Markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly every day (as indicated by either subjective account or observation made by others).
3. Significant weight loss when not dieting, or weight gain (eg, a change of >5% of body weight in a month), or decrease or increase in appetite nearly every day.
4. Insomnia or hypersomnia nearly every day.
5. Psychomotor agitation or retardation nearly every day (observable by others, not merely subjective feelings of restlessness or being slowed down).
6. Fatigue or loss of energy nearly every day.
7. Feelings of worthlessness or excessive or inappropriate guilt (which may be delusional) nearly every day (not merely self-reproach or guilt about being sick).
8. Diminished ability to think or concentrate, or indecisiveness, nearly every day (either by subjective account or as observed by others).
9. Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt or a specific plan for committing suicide.

Source: Adapted from the American Psychiatric Association. 2013. *Diagnostic and Statistical Manual of Mental Disorders*, 5th ed. Washington, DC: American Psychiatric Association.

by Hamlet's complaint, "How weary, stale, flat, and unprofitable seem to me all the uses of this world!" When depression is severe, individuals may suffer intense mental anguish and a pervasive inability to experience pleasure, a condition known as anhedonia.

Physiologic symptoms of depression include sleep disturbance, most often insomnia with early morning awakening, but occasionally excessive sleeping; loss of appetite and weight loss but occasionally excessive eating; decreased interest in sexual activity; and decreased energy. Some severely affected individuals exhibit slowed motor movements, described as psychomotor retardation, whereas others may be agitated, exhibiting such symptoms as pacing. Cognitive symptoms are evident in both the content of thoughts (hopelessness, thoughts of worthlessness and guilt, suicidal thoughts and urges) and in cognitive processes (difficulty concentrating, slow thinking, and poor memory).

In the most severe cases of depression, psychotic symptoms may occur, including delusions (unshakable false beliefs that cannot be explained by a person's culture) and hallucinations. When psychotic symptoms occur in depression, they typically reflect the person's thoughts of being undeserving, worthless, or bad. A severely depressed person might, for example, believe that he is emitting a potent odor because he is rotting from the inside.

The most severe outcome of depression is suicide, which represents a significant cause of death worldwide; the World Health Organization estimates that there are 800,000 deaths by suicide annually. More than 90% of suicides are associated with mental illness, with depression being the leading risk factor, especially when accompanied by substance use disorders.

Major Depressive Disorder Often Begins Early in Life

Major depressive disorder often begins early in life, but first episodes do occur across the life span. Those who have had a first episode in childhood or adolescence often have a family history of the disorder and have a high likelihood of recurrence. Once a second episode has occurred, a pattern of repeated relapse and remission often sets in. Some people do not recover completely from acute episodes and have chronic, albeit milder, depression, which can be punctuated by acute exacerbations. Chronic depression, even when symptoms are less severe than those of an acute episode, can prove extremely disabling because of long-term erosion of a person's ability to function in life roles. Major depressive disorder in childhood occurs equally in males and females. After puberty, however, it occurs more commonly in females; the ratio of females to males is approximately 2:1 across countries and cultures.

A Diagnosis of Bipolar Disorder Requires an Episode of Mania

Bipolar disorder is named for its chief symptom, swings of mood between mania and depression; indeed, the influential 19th-century psychiatrist Emil Kraepelin called this condition the manic-depressive insanity. By convention, a diagnosis of bipolar disorder requires at least one episode of mania. Mania is typically associated with recurrent episodes of depression, whereas mania without depression is distinctly uncommon.

Manic episodes are typically characterized by elevated mood, although some individuals are predominantly irritable. During manic episodes, individuals have markedly increased energy, a decreased need for sleep, and occasionally a decreased desire for food (Table 61–2). People with mania are typically impulsive and engage excessively in reward-directed

Table 61–2 Symptoms of a Manic Episode

A. A distinct period of abnormally and persistently elevated, expansive, or irritable mood, and abnormally and persistently increased goal-directed activity or energy, lasting at least 1 week (or any duration if hospitalization is necessary).

B. During the period of mood disturbance and increased energy or activity, three (or more) of the following symptoms (four if the mood is only irritable) have persisted and have been present to a significant degree:
   1. Inflated self-esteem or grandiosity.
   2. Decreased need for sleep (eg, feels rested after only 3 hours of sleep).
   3. More talkative than usual or pressure to keep talking.
   4. Flight of ideas or subjective experience that thoughts are racing.
   5. Distractibility (ie, attention too easily drawn to unimportant or irrelevant external stimuli).
   6. Increase in goal-directed activity (either socially, at work or school, or sexually) or psychomotor agitation (ie, purposeless non–goal-directed activity).
   7. Excessive involvement in pleasurable activities that have a high potential for painful consequences (eg, engaging in unrestrained buying sprees, sexual indiscretions, or foolish business investments).

Source: Adapted from the American Psychiatric Association. 2013. *Diagnostic and Statistical Manual of Mental Disorders*, 5th ed. Washington, DC: American Psychiatric Association.

behaviors, often with poor judgment characterized by extreme optimism. For example, a person may go on spending sprees well beyond his or her means or on uncharacteristic binges of drug and alcohol use or sexual behavior. Self-esteem is typically inflated, often to delusional levels. For example, an individual might falsely believe himself to have extensive influence on events or to be a significant religious figure. In antiquity, mania was described as "a state of raving madness with exalted mood." However, such elevated mood may be brittle, with sudden intrusions of anger, irritability, and aggression.

Mania, like depression, affects cognitive processes, often impairing attention and verbal memory. During a manic episode, a person's speech is often rapid, profuse, and difficult to interrupt. The person may jump quickly from idea to idea, making comprehension of speech difficult. Psychotic symptoms commonly occur during manic episodes and are generally consistent with the person's mood. For example, people with mania may have delusions of possessing special powers or of being objects of adulation.

The depressive episodes that occur in bipolar disorder are symptomatically indistinguishable from those in unipolar depression, but are often more difficult to treat. For example, they are often less responsive to antidepressant medications. Longitudinal studies have found that the most common affective state of bipolar patients between severe acute episodes of mania or depression is not healthy mood (euthymia), as was often taught in older textbooks, but a state of chronic depression.

Historically, the concept of bipolar disorder described patients who experienced full manic episodes, which often included psychotic symptoms and necessitated hospitalization (Table 61–2). In recent decades, diagnostic classifications have added type 2 bipolar disorder in which mild manias (also called hypomanias) alternate with depressive episodes. The manic episodes of type 2 bipolar disorder are, by definition, not accompanied by psychosis or severe enough to require hospitalization. Whether this represents a variant of classic (type 1) bipolar disorder or some other pathophysiology is not yet known, although genetic dissection of mood disorders may offer some clarification in the near future.

Bipolar disorder generally begins in young adulthood, but the onset may occur earlier or as late as the fifth decade of life. Many manic episodes often lack an obvious precipitant; however, sleep deprivation can initiate a manic episode in some individuals with bipolar disorder. For such individuals, travel across time zones or shift work represents a risk. The rate of cycling among mania, depression, and periods of normal mood varies widely among bipolar patients. Individuals with short, rapid cycles tend to be less responsive to mood-stabilizing drugs.

Anxiety Disorders Represent Significant Dysregulation of Fear Circuitry

Anxiety disorders are the most common psychiatric disorders worldwide. In the United States, 28.5% of the population suffers from one or more anxiety disorders over the course of their lifetimes. Some anxiety disorders are mild, such as the simple phobias that involve rarely encountered stimuli; others, such as panic disorder or posttraumatic stress disorder, are often highly debilitating based on the severity of symptoms, interference with functioning, and chronicity.

Anxiety and fear are related emotional states; both are critical to surviving dangers that might be encountered throughout life. The major distinction is that fear is a response to threats that are present and clearly signify danger, whereas anxiety is a state of readiness for threats that are less specific either in proximity or timing. The neural circuits of fear and anxiety strongly overlap, as do their physiological, behavioral, cognitive, and affective aspects.

Fear is normally a transient adaptive response to danger that, like pain, serves as a survival mechanism. Like pain, fear is alerting and aversive and motivates more or less immediate behavioral responses. Thus, fear interrupts ongoing behaviors, supplanting them with such responses as avoidance or defensive aggression. To prepare the body to cope physiologically, fear circuitry activates the sympathetic nervous system and causes release of stress hormones. This "fight or flight" response facilitates blood flow to skeletal muscle, increases metabolic activity, and elevates pain thresholds. Like reward and other survival-relevant emotional responses, fear strongly facilitates the encoding and consolidation of both implicit and explicit memories that prepare an organism to respond rapidly and effectively to future predictive cues. (Fear circuitry is described in Chapter 42.)

Many cognitive and physiological components of anxiety are similar to fear, but typically exhibit lower intensity and a more protracted time course. Anxiety is adaptive when proportionate to the probability and likely severity of a threat, leading to appropriate levels of arousal, vigilance, and physiological preparedness. Given the dangerous, indeed potentially lethal, consequences of ignoring even ambiguous threat cues, failure to mount appropriate anxiety responses can prove

highly maladaptive. However, excessive contextually inappropriate and prolonged vigilance, tension, and physiological activation can be the basis of distressing and disabling anxiety disorders or anxiety symptoms that may accompany depression. Risk factors for anxiety disorders include a person's genetic background, developmental experience, and lessons learned not only from direct experience but also taught by families, peers, schools, and other institutions.

Cues that elicit anxiety may be environmental or interoceptive (ie, arising from within the body, such as abdominal discomfort or heart palpitations). Social cues and social situations can be a major source of anxiety. In humans, anxiety states can also be initiated by trains of thought that elicit memories or imagination of danger. Anxiety can also arise from stimuli that are processed unconsciously because of their brevity or ambiguity, and the resulting emotion might then be experienced as arising spontaneously. In contrast to fear, which is initiated and terminated by the presence or termination of clear stimuli denoting threat, anxiety has a more variable time course. Anxiety states may be prolonged if the potential for danger or harm is long-lasting or if there is no clear safety signal.

Anxiety disorders and the anxiety that may accompany major depression are associated with diverse symptoms. Affected individuals may develop excessive preoccupation with possible threats and attentional biases toward cues interpreted as threatening. Such cognitive states are often associated with persistent worry, tension, and vigilance. Common physiological symptoms include hyperarousal, as evidenced by a low threshold for being startled, difficulty sleeping, and sympathetic nervous system activation, including a rapid, pounding heartbeat. Individuals with anxiety may become exquisitely aware of their heartbeat or breathing, which can become a source of preoccupation and worry in their own right. Sympathetic nervous system activation may reach extreme levels of intensity during a panic attack, one of the most severe manifestations of anxiety.

In anxiety disorders, cognitive, physiological, and behavioral responses that would be adaptive in the face of a serious threat may be maladaptively activated by innocuous stimuli, may be inappropriately intense for the situation, and may have a protracted time course in which safety signals fail to terminate the symptoms. Affected individuals may avoid places, people, or experiences that, although objectively safe, have become associated with perceptions of threats or the experience of anxiety. When severe, such avoidance can impair the ability of affected individuals to function in different capacities or roles.

Because there are no biomarkers or objective medical tests for particular constellations of anxiety symptoms, current psychiatric classifications such as the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) classify anxiety disorders based on clinical histories, such as the nature, intensity, and time course of symptoms, the role of external cues in triggering episodes, and associated symptoms. The DSM-5 divides pathological anxiety syndromes into several distinct disorders: panic disorder, posttraumatic stress disorder, generalized anxiety disorder, social anxiety disorder (previously called social phobia), and simple phobias. For heuristic purposes, these disorders are discussed below, but current evidence from long-term clinical observation and from family, twin, and epidemiological studies does not support dividing anxiety symptoms into discrete nonoverlapping categories. Rather, the evidence suggests that pathological anxiety symptoms and symptoms of depression might be better conceptualized as a continuum or spectrum in which individuals experience varying symptoms that cross current DSM boundaries.

Consistent with the concept of a symptom spectrum, anxiety disorders and depression do not often occur together across generations in families as distinct DSM-5 categories; instead, diverse patterns of anxiety and depressive symptoms are typically observed among affected family members. Twin studies that compare concordance for traits in monozygotic and dizygotic twin pairs find significant shared genetic risk across multiple anxiety disorders and major depression. In addition, epidemiological studies find that individuals diagnosed with one categorical DSM-5 anxiety disorder, during, for example, teen years, have a high probability of developing new anxiety or depressive symptoms over the next decade that could result in the person being diagnosed with multiple disorders based on DSM-5 classifications. The high frequency at which putatively distinct DSM-5 anxiety disorders and depression co-occur and the results of family and twin studies suggest significant sharing of etiologic factors and pathogenic mechanisms among anxiety disorders and major depression. Nevertheless, individual disorders that are listed in DSM-5 are briefly described below.

Panic attacks are a severe manifestation of anxiety. They are characterized by discrete periods (that can last for many minutes) of intense foreboding, a sense of doom, fear of losing control over oneself, or fear of death. They are associated with prominent bodily symptoms such as heart palpitations, inability to catch one's breath, sweating, paresthesias, and dizziness (Table 61–3).

Table 61–3 Symptoms of a Panic Attack

A discrete period of intense fear or discomfort in which four (or more) of the following symptoms develop abruptly and reach a peak within 10 minutes.

1. Palpitations, pounding heart, or accelerated heart rate
2. Sweating
3. Trembling or shaking
4. Sensations of shortness of breath or smothering
5. Feeling of choking
6. Chest pain or discomfort
7. Nausea or abdominal distress
8. Feeling dizzy, unsteady, lightheaded, or faint
9. Chills or heat sensations
10. Paresthesias (numbness or tingling sensations)
11. Derealization (feelings or unreality) or depersonalization (being detached from oneself)
12. Fear of losing control or "going crazy"
13. Fear of dying

Source: Adapted from the American Psychiatric Association. 2013. *Diagnostic and Statistical Manual of Mental Disorders*, 5th ed. Washington, DC: American Psychiatric Association.

Panic attacks often give rise to anxiety about future episodes such that the contexts in which attacks have occurred can become phobic stimuli that trigger subsequent attacks (fear conditioning). As a result, some severely affected individuals restrict their activities to avoid situations or places in which panic attacks have occurred or from which they fear they might not be able to escape should they experience an attack. The most severely affected may develop generalized phobic avoidance, leading them to become housebound, a state described as agoraphobia. Current diagnostic classification systems such as the DSM-5 define panic disorder based on the number and frequency of attacks and whether or not a phobic trigger can be identified. Such detailed criteria lack a strong empirical basis, but it is certainly the case that individuals who have recurrent panic attacks along with other anxiety symptoms are not only highly distressed but may also be significantly disabled.

Posttraumatic stress disorder (PTSD) follows an experience of severe danger or injury. Under different names and descriptions, including shell shock, a term coined during World War I, PTSD has long been recognized as a result of combat. More recently, civilian traumas such as assault, rape, or automobile crashes have been recognized as potential causes of PTSD. The current approach to PTSD was formalized by the American Psychiatric Association based on the experience of Vietnam War veterans.

PTSD is initiated by a traumatic experience. Its cardinal symptoms include intrusive reexperiencing of the traumatic episode, typically initiated by cues such as sounds, images, or other reminders of the trauma. For example, a person who has been assaulted might respond potently to an unexpected touch from behind. Such episodes are often characterized by activation of the sympathetic nervous system and, when severe, may be characterized by "fight or flight" responses. The reexperiencing of a traumatic event may also occur in the form of nightmares. Other symptoms of PTSD include emotional numbness that may interfere with relationships and social interactions, insomnia, chronic hyperarousal including excessive vigilance, sympathetic nervous system activation, and an exaggerated startle response to an innocuous stimulus such as a touch or sound.

Generalized anxiety disorder (GAD) is diagnosed when a person suffers chronic worry and vigilance not warranted by circumstances. The worry is accompanied by physiological symptoms such as heightened sympathetic nervous system activation and motor tension. GAD commonly co-occurs with major depressive disorder.

Social anxiety disorder is characterized by a persistent fear of social situations, especially situations in which one is exposed to the scrutiny of others. The affected person has an intense fear of acting in a way that will prove humiliating. Stage fright is a form of social anxiety that is limited to circumstances of performance, such as public speaking. Social anxiety disorder can lead to avoidance of verbal classroom participation or communicating with others at work and can therefore prove disabling as well as distressing.

Simple phobias consist of intense and inappropriately excessive fear of specific stimuli, such as elevators, flying, heights, or spiders.

Both Genetic and Environmental Risk Factors Contribute to Mood and Anxiety Disorders

Bipolar disorder, major depression, and anxiety disorders all run in families. Twin studies that compare the rate of concordance of monozygotic and dizygotic twin pairs demonstrate significant heritabilities among these disorders, where heritability represents the percentage of the variation in a phenotype explained by genetic variation. Among mood and anxiety disorders, bipolar disorder has the highest heritability (70%–80%); major depression and anxiety disorders exhibit lower but still significant heritabilities (approximately 35%), with greater roles for developmental

and environmental risk factors. Although there is an important role for genes in the pathogenesis of mood and anxiety disorders, all of them exhibit non-Mendelian patterns of transmission across generations, including frequent co-occurrence of major depression and anxiety disorders. Such patterns reflect the complexity of genetic and nongenetic risk factors.

Molecular genetic studies aimed at discovering the precise DNA sequence variants (alleles) that predispose to mood and anxiety disorders have been initiated. Such studies are challenging because the risk architecture of these, and indeed all, common psychiatric disorders is highly polygenic, meaning that population risk appears to involve many thousands of common and rare alleles linked to or contained within many hundreds of genes. Unlike some neurologic disorders such as Huntington disease, there is no "depression gene" or "anxiety gene." Disease-associated alleles confer small additive effects on the risk of an illness. The risk for any given individual results from genetic loading (comprised of diverse combinations of disease-associated alleles) acting in concert with developmental and environmental factors. This polygenic architecture explains non-Mendelian patterns of transmission and the diverse combinations of depressive and anxiety symptoms observed within families and across populations.

The lack of objective diagnostic tests for mood and anxiety disorders means that any study cohort is likely to have some proportion of diagnostic misclassification. As a result, the search for common disease-associated variants by genome-wide association studies (GWAS) and rare disease-associated variants by DNA sequencing requires significant statistical power conferred by very large cohorts and by meta-analyses conducted across multiple cohorts. Early results of GWAS have been reported for major depression and bipolar disorder; in both cases, several significant genome-wide loci have been found to date, but not yet enough to identify molecular pathways of pathogenesis with any certainty. Whole-exome sequencing (ie, DNA sequencing of all genomic regions that encode proteins) and whole-genome sequencing are being conducted for bipolar disorder.

The highly polygenic risk architecture of mood and anxiety disorders means that there is no diagnostic value in testing for one or a few risk gene variants that might be associated with these disorders. Rather, polygenic risk scores (PRS), based on the sum of all genetic risk variants for a trait, are emerging as useful tools to stratify individuals in epidemiological and clinical studies by severity of genetic risk. A discrepant PRS within a clinical cohort, eg, showing low depression risk in a study of people with major depression, would suggest misclassification. It is important to emphasize that the polygenic nature of risk for mood and anxiety disorders and the significant contribution of environmental risk factors mean that, like any genetic test, the PRS provides only a probability.

As more is learned, the PRS can be combined with other measures to yield a more predictive risk score, just as modern cardiac risk models increasingly include genetic measures, smoking history, lipid levels, and blood pressure. For mood and anxiety disorders, one type of measure that shows early promise is identification of intrinsic patterns of neural connectivity derived from resting-state functional magnetic resonance imaging (fMRI; imaging conducted when subjects are not engaged in task performance). Differing patterns of connectivity could potentially distinguish among different forms of disorder.

Epidemiological evidence has identified significant developmental risk factors for major depression and anxiety disorders. The best documented is a history of physical or sexual abuse early in life, serious child neglect, or other early, severe stressors. Investigations of such early stressors have focused on possible roles for altered reactivity of the hypothalamic-pituitary-adrenal (HPA) axis. Studies of early stress in animal models suggest that epigenetic regulation of gene expression may have a role in altering developmental trajectories. Such results cannot be readily followed up in humans because of lack of access to human brain tissue and thus remain hypothetical.

Other risk factors for depression and anxiety disorders include alcohol and other substance use disorders and the presence of other psychiatric disorders, such as attention deficit hyperactivity disorder, learning disorders, and obsessive-compulsive disorder. There is also evidence that alcoholism and other substance abuse disorders may be initiated by misguided attempts at self-medication of depression or anxiety, in turn worsening the underlying condition.

Environmental factors that may trigger new episodes of depression or anxiety include life transitions such as marriage, a new job, or retirement. Serious illness, whether acute or chronic, is also associated with the onset of major depression and anxiety. Some neurological disorders are associated with an elevated risk of depression, including Parkinson disease, Alzheimer disease, multiple sclerosis, and stroke. Some prescribed medications, such as interferons, also frequently trigger depression. When major depression accompanies a chronic illness such as type 2 diabetes or cardiovascular disease, the overall medical outcomes are worse, as a result of both the physiological

effects of depression, such as increased release of stress hormones (see below) and decreased motivation to engage in rehabilitative regimens.

Depression and Stress Share Overlapping Neural Mechanisms

Depression and responses to stress exhibit complex but significant interactions. As already noted, severe childhood adversity is a developmental risk factor for depression; moreover, depressive episodes may be initiated by a stressful experience. Conversely, the experience of depression is itself stressful because of the suffering it causes and its negative effects on functioning. Symptomatically, depression shares several physiological features with chronic stress, including changes in appetite, sleep, and energy. Both major depression and chronic stress are associated with persistent activation of the HPA axis (Figure 61–1).

Many but not all individuals with major depression and many in the depressed phase of bipolar disorder exhibit excess synthesis and secretion of the glucocorticoid stress hormone cortisol and the factors that regulate it, corticotropin-releasing hormone (CRH) and adrenocorticotropic hormone (ACTH). In a healthy state, a *transient* increase in cortisol secretion, as occurs in response to acute stress, shifts the body to a catabolic state (making glucose available to confront the stressor or threat), increases subjective energy levels, sharpens cognition, and may increase confidence. However, a *chronic* increase in glucocorticoids may contribute to depression-like symptoms. For example, many people with Cushing disease (in which pituitary tumors secrete excess ACTH, leading to excess cortisol) experience symptoms of depression.

Feedback mechanisms within the HPA axis normally permit cortisol (or exogenously administered glucocorticoids) to inhibit CRH and ACTH secretion and therefore to suppress additional cortisol synthesis and secretion. In approximately half of people with major depression, this feedback system is impaired; their HPA axis becomes resistant to suppression even by potent synthetic glucocorticoids such as dexamethasone. Although readily measurable disturbances of the HPA axis have not proven sensitive or specific enough to be used as a diagnostic test for depression, the observed abnormalities suggest strongly that a pathologically activated stress response is often an important component of depression.

The relationship of stress with depression has led to the development of several chronic stress paradigms in rodent models of depression. The reliance on

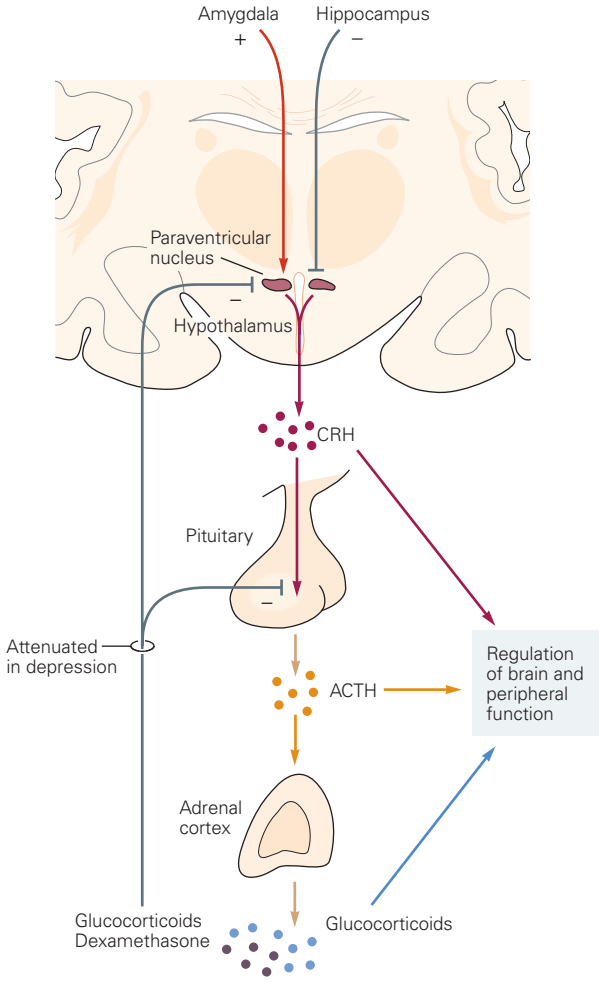

Figure 61–1 The hypothalamic-pituitary-adrenal axis. Neurons in the paraventricular nucleus of the hypothalamus synthesize and release corticotropin-releasing hormone (**CRH**), the key regulatory peptide in the hormonal cascade activated by stress. The CRH neurons have a circadian pattern of secretion, and the stimulatory effects of stress on CRH synthesis and secretion are superimposed on this basal circadian pattern. Excitatory fibers from the amygdala convey information about stressful stimuli that activates CRH neurons; inhibitory fibers descend from the hippocampus onto the paraventricular nucleus. CRH enters the hypophyseal portal system and stimulates the corticotropic cells in the anterior pituitary that synthesize and release adrenocorticotropic hormone (**ACTH**). The released ACTH enters the systemic circulation and stimulates the adrenal cortex to release glucocorticoids. In humans, the major glucocorticoid is cortisol; in rodents, it is corticosterone. Both cortisol and synthetic glucocorticoids such as dexamethasone act at the level of the pituitary and hypothalamus to inhibit further release of ACTH and CRH, respectively. The feedback inhibition by glucocorticoids is attenuated in major depression and the depressed phase of bipolar disorder. (Adapted, with permission, from Nestler et al. 2015.)

stress-induced syndromes in these animal models has been strengthened by the observation that many antidepressant drugs reverse stress-induced changes in physiology or behavior in these animals. However, the degree to which animals subjected to diverse chronic stressors actually model the disease mechanisms underlying depression in human beings remains unknown. Concern about overreliance on stress-based and other rodent models is indicated by the failure to identify new antidepressant mechanisms despite more than 50 years of trying. Drug screens using such models have only identified molecules with actions similar to prototype antidepressant drugs that were first identified by their unexpected psychotropic effects on humans.

Dysfunctions of Human Brain Structures and Circuits Involved in Mood and Anxiety Disorders Can Be Identified by Neuroimaging

Investigation of human brain regions and the neural circuitry involved in mood and anxiety disorders has relied on noninvasive structural and functional neuroimaging, neurophysiologic testing, and postmortem analyses. More recently, information is being gleaned from neuroimaging of patients being treated with deep brain stimulation.

Identification of Abnormally Functioning Neural Circuits Helps Explain Symptoms and May Suggest Treatments

Functional neuroimaging and electrophysiological studies are being pursued in order to elucidate abnormalities in circuit activity and in patterns of intrinsic connectivity in mood and anxiety disorders. Given the heterogeneity of major depression, bipolar disorder, and anxiety disorders defined by current diagnostic methods, it has been challenging to identify robust and replicable abnormalities. In addition, the use of diverse cognitive and emotional tasks to experimentally probe mood and anxiety disorders has limited researchers' ability to replicate and confirm findings. Overcoming the resulting uncertainties will require larger numbers of subjects, application of data standards that permit meta-analyses, and increasingly, methods such as use of the PRSs to stratify subjects.

Despite current limitations, fMRI and electrophysiological studies of mood and anxiety disorders have begun to provide initial empirical leads about circuit abnormalities in mood and anxiety disorders. Resting-state fMRI studies comparing subjects with major depression and healthy control subjects suggest differences in patterns of intrinsic connectivity, specifically within neural circuits that regulate "top down" control of cognition and emotion—the "cognitive control network"—and in circuits that process significant emotional and motivational stimuli—"the salience network" (Figure 61–2). Despite the need for replication, these findings are noteworthy because they are consistent with results from task-based imaging studies of humans (eg, studies of fear conditioning) and animal studies that investigate responses to aversive stimuli.

In healthy human subjects, regions of the amygdala are activated by threatening stimuli and during fear conditioning, such as pairing a previously neutral tone with a mild shock. Beginning with the work of Charles Darwin, human faces expressing fear have been recognized to elicit anxiety responses across diverse human cultures, presumably as a mechanism to communicate the presence of danger among members of a group.

The effects of fearful and other emotion-expressing faces on measurements of autonomic activity and brain activity measured by fMRI or by electroencephalography have been studied in subjects with anxiety disorders or with major depression. In one such paradigm, fearful faces are shown very briefly (33 ms) while the subject is in an MRI scanner. This presentation is followed by a neutral face (referred to as backward masking). Under such circumstances, subjects report that they have no awareness of having seen the fearful face. Yet they exhibit an altered galvanic skin response, a measure of sympathetic activation, as well as activation of the basal amygdala, the amygdala region that processes sensory inputs and that responds selectively to threat. Several functional neuroimaging studies of individuals with PTSD, other anxiety disorders, and major depression have demonstrated heightened activity in the amygdala, activation even to innocuous stimuli, and persistence of amygdala activity in contrast to normal patterns of adaptation (Figure 61–3).

Functional neuroimaging studies of anxiety disorders and major depression have also found decreased activity in prefrontal cortical regions that are interconnected with the basal amygdala. Studies of animals with prefrontal cortical lesions demonstrate that projections from the prefrontal cortex to the basal amygdala are necessary for cognitive control over aversive information. In individuals suffering from anxiety disorders or major depression, reduced activation of the prefrontal cortex by aversive stimuli is consistent with cognitive testing that demonstrates decreased cognitive control and might contribute to excessive and persistent anxiety and other negative emotions.

Electrophysiological and functional neuroimaging studies of both major depression and bipolar disorder

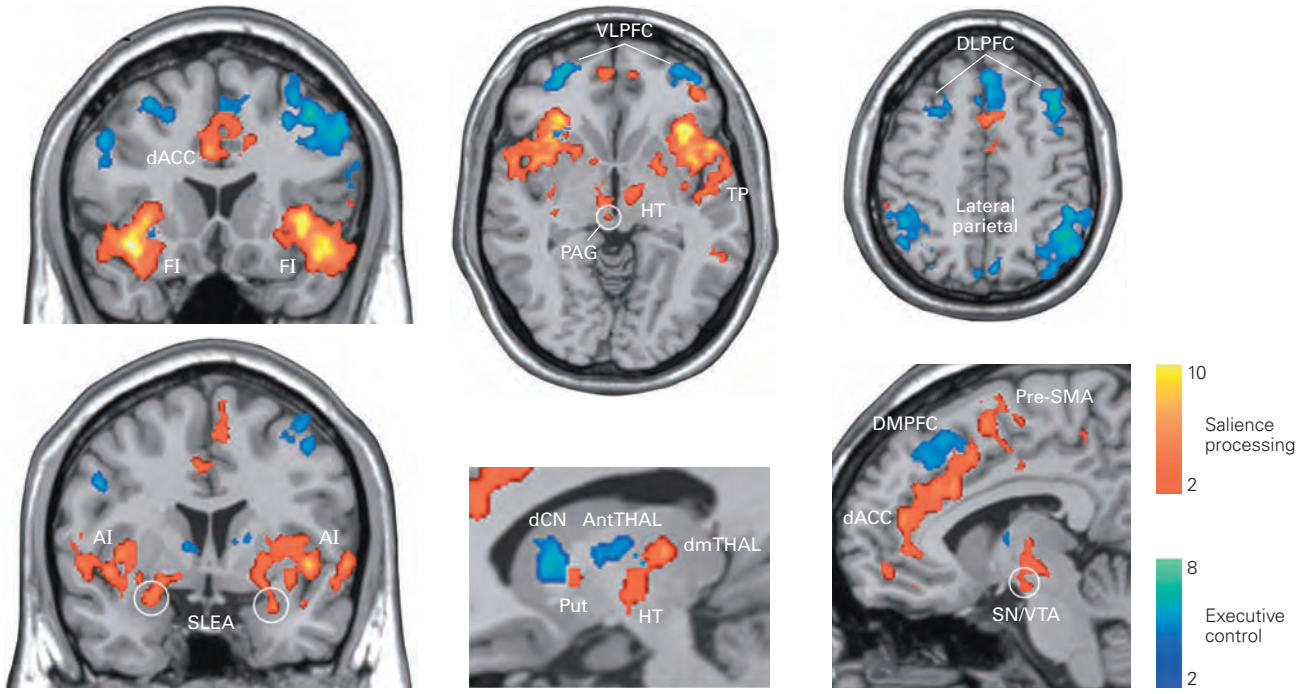

Figure 61–2 **Mood disorders involve independent neural networks associated with processing of emotional salience and cognitive control.** Statistical analysis (independent component analysis) applied to resting-state functional magnetic resonance imaging data identifies separable networks that compute emotional salience (**red-orange**) and regulate cognitive control/executive function (**blue**). The emotional salience network links dorsal anterior cingulate cortex (**dACC**) and frontoinsular cortex (**FI**) with subcortical structures involved in emotion. The cognitive control network links the dorsolateral prefrontal (**DLPFC**) and parietal cortices and several subcortical structures. The brain regions shown to be networked in this study have been implicated in major depression by multiple independent studies. (Abbreviations: **AI**, anterior insula; **antTHAL**, anterior thalamus; **dCN**, dorsal caudate nucleus; **DMPFC**, dorsomedial prefrontal cortex; **dmTHAL**, dorsomedial thalamus; **HT**, hypothalamus; **PAG**, periaqueductal gray matter; **Pre-SMA**, pre–supplementary motor area; **Put**, putamen; **SLEA**, sublenticular extended amygdala; **SN/VTA**, substantia nigra and ventral tegmental area of the midbrain; **TP**, temporal pole; **VLPFC**, ventrolateral prefrontal cortex.) Figure 61–3 **Amygdala activation in response to a masked presentation of a fearful stimulus.** A human subject observes projected images while being scanned by magnetic resonance imaging. When a fearful face is presented for a very brief time followed by presentation of a neutral face, a protocol called backward masking, the subject is not consciously aware of the fearful face. Under these conditions, the basolateral region of the amygdala is more strongly activated in individuals with anxiety disorder than in normal individuals. (Reproduced, with permission, from Etkin et al. 2004.)

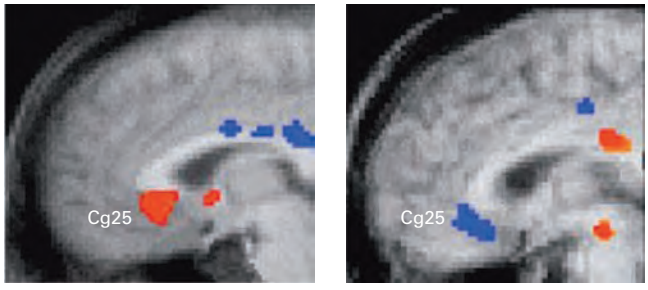
have shown abnormal functioning of the rostral and ventral subdivisions of the anterior cingulate cortex (ACC), a region of prefrontal cortex that participates in the emotional salience network. The rostral and ventral ACC have extensive connections with the hippocampus, amygdala, orbital prefrontal cortex, anterior insula, and nucleus accumbens and are involved in the integration of emotion, cognition, and autonomic nervous system function. The caudal subdivision of the ACC is involved in cognitive processes involved in control of behavior; it has connections with dorsal regions of the prefrontal cortex, secondary motor cortex, and posterior cingulate cortex.

Although abnormal function in both subdivisions of the ACC has been observed in depressive episodes, the most consistent abnormality observed in major depression and in the depressed phase of bipolar disorder is increased activity in the rostral and ventral subdivisions, especially in the subgenual region ventral to the genu (or "knee") of the corpus callosum. In a study using positron emission tomography, effective treatment of major depression with selective serotonin reuptake inhibitor antidepressants was correlated with decreased activity in the rostral ACC, whereas self-induced sadness in healthy subjects increased activity (Figure 61–4). Based on such studies, the rostral anterior (subgenual) cingulate cortex has been used as a target for electrode placement in deep brain stimulation for treatment-resistant major depression, which is operationally defined as depressive illness that has been unresponsive to antidepressant medication and psychotherapy.

Functional abnormalities of brain reward circuitry may also play a role in the symptoms of mood disorders. The reward circuitry comprises the dopaminergic projections from the ventral tegmental area of the midbrain to forebrain targets, including the nucleus accumbens, habenula, prefrontal cortex, hippocampus, and amygdala (Chapter 43). Under normal conditions, these pathways are involved in the valuation of rewards (eg, palatable food, sexual activity, and social interactions) and in motivating the necessary behavior to obtain them. Reward processing appears to be abnormal in depression, based on such symptoms as decreased interest in previously pleasurable activities, decreased motivation, and, when depression is severe, the inability to experience pleasure (anhedonia). Although less well studied, reward processing is also likely abnormal in mania, which is characterized by excessive engagement in goal-directed behaviors, even when they are maladaptive, such as uncontrolled spending, dangerous drug use, and promiscuous sexual activity.

In a recent analysis of resting-state fMRI, data showed that patients with major depression could be stratified based on connectivity patterns that correlated with their degree of anhedonia and anxiety. However, although modulation of the reward circuitry has been considered as a possible treatment for major depression, it has proven difficult in practice. For example, drugs known to activate this circuitry by



Induced sadness in healthy subjects Depression recovery with SSRI

Figure 61–4 Activity in the rostral anterior (subgenual) cingulate cortex is increased by sadness and decreased by successful treatment of major depression with an antidepressant. (Reproduced, with permission, from Mayberg et al. 1997.)

Left. Healthy volunteers provided a script of their saddest memory that was later used to generate transient sadness while undergoing positron emission tomography (PET). The rostral anterior cingulate cortex was activated (**red** pseudo-color in the sagittal section of the human brain) was activated when the sad story was read. **Cg25** is an alternative nomenclature for the cingulate gyrus, Brodmann area 25. The PET ligand was oxygen-15–labeled water, used to measure cerebral blood flow as a proxy for brain activity.

Right. Elevated metabolism in the rostral anterior cingulate cortex was confirmed in subjects with major depression. Following successful treatment with a selective serotonin reuptake inhibitor (**SSRI**) antidepressant, brain activity in Cg25 decreased (**blue** pseudo-color in the sagittal section of the human brain). The PET ligand was 2-deoxyglucose, used to measure cerebral metabolism as a proxy for brain activity.

increasing synaptic dopamine, such as amphetamine and cocaine, pose a high risk of overuse and addiction. More recently, tests of drugs that release reward circuits from inhibitory control, such as kappa opiate receptor antagonists, have been initiated in patients with major depression.

A Decrease in Hippocampal Volume Is Associated With Mood Disorders

The best-established structural abnormality in mood disorders is decreased hippocampal volume in individuals with major depression compared with healthy subjects. Recent studies of patients with major depression and bipolar disorder have found hippocampal volume loss in unmedicated subjects in regions of the cerebral cortex associated with the control of emotion. Such studies, which still need replication, show both overlapping and nonoverlapping patterns of volume loss in patients with major depression compared with bipolar disorder. Volume reductions observed in patients with major depression correlate with the duration of depressive episodes when controlling for duration of medication use. These findings suggest that in major depression the volume losses result from persistent illness and do not represent an antecedent risk factor. Some researchers have hypothesized that elevated cortisol levels in patients with major depression might be associated with reduced hippocampal volumes.

Reduced hippocampal volume has also been reported in cases of PTSD. In contrast with major depression, studies of monozygotic twins discordant for PTSD suggest that small hippocampi precede onset of the disorder and may thus represent a risk factor instead of a result of the disorder.

The acquired loss of hippocampal volume in major depression could result from loss of dendrites and dendritic spines, from decreased cell numbers (neurons or glia), or both. Given the relationship of stress and depression, excessive cortisol secretion could play a causal role in either type of loss. A decrease in hippocampal cell number could be explained by the fact that stress and elevated glucocorticoid levels suppress adult hippocampal neurogenesis, as shown in studies of several animal species.

In several mammals, including humans, new granule cells within the dentate gyrus of the hippocampus are produced during adult life. Studies of rodents have shown that these new neurons can be incorporated into functional neural circuits where they initially exhibit heightened structural and synaptic plasticity. A role for cell death as a balance to adult neurogenesis is less well studied.

In rodents, stressful or aversive treatments or administration of glucocorticoids inhibits the proliferation of granule cell precursors and thus suppresses normal rates of neurogenesis in the hippocampus. Antidepressants, including the selective serotonin reuptake inhibitors, exert an opposite effect, increasing the rate of neurogenesis. Thus, excess secretion of glucocorticoid stress hormones, as occurs in depression, could cause hippocampal volume loss by inhibiting neurogenesis over time. Because glucocorticoid receptors in the hippocampus are required for inhibitory feedback to hypothalamic neurons that synthesize and release CRH, impairments of hippocampal function could further impair feedback regulation of the HPA axis, creating a vicious cycle.

The hippocampus permits the brain to resolve differences among closely related stimuli (pattern separation) and provides contextual information that facilitates interpretation of the survival significance of a stimulus. Such information is needed by the organism to accurately identify threats that are signaled within a stream of complex sensory inputs. In animal studies, hippocampal lesions increase anxiety responses; it is thought that the resulting impairment of pattern separation and processing of contextual information permits threat-related memories to generalize inappropriately and thus to become associated with innocuous stimuli. Physiological and behavioral evidence suggests that newborn neurons within the dentate gyrus of the hippocampus play a particularly important role in pattern separation. Thus, inhibition of neurogenesis might contribute to anxiety symptoms that often accompany major depression, and abnormally low hippocampal volumes might increase the risk of PTSD.

Major Depression and Anxiety Disorders Can Be Treated Effectively

Major depressive disorder can be treated effectively with antidepressant drugs, cognitive psychotherapy, and electroconvulsive therapy. Major depressive disorder refractory to other interventions is being treated experimentally with deep brain stimulation targeted to the subgenual prefrontal cortex and other targets, including the nucleus accumbens.

Current Antidepressant Drugs Affect Monoaminergic Neural Systems

Named for their first clinical indication, the antidepressant drugs have broader utility than suggested by their name. Indeed, antidepressants are also the first-line

drugs for the treatment of anxiety disorders. Along with frequent co-occurrence and sharing of risk factors and some neural circuits, the overlap in effective treatment modalities is further evidence that mood and anxiety disorders are related.

All widely used antidepressant drugs increase activity in monoaminergic systems in the brain, most significantly serotonin and norepinephrine, although some antidepressants exert modest effects on dopamine as well. The relevant monoamine neurotransmitters—serotonin, norepinephrine, and dopamine—are synthesized by cells that reside within brain stem nuclei (Chapter 40). Serotonergic and noradrenergic neurons in the pons and medulla project widely to highly diverse terminal fields in brain regions that include the hypothalamus, hippocampus, amygdala, basal ganglia, and cerebral cortex (Figures 61–5 and 61–6). Dopaminergic neurons in the ventral tegmental area and substantia nigra pars compacta of the midbrain project to somewhat less widespread areas. Ventral tegmental neurons project to the hippocampus, amygdala, nucleus accumbens, and prefrontal cortex; substantia nigra neurons innervate the caudate and putamen. The widely divergent projections of these monoaminergic neurons permit them to influence functions such as arousal, attention, vigilance, motivation, and other cognitive and emotional states that require integration of multiple brain regions.

Serotonin, norepinephrine, and dopamine are synthesized from amino acid precursors and packaged into synaptic vesicles for release. Monoamines in the cytoplasm that are outside of vesicles are metabolized by the enzyme monoamine oxidase (MAO), which is associated with the outer leaflet of mitochondrial

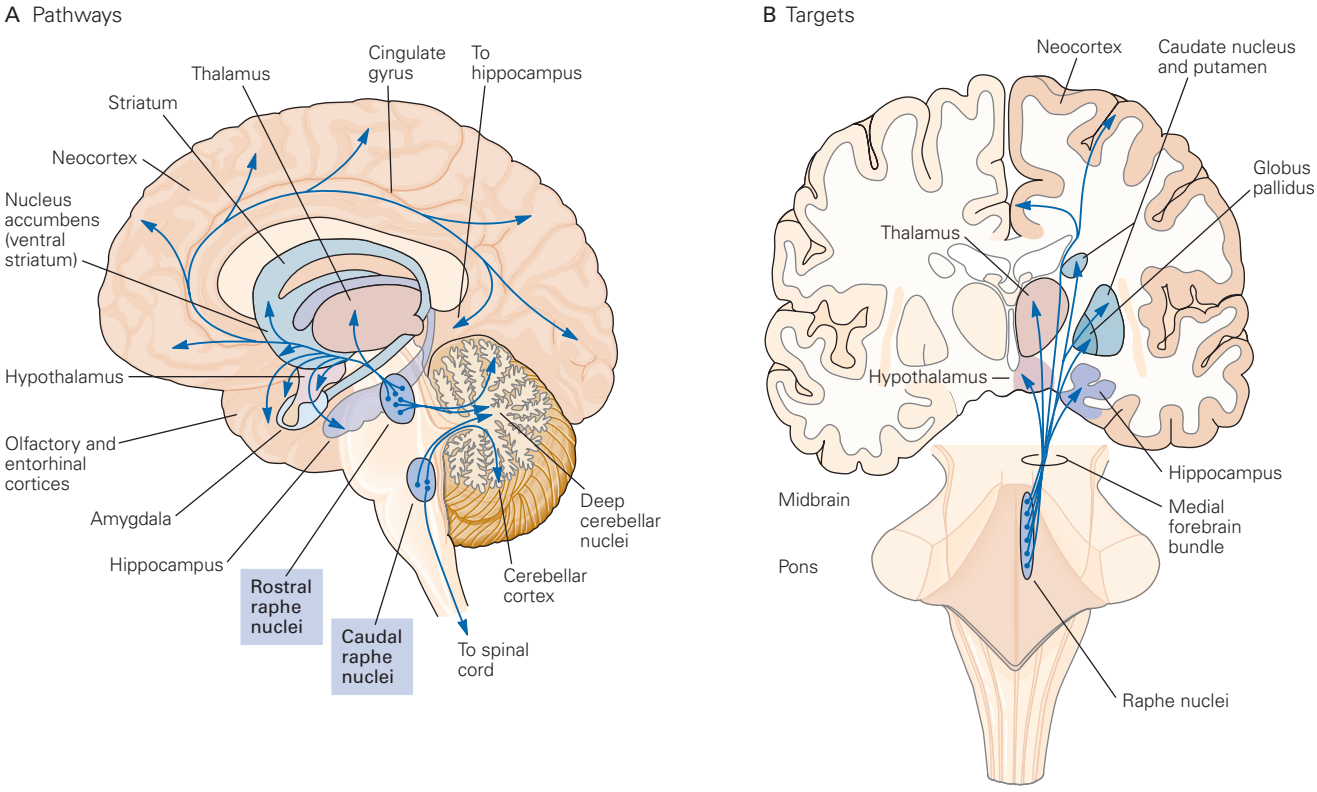


Figure 61–5 The major serotonergic systems in the brain arise in the raphe nuclei of the brain stem. Serotonin is synthesized in a group of brain stem nuclei called the raphe nuclei. These neurons project throughout the neuraxis, ranging from the forebrain to the spinal cord. The serotonergic projections are the most massive and diffuse of the monoaminergic systems, with single serotonergic neurons innervating hundreds of target neurons. (Adapted, with permission, from Heimer 1995.)

A. A sagittal view of the brain illustrates the raphe nuclei. In the brain, these nuclei form a fairly continuous collection of cell groups close to the midline of the brain stem and extending along its length. In the drawing here, they are shown in more distinct rostral and caudal groups. The rostral raphe nuclei project to a large number of forebrain structures.

B. This coronal view of the brain illustrates some of the major structures innervated by serotonergic raphe nuclei neurons.

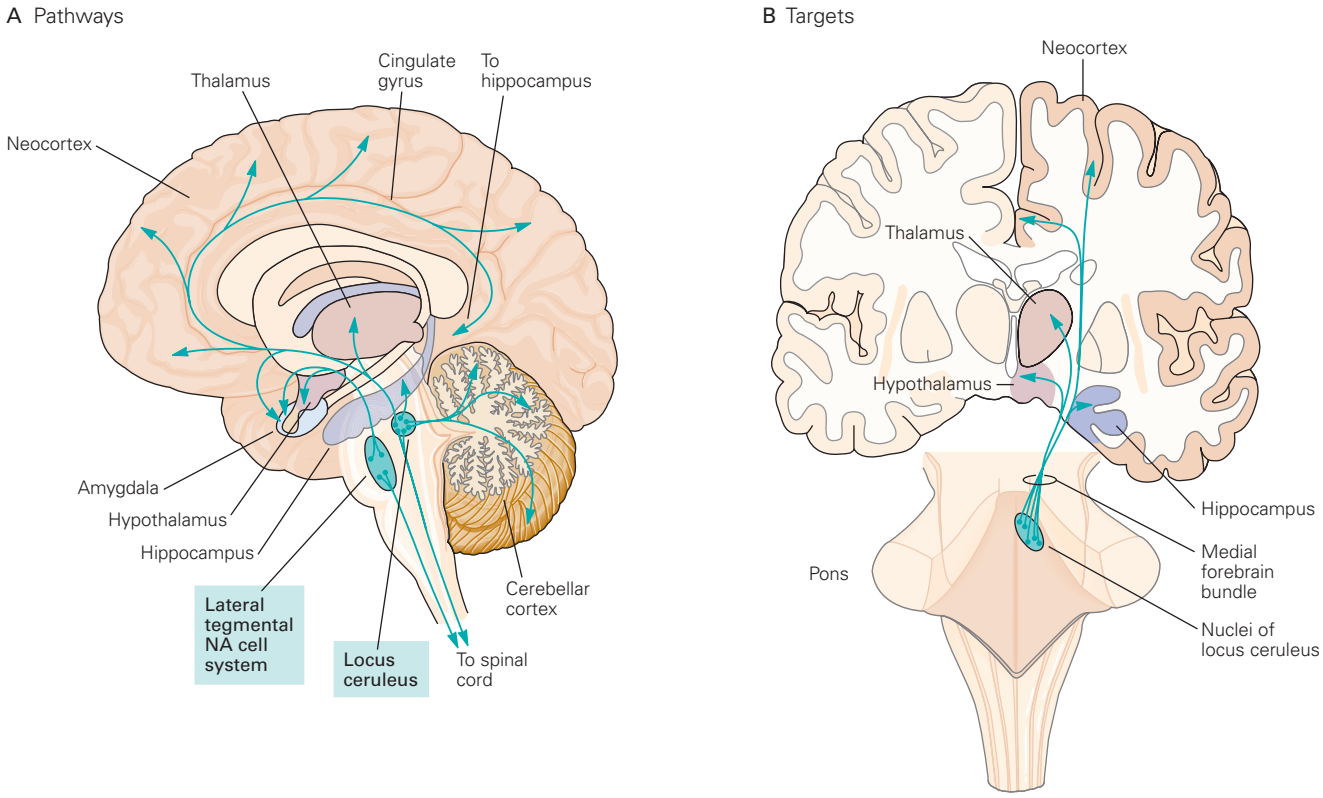

Figure 61–6 The major noradrenergic projection of the forebrain arises in the locus ceruleus. (Adapted, with permission, from Heimer 1995.)

A. Norepinephrine is synthesized in several brain stem nuclei, the largest of which is the nucleus locus ceruleus, a pigmented nucleus located just beneath the floor of the fourth ventricle in the rostrolateral pons. A lateral midsagittal view demonstrates the course of the major noradrenergic (NA) pathways from the locus ceruleus and lateral brain stem tegmentum. Axons from the locus ceruleus project rostrally into the forebrain and also into the cerebellum and spinal cord; axons from noradrenergic nuclei in the lateral brain stem tegmentum project to the spinal cord, hypothalamus, amygdala, and ventral forebrain.

B. A coronal section shows the major targets of neurons from the locus ceruleus.

membranes. After vesicular release, monoamine neurotransmitters bind synaptic receptors to exert their biological effect or are cleared from the synapse by specific transporter proteins located on the presynaptic cell membrane.

The most widely used antidepressant drugs fall into several major groupings, which affect monoaminergic neurons and their targets (Figure 61–7). The *MAO inhibitors* discovered in the 1950s, such as phenelzine and tranylcypromine, are effective against both depression and anxiety disorders but are rarely used today because of their side effects. MAO inhibitors block the capacity of MAO to break down norepinephrine, serotonin, or dopamine in presynaptic terminals, thus making extra neurotransmitter available for packaging into vesicles and for release.

Two forms of MAO, types A and B, are found in the brain. Type A is also found in the gut and liver, where it catabolizes bioactive amines that are present in foods. Inhibition of MAO-A permits bioactive amines such as tyramine to enter the bloodstream from foods that contain it in high concentrations, such as aged meats and cheeses. Transporters shuttle these amines into the terminals of sympathetic neurons, where they can displace endogenous vesicular norepinephrine and epinephrine into the cytoplasm, leading to nonvesicular release that causes significant elevations of blood pressure.

The *tricyclic antidepressants*, also first identified in the mid-1950s, include imipramine, amitriptyline, and desipramine; these block the norepinephrine transporter (NET), the serotonin reuptake transporter (SERT), or both. These drugs are effective in treating both depression and anxiety disorders. However, in addition to their therapeutic targets, the older tricyclic drugs also block many neurotransmitter receptors,

including the muscarinic acetylcholine, histamine H_1, and α_1 noradrenergic receptors, producing a panoply of side effects.

The *selective serotonin reuptake inhibitors* (SSRIs) such as fluoxetine, sertraline, and paroxetine, first approved in the 1980s, have no greater efficacy than the older tricyclic antidepressants and MAO inhibitors but are widely used because they have milder side effects and are far safer if taken in overdose. As their name implies, they selectively inhibit SERT. They are effective for major depressive disorder and many anxiety disorders. In high doses, selective serotonin reuptake inhibitors are also effective for symptoms of obsessive-compulsive disorder. Selective norepinephrine and serotonin-norepinephrine reuptake inhibitors have also been developed; these drugs have side effect profiles similar to those of selective serotonin reuptake inhibitors but are useful for some patients who do not benefit from inhibition of SERT alone.

Despite knowledge of the initial molecular targets that mediate the effects of antidepressant drugs, MAO or monoamine transporters, the ultimate molecular mechanisms by which they relieve depression remain unknown. One major challenge to understanding the therapeutic action of these drugs is the delay in their therapeutic effects. Although antidepressant drugs bind to and inhibit MAO, NET, or SERT with their first dose, several weeks of treatment are typically required to observe a lifting of depressive symptoms.

Several hypotheses have been put forward to explain this delay. One is that a slow buildup of newly synthesized proteins alters the responsiveness of neurons in a manner that treats the depression. Another is that increases in the levels of synaptic transmission of serotonin or norepinephrine rapidly increase plasticity in different emotion-processing circuits and that the latency to therapeutic benefit reflects the time it takes for new experiences to alter synaptic weights. A third hypothesis is that antidepressant efficacy is mediated in part by enhancement of hippocampal neurogenesis. Narrowing down the possible therapeutic mechanisms is challenging because of the lack of good animal models of depression. Without an animal model, it is not possible to know which of the many observable molecular, cellular, and synaptic changes cause depression or underlie the therapeutic actions of effective antidepressants.

Ketamine Shows Promise as a Rapidly Acting Drug to Treat Major Depressive Disorder

Ketamine, which blocks the *N*-methyl-D-aspartate (NMDA) glutamate receptor, is currently used in pediatric anesthesia for its ability to produce dissociative experiences as well as analgesia. It has been studied in randomized clinical trials with subjects suffering from major depression. In the trials, ketamine was administered by intravenous infusion; it produced an antidepressant effect within 2 hours, a significant advantage over existing antidepressant drugs that typically take weeks to show benefit. The therapeutic effects of ketamine last for approximately 7 days, after which second and third doses may continue to be effective. If such results become widely replicated, ketamine would represent the first antidepressant drug that does not exert its primary action on monoamine neurotransmission. Studies to identify mechanisms by which ketamine relieves depression, like those for older antidepressants, are challenging in part because of the lack of good animal models of depression.

At higher doses, ketamine is misused as a recreational drug to produce euphoria, dissociation, depersonalization, and hallucinations. Ketamine has also been used in laboratory settings to induce cognitive symptoms reminiscent of schizophrenia in human subjects. Although the advantages of a rapidly acting antidepressant would be significant, for example in treating acutely suicidal individuals, the unwanted psychotropic effects of ketamine make its use problematic. Attempts to develop alternative NMDA receptor blockers in which the antidepressant effects might be separated from psychotropic side effects are under way.

Psychotherapy Is Effective in the Treatment of Major Depressive Disorder and Anxiety Disorders

Short-term symptom-focused psychotherapies have been developed for depression and anxiety and tested in clinical trials. The best-studied psychotherapies are the cognitive behavioral therapies. Cognitive therapies that might be used to treat major depression focus on identifying and correcting excessively negative interpretations of events and of interactions with other people. For example, many depressed people exhibit a strong attentional bias toward negative information, automatically interpret neutral events as negative, and read evidence of disapproval into the behavior of others. Such automatic negative thinking, which can initiate or perpetuate depressed mood, can be much improved through cognitive psychotherapies.

Therapies with a more behavioral component have proven useful in the treatment of anxiety disorders such as phobias or PTSD. In exposure therapy, the affected individual is directed to vividly recollect phobic stimuli that trigger anxiety or avoidance. The therapist provides a safe context for such experiences

Figure 61–7 (Opposite) Actions of antidepressant drugs at serotonergic and noradrenergic synapses. The figure shows the pre- and postsynaptic sides of serotonergic and noradrenergic synapses. Serotonin and norepinephrine are synthesized from amino acid precursors by enzymatic cascades. The neurotransmitters are packaged in synaptic vesicles; free neurotransmitter within the cytoplasm is metabolized by monoamine oxidase (**MAO**), an enzyme associated with the abundant mitochondria found in presynaptic terminals. Upon release, serotonin and norepinephrine interact with several types of pre- and postsynaptic receptors. Each neurotransmitter is cleared from the synapse by a specific transporter. The serotonin and norepinephrine transporters and MAO are targets of antidepressant drugs.

A. Important sites of drug action at serotonergic synapses. Not all actions described are shown in the figure.

1. *Enzymatic synthesis*. Inhibition of synthesis of the rate-limiting enzyme tryptophan hydroxylase by *p*-chlorophenylalanine initiates the cascade that converts tryptophan to 5-OH-tryptophan, the precursor of 5-hydroxytryptophan (**5-HT**, serotonin).

2. *Storage*. Reserpine and tetrabenazine interfere with the transport of serotonin and catecholamines into synaptic vesicles by blocking the vesicular monoamine transporter $VMAT_2$. As a result, cytoplasmic serotonin is degraded (see step 6 below), and thus, the neuron is depleted of neurotransmitter. Reserpine was used as an antihypertensive drug but commonly caused depression as a side effect.

3. *Presynaptic receptors*. Agonists at presynaptic receptors produce negative feedback on neurotransmitter synthesis or release. The agonist 8-hydroxy-diprolamino-tetraline (8-OH-DPAT) acts on $5\text{-}HT_{1A}$ receptors on the presynaptic neuron. The antimigraine triptan drugs (eg, sumatriptan) are agonists at $5\text{-}HT_{1D}$ receptors.

4. *Postsynaptic receptors*. The hallucinogen lysergic acid diethylamide (LSD) is a partial agonist at $5\text{-}HT_{2A}$ receptors on postsynaptic serotoninergic neurons. Second-generation antipsychotic drugs, such as risperidone and olanzapine, are antagonists at $5\text{-}HT_{2A}$ receptors in addition to their ability to block D_2 dopamine receptors. The antiemetic compound ondansetron is an antagonist at $5\text{-}HT_3$ receptors, the only ligand-gated channel among the monoamine receptors. Its key site of action is in the medulla.

5. *Uptake*. The selective serotonin reuptake inhibitors, such as fluoxetine and sertraline, are selective blockers of the serotonin transporter. The tricyclic drugs have mixed actions; some, such as clomipramine, are relatively selective for the serotonin transporter. Uptake blockers increase synaptic concentrations of serotonin. Amphetamines enter monoaminergic neurons via the uptake transporter and bind to the vesicular transporter found on the membranes of synaptic vesicles, causing reverse transport of the monoamine neurotransmitter into the cytoplasm. The neurotransmitter is then reverse-transported out of the neuron into the synapse via the uptake transporter.

6. *Degradation*. Phenelzine and tranylcypromine, both of which are effective for depression and panic disorder, block MAO-A and MAO-B. Moclobemide, effective against depression, is selective for MAO-A; selegiline, which has been used to treat Parkinson disease, is selective for MAO-B in low doses. (Abbreviation: **5-HIAA**, 5-hydroxyindoleacetic acid.)

B. Important sites of drug action at noradrenergic synapses.

1. *Enzymatic synthesis*. The competitive inhibitor α-methyltyrosine blocks the reaction catalyzed by tyrosine hydroxylase that converts tyrosine to DOPA. A dithiocarbamate derivative, FLA-63 (not shown), blocks the reaction that converts DOPA to dopamine.

2. *Storage*. Reserpine and tetrabenazine interfere with the transport of norepinephrine (**NE**), dopamine, and serotonin into synaptic vesicles by blocking the vesicular monoamine transporter $VMAT_2$. As a result, the cytoplasmic neurotransmitter is degraded (see below), and thus the neuron is depleted of neurotransmitter.

3. *Presynaptic receptors*. Agonists at presynaptic receptors produce negative feedback on neurotransmitter synthesis or release. Clonidine is an agonist at α_2-adrenergic receptors, inhibiting NE release. It has anxiolytic and sedative effects and is also used to treat attention deficit hyperactivity disorder. Yohimbine is an antagonist at α_2-adrenergic receptors; it induces anxiety.

4. *Postsynaptic receptors*. Propranolol is an antagonist at β-adrenergic receptors that blocks many effects of the sympathetic nervous system. It is used to treat some forms of cardiovascular disease but is commonly used to block anxiety during performance situations. Phenoxybenzamine is an agonist at α-adrenergic receptors.

5. *Uptake*. Certain tricyclic antidepressants, such as desipramine, and newer NE selective reuptake inhibitors, such as reboxetine, selectively block the NE transporter, thus increasing synaptic NE. Amphetamines enter monoaminergic neurons via the uptake transporter and interact with the vesicular transporter (the transporter on synaptic vesicles) to release neurotransmitter into the cytoplasm. The neurotransmitter is then pumped out of the neuron into the synapse via the uptake transporter acting in reverse.

6. *Degradation*. At the postsynaptic neuron, tropolone inhibits the enzyme catechol *O*-methyltransferase (**COMT**), which inactivates NE (**step 6a**). Normetanephrine (**NM**) is formed by the action of COMT on NE. At the presynaptic neuron, degradation by MAO is blocked by the MAO inhibitors phenelzine and tranylcypromine.

and also suggests new interpretations of such stimuli that help the patient cope with the experience. Where possible and when tolerable to patients, gradual transition to real-world exposures to phobic stimuli can be employed.

Exposure therapy produces extinction learning in analogy with studies of animal behavior. The memory of the phobic stimulus is not erased, but the fearful response is suppressed by new information that the stimulus and the context in which it is experienced are not dangerous. Animal physiology and lesioning studies and human imaging studies demonstrate that the prefrontal cortex is required for extinction learning and that the hippocampus is required for learning new contexts for familiar events or stimuli (eg, that a helicopter flying overhead does not portend an attack).

Electroconvulsive Therapy Is Highly Effective Against Depression

Although it still conjures up negative images in the popular imagination, electroconvulsive therapy (ECT) administered with modern anesthesia is medically safe and a tolerable patient experience, and it remains a highly effective intervention for the acute treatment of serious major depressive disorder. It is most often used when depressive symptoms are severe and medications and psychotherapies have proven ineffective. It is also effective in both the depressed and manic phases of bipolar disorder. It is not effective for anxiety disorders in the absence of a mood disorder and is not used to treat them clinically.

Generally, six to eight treatments are given, most commonly on an outpatient basis. Patients are anesthetized, and electrical stimulation is administered just above the threshold to produce electroencephalographic evidence of a generalized seizure. The major side effect is a variable degree of anterograde and retrograde amnesia. Amnesia can be minimized, but not eliminated, by placing the electrodes unilaterally and using the lowest level of electrical stimulation needed. Rodents given ECT exhibit massive release of neurotransmitters, which causes significant activation of gene expression, presumably leading to large-scale neural plasticity. However, the precise molecules, cells, and circuits involved in the therapeutic response remain unknown.

Newer Forms of Neuromodulation Are Being Developed to Treat Depression

Other forms of therapeutic electrical stimulation of the brain are being explored, motivated by the desire to improve upon the therapeutic effects of ECT while diminishing its side effects. These approaches are often described as "neuromodulation."

Transcranial magnetic stimulation (TMS) employs a device on the scalp to deliver brief pulses of rapidly alternating magnetic stimulation. This induces currents to flow within axons in regions of cerebral cortex beneath the device. Daily administration of TMS over the left prefrontal cortex is safe and was effective enough to have received regulatory approval by the US Food and Drug Administration. Nonetheless, in subsequent trials, its efficacy appears to be only modest. Additional clinical experiments are under way aimed at improving efficacy.

Alternative therapies under development include magnetic seizure therapy, an alternative to ECT in which a magnetic field is the used to produce a seizure. The hope for this experimental therapy is to reproduce the efficacy of ECT with less anterograde and retrograde amnesia.

Deep brain stimulation (DBS), mentioned above, is an invasive neuromodulatory treatment in wide use for treatment of the motor symptoms of Parkinson disease and of essential tremor. For treatment of Parkinson disease, an electrode is typically placed within the subthalamic nucleus, a component of basal ganglia circuitry involved in motor control that is well understood compared with circuits that regulate mood. A DBS electrode is connected by a wire that exits the skull and travels under the scalp and skin of the neck to a controller and battery pack that resides in the chest, much like a cardiac pacemaker battery. The rate at which the electrode stimulates its target can be controlled externally and is typically adjusted by the treatment team to optimize the therapeutic response. During the past decade, clinical trials of DBS have been extended from Parkinson disease and other movement disorders to psychiatric disorders. In addition to its use in treatment-refractory depression, DBS is being studied for the treatment of obsessive-compulsive disorder.

Several locations in the brain have been targets for DBS to treat depression. As described in Figure 61–4, the rostral anterior (subgenual) cingulate cortex is activated by sadness. Accordingly, it has been used as a DBS target for treatment-resistant depression (Figure 61–8). In some clinical series, 60% of treatment-resistant patients achieved stable improvement with stimulation of the subgenual cingulate cortex. However, similar levels of efficacy using this target could not be replicated in a large multisite clinical trial. Differences in patient selection, interindividual differences in brain anatomy, or small differences in electrode placement may account for the disparate results seen to date. To

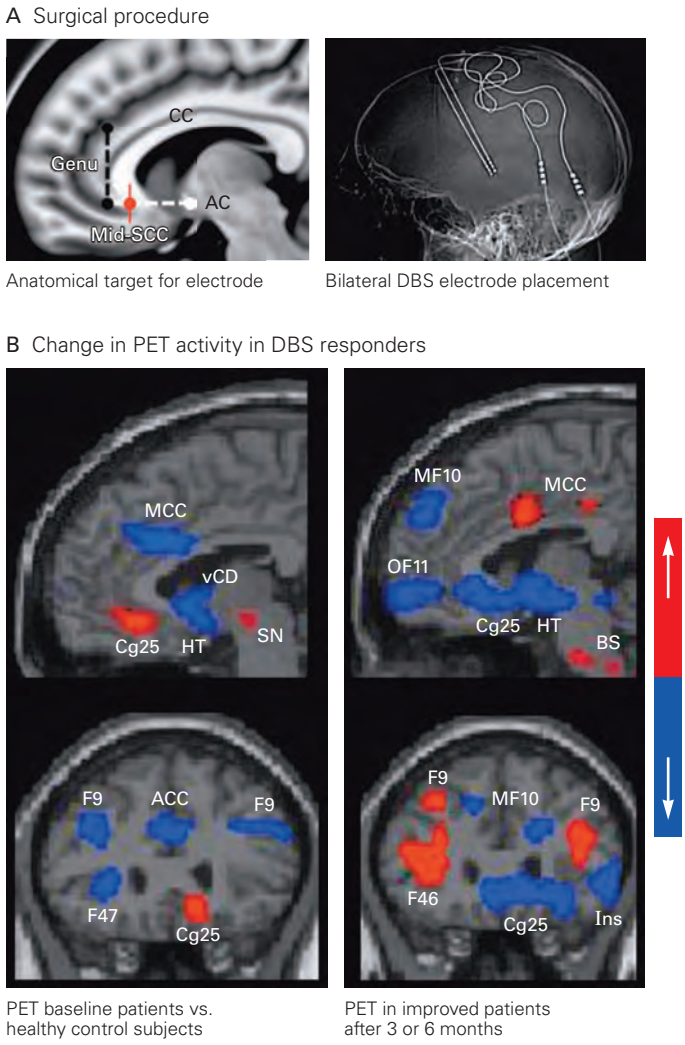

Figure 61–8 Electrode placement for deep brain stimulation (DBS) in the rostral anterior cingulate cortex and measurement of response by [18F] fluoro-2-deoxyglucose positron emission tomography (PET). (Reproduced, with permission, from Helen Mayberg.)

A. *Left:* The rostral anterior (subgenual) cingulate cortex, Brodmann area 25 (**Cg25**), is an anatomic target for DBS for patients with treatment-resistant depression. (Sagittal section; electrode site in **red**; corpus callosum is just superior and shown in **white**; **dotted line**, position of the electrode relative to the AC-genu line.) (Abbreviations: **AC**, anterior commissure; **Mid-SCC**, mid-subcallosal cingulate.) *Right:* A PET scan shows placement of the electrodes in the brain of a patient undergoing stimulation of the rostral anterior cingulate cortex. (Sagittal section.)

B. PET scans show the changes in activity in patients with treatment-resistant depression who have improved with stimulation of the rostral anterior cingulate cortex. The **top** panels are sagittal sections; the **bottom** panels are coronal sections. *Left:* Pretreatment metabolic activity in patients with treatment-resistant depression. **Red** pseudo-color denotes elevated metabolic activity compared with healthy control subjects (note elevated activity in Cg25 before DBS); **blue** denotes lower metabolic activity. *Right:* Averages of patients who have improved at 3 or 6 months after initiation of DBS. Activity in Cg25 is decreased (**blue**) in patients who have had a positive response to stimulation. (Abbreviations: **ACC**, anterior cingulate cortex; **BS**, brain stem; **F9**, dorsolateral prefrontal cortex; **F46**, prefrontal cortex; **F47**, ventrolateral prefrontal cortex; **HT**, hypothalamus; **Ins**, insula; **mF10**, medial frontal cortex; **MCC**, middle cingulate cortex; **OF11**, orbital frontal cortex; **SN**, substantia nigra; **vCD**, ventral caudate.)

put it simply, depression is highly heterogeneous, and it should not be surprising that a single DBS target is not useful for all treatment-resistant patients.

Lacking good animal models of mood disorders, human DBS treatment trials may provide a particularly important source of information about the brain circuitry responsible for the symptoms of mental disorders. Although careful attention must be paid to obtaining informed consent and to safety, especially when the judgment of patients is influenced by severe depression, DBS may provide an opportunity to learn about mood regulation. In particular, newly developed electrodes not only stimulate a DBS target but can also record extracellular neuronal activity. Such "read–write" electrodes, currently being used in research settings only, may not only improve clinical results but also advance our knowledge of circuit dysfunction and therapeutic modulation in psychiatric disorders.

Bipolar Disorder Can Be Treated With Lithium and Several Anticonvulsant Drugs

In 1949, John Cade discovered the calming effects of lithium in guinea pigs and, soon thereafter, in a small clinical trial in bipolar patients. Cade's observations initiated the modern era of psychopharmacology in which drugs, ultimately subjected to randomized, blinded clinical trials, were used to treat specific symptoms of mental disorders. Lithium eventually proved to be effective in treating acute episodes of mania and in stabilizing mood by reducing the frequency of cycling into mania and depression.

Several drugs initially developed to treat epilepsy, such as valproic acid and lamotrigine, have also been shown to be effective in treating acute mania and for mood stabilization and can serve as substitutes for lithium. In addition, antipsychotic drugs effectively

ameliorate symptoms of acute mania and, at low doses, can also help stabilize mood. None of these drugs exerts therapeutic effects rapidly; improvements in mental state and behavior may take several weeks.

The mechanisms by which lithium and anticonvulsant drugs exert beneficial effects on mania and on mood cycling are not known. Unlike the antidepressant and antipsychotic drugs, however, there remain open questions about the initial molecular target of lithium in the nervous system relevant to the initiation of its therapeutic effects. This lack of certainty reflects the many actions of lithium at therapeutic concentrations in the brain. The most likely molecular target is inhibition of glycogen synthase kinase type 3β (GSK3β), a component of the Wnt signaling pathway that has many functions in the nervous system. As in the case of other drugs to treat psychiatric disorders, investigation of the therapeutic mechanism of lithium and of the mood-stabilizing properties of anticonvulsants is impeded by the lack of an animal model of bipolar disorder.

Whatever the molecular mechanisms of lithium or the anticonvulsants, mood stabilizers appear to dampen the dynamics of mood regulatory systems. Mood is regulated by the external environment as well as several internal inputs, including the internal hormonal milieu, immune modulators, and circadian controls (eg, both the serotonergic and noradrenergic systems show diurnal variations closely coupled with the sleep–wake cycle). The integration of these systems is complex, involving dynamic interactions that are still poorly understood.

Second-Generation Antipsychotic Drugs Are Useful Treatments for Bipolar Disorder

All antipsychotic drugs act by blocking D_2 dopamine receptors, but these drugs have long been recognized to have therapeutic effects not only in the treatment of the psychotic symptoms of schizophrenia, severe mood disorders, and many other conditions, but also in the treatment of acute manic episodes. The side effects of first-generation antipsychotic drugs are severe, most prominently Parkinson-like motor side effects that result from D_2 dopamine receptor antagonism.

Most second-generation drugs have somewhat lower affinity for D_2 dopamine receptors than first-generation drugs and, in addition, have other receptor effects, such as blocking serotonin 5-HT_{2A} receptors, resulting in a lower liability for severe motor side effects. These drugs are by no means free of serious side effects; most cause weight gain and associated metabolic conditions. However, their relative tolerability and their effects on serotonin receptors have made them an important treatment for the depressed phase of bipolar disorder as well as the treatment of acute mania. They have gained an important role in therapeutics because bipolar depression is less likely to respond to antidepressant drugs than unipolar depression.

Highlights

1. Mood disorders are divided into unipolar and bipolar disorder based on whether depression occurs alone (unipolar) or whether a person also suffers from episodes of mania. Unipolar and bipolar disorders have different familial patterns of transmission.
2. Clinically significant unipolar depression, often denoted as major depressive disorder (major depression), differs from normal sadness by its persistence, pervasiveness, and association with physiological, cognitive, and behavioral symptoms.
3. Major depression is common (15%–20% lifetime prevalence) and disabling, making it a leading cause of disability worldwide. Bipolar disorder is less common (1% lifetime prevalence worldwide) but tends to produce severe symptoms that often require hospitalization.
4. Anxiety disorders are the most common psychiatric disorders. They range in severity from highly disabling cases of panic disorder and posttraumatic stress disorder (PTSD) to simple phobias. They often co-occur with major depression.
5. Mood and anxiety disorders have both genetic and nongenetic components of risk. Bipolar disorder is more heritable than major depression or anxiety disorders. Childhood adversity and later environmental stressors play a significant role in susceptibility to major depression and anxiety disorders. Genetic analyses of bipolar disorder, major depression, and PTSD are beginning to yield molecular clues to pathogenesis.
6. The neural circuitry of fear and anxiety disorders involves the amygdala and its interconnections with the prefrontal cortex. The neural circuitry of major depression and bipolar disorder is less well understood. However, neuroimaging in humans with major depression implicated circuits involved in the processing of emotional salience and in cognitive control.
7. Bipolar disorder can be treated with lithium, certain anticonvulsant drugs such as valproic acid, and second-generation antipsychotic drugs, although many patients have residual symptoms, most commonly depression.

8. Major depression and anxiety disorders can be treated with diverse antidepressant drugs and by cognitive and behavioral therapies. Electroconvulsive therapy is effective for major depression that is unresponsive to medications.
9. Experimental treatments such as deep brain stimulation are being investigated for treatment of major depression and other psychiatric disorders. The development of electrodes that can record as well as stimulate promise greater insight in human neural circuit function in disease and its treatment.

Disorders Affecting Social Cognition: Autism Spectrum Disorder

Mental retardation, now referred to widely as *intellectual disability*, is currently defined as having an IQ below 70 accompanied by marked deficits in adaptive functioning. Both terms have been broadly used to label a variety of cognitive impairments linked to prenatal or early postnatal brain abnormalities. For decades, subsets of individuals with rare intellectual disability syndromes, such as Rett syndrome or fragile X syndrome, have been characterized by their genetic etiologies. We are now beginning to elucidate the complex genetics of more prevalent neurodevelopmental disorders without distinct physical features that distinguish them, including so-called *idiopathic* or *nonsyndromic* forms of autism spectrum disorder (ASD). The combination of insights resulting from the intensive study of rare genetic syndromes coupled with successes in unraveling the genetics underlying idiopathic ASD has transformed our understanding of normal and pathological development of the human brain.

Common to all of these disorders are mental impairments that persist throughout life, hampering development and learning. Generally speaking, even if all mental functions seem to be affected, conditions with distinct etiologies and natural histories can be differentiated because some cognitive domains tend to be

more impaired than others. And indeed, these differences are reified in diagnostic schemes that draw distinctions between developmental abnormalities that affect primarily general cognition, social cognition, or perception. These differential cognitive and behavioral vulnerabilities may provide useful clues about the origin and developmental time course of specific mental functions in normal development.

In this chapter, we focus principally on neurodevelopmental disorders that include abnormalities in social functioning, including ASD, fragile X syndrome, Williams syndrome, Rett syndrome, and Angelman and Prader-Willi syndromes. These conditions all impair highly sophisticated brain functions including social awareness and communication. ASD is a prime focus for several reasons: the high prevalence in the population; the overlap in genetic risks with other common neuropsychiatric conditions, including schizophrenia; and the absence of a defining neuropathology. They are also exemplars of the etiological and phenotypic heterogeneity common to many psychiatric syndromes. In this respect, ASD is a paradigmatic neuropsychiatric syndrome.

Autism Spectrum Disorder Phenotypes Share Characteristic Behavioral Features

Profound social disability has probably always been with us, but the characterization of autism as a medical syndrome was first described in the literature in 1943 by Leo Kanner and in 1944 by Hans Asperger. Today, clinicians and researchers think of autism as a spectrum of disorders with two defining but highly variable diagnostic features: impaired social communication and stereotyped behaviors with highly restricted interests.

Until recently, the term "Asperger syndrome" was used to describe individuals who met these two diagnostic criteria, but in whom language acquisition was not delayed and IQ was in the normal range. In the most recent edition of the standard psychiatric diagnostic manual, *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5), Asperger syndrome along with a distinct disorder known as pervasive developmental disorder not otherwise specified—designed to capture individuals with deficits in social communication who did not meet full criteria in other areas—were eliminated in favor of including variations within a single spectrum construct.

Autism spectrum disorder is present in at least 1.5% of the population. Rigorous epidemiological studies estimate prevalence as high as 2.6% for the full spectrum of social disability, far higher than estimated only decades ago. The reasons for the increase in the prevalence over a relatively short time frame are of considerable interest and active debate, particularly among the lay public. Within the scientific community, a consensus has emerged that this increase reflects a combination of changing diagnostic criteria, increased awareness among families and health care professionals, "diagnostic substitution" (in which individuals who formerly would have been diagnosed with intellectual disability are now more likely to be identified as socially disabled), and some true increase in incidence. These issues will be discussed below with regard to genetic risks.

Autism spectrum disorders occur predominantly in males, although the typically cited 4:1 male-to-female ratio has recently been called into question based on concerns about male bias in the approaches used to ascertain the diagnosis, including the diagnostic instruments. Even accounting for these challenges, however, the cumulative evidence suggests a ratio bias of at least 2:1 to 3:1 male excess. Individuals across the IQ spectrum are affected, and based on current diagnostic practices, about half of all individuals with ASD also have intellectual disability. By definition, ASD must be detectable before 3 years of age, but recent studies have shown that it is possible to identify affected children in high-risk families well within the first year of life. ASD occurs in all countries and cultures and in every socioeconomic group.

Although ASD clearly affects the brain, no definitive biological markers have yet been identified; thus, diagnosis is based on behavioral criteria. This does not mean that there are not strong biological correlates, including specific gene mutations and neuroimaging findings, but none of these are sufficiently specific or predictive to be useful as an alternative to the gold standard of clinical assessment. Moreover, because behavior is variable during development and depends on a number of factors—age, environment, social context, and availability and duration of remedial help—no single behavior is likely ever to be conclusively diagnostic.

Like other neurodevelopmental syndromes, ASD typically endures throughout life. However, in recent longitudinal studies, approximately 10% of clearly affected children showed improvement, with little or no evidence of social disability later in life. Autism is not progressive. On the contrary, special educational programs and professional support often lead to improvements in behavior and adaptive functioning with age.

Autism Spectrum Disorder Phenotypes Also Share Distinctive Cognitive Abnormalities

Social Communication Is Impaired in Autism Spectrum Disorder: The Mind Blindness Hypothesis

One cognitive theory of social communication postulates that humans have a particularly well-developed ability to understand the mental states of others in an intuitive and fully automatic fashion. Watching a young person surreptitiously trying to open a car door without a key, you instantly understand that she believes she can break in while being unobserved, and you expect her to run away as soon as she realizes someone is watching. Thus, you explain and predict her behavior by inferring her mental states (desires, intentions, beliefs, knowledge) from her overt behavior. This so-called mentalizing ability, termed a *theory of mind*, is thought to depend on specific brain mechanisms and circuits underlying social cognition (Figure 62–1). Further, it is postulated that mentalizing is impaired in ASD, with profound effects on social development.

It is now generally agreed that insight into the mental state of others depends on the capacity to mentalize spontaneously. Spontaneous mentalizing allows us to appreciate that different people have different

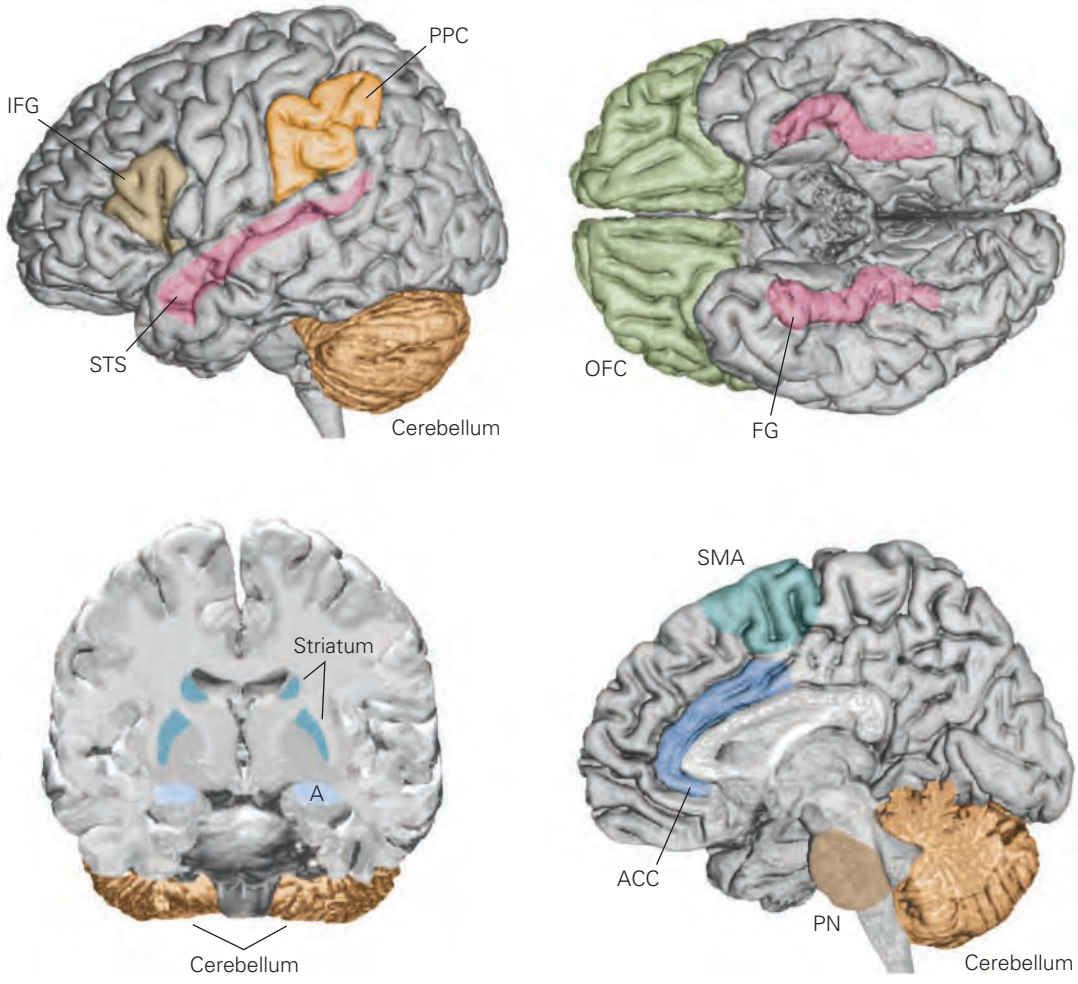

Figure 62–1 Brain areas implicated in the three core deficits characteristic of autism: impaired social interaction, impaired language and communication, and severely restricted interests with repetitive and stereotyped behaviors. Areas implicated in social deficits include the orbitofrontal cortex (**OFC**), the anterior cingulate cortex (**ACC**), and the amygdala (**A**). Cortex bordering the superior temporal sulcus (**STS**) has been implicated in mediating the perception that a living thing is moving and gaze perception. Face processing involves a region of the inferior temporal cortex within the fusiform gyrus (**FG**). Comprehension and expression of language involve a number of regions including the inferior frontal region, the striatum, and subcortical areas such as the pontine nuclei (**PN**). The striatum has also been implicated in the mediation of repetitive behaviors. (Abbreviations: **IFG**, inferior frontal gyrus; **PPC**, posterior parietal cortex; **SMA**, supplementary motor area.)

thoughts and that thoughts are internal and different from external reality.

The inability to mentalize, or "mind blindness," was first tested in children with autism using a simple puppet game, the Sally-Anne test. Young children with ASD, unlike those with Down syndrome or typically developing 4-year-olds, cannot predict where a puppet will first look for an object that was moved while the puppet was out of the room. They are not able to imagine that the puppet will "think" that the object will be where the puppet had left it (Figure 62–2). Many children with ASD eventually do learn to pass this task, but on average with a 5-year delay. Mentalizing acquired so slowly remains effortful and error-prone even in adulthood.

At the same time, young children with ASD show excellent appreciation of physical causes and events. For instance, a child who is incapable of falsely telling another that a box is locked is quite capable of locking the same box to prevent its contents from being stolen.

Variations of the Sally-Anne test and other mentalizing tasks have been used with children and adults with ASD since the mid-1980s (Figure 62–3).

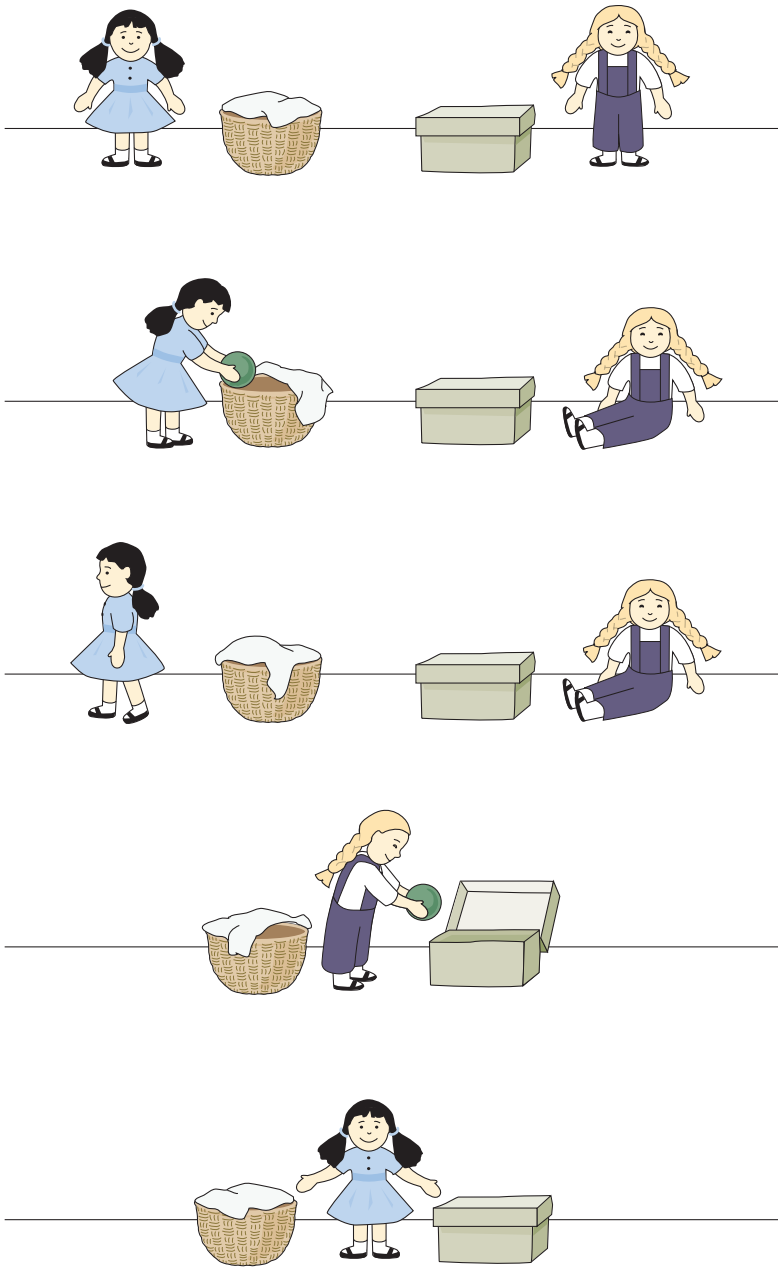

Figure 62–2 The Sally-Anne test. This first test of the "theory of mind" begins with a scripted performance using two dolls. Sally has a basket; Anne has a box. Sally puts a ball into her basket. She goes for a walk and leaves the room. While Sally is outside, naughty Anne takes the ball out of the basket and puts it into her box. Now Sally comes back from her walk and wants to play with her ball. Where will she look for the ball, the basket or the box? The answer, the basket, is obvious to most typically developing 4-year-olds but not to autistic children of the same or even higher mental age. (Adapted from original artwork by Axel Scheffler.)

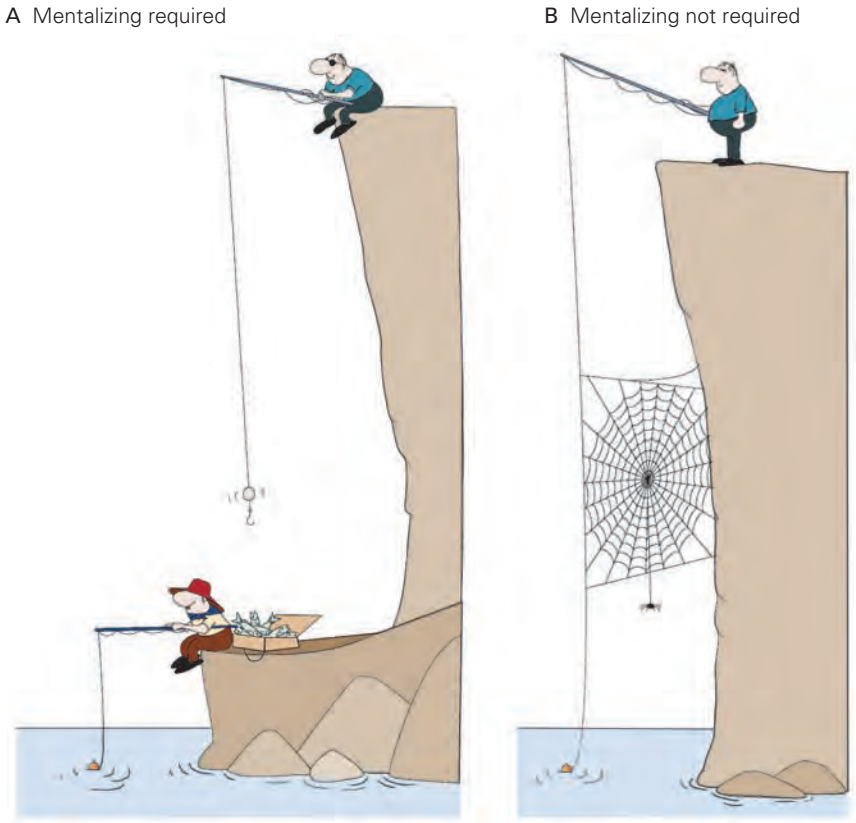

Figure 62–3 Examples of cartoons used in imaging studies of "mentalizing." Participants were asked to consider the meaning of each picture (silently) and then to explain them. In a functional magnetic resonance imaging study, normal adults passively viewed cartoons that require mentalizing versus those that do not. A characteristic network of brain regions is activated in each subject (see Figure 62–4). (Adapted from Gallagher et al. 2000.)

Functional neuroimaging has been used to examine activity in the brain of healthy subjects while they are engaged in tasks that necessitate thinking about mental states. A wide range of tasks using visual and verbal stimuli has been used in these studies. In an early positron emission tomography study, adults in a control cohort viewed silent animations of geometric shapes. In some of the animations, the triangles move in scripted scenarios designed to evoke mentalizing (eg, triangles tricking each other). In other animations, the triangles move randomly in a manner that does not evoke mentalizing. Comparison of the scans made while subjects viewed each type of animation reveals a specific network of four brain centers involved in mentalizing (Figure 62–4). Functional magnetic resonance imaging (MRI) studies using the same animations have shown that activity in this network is reduced in subjects with ASD.

This network has four components. The first, in the medial prefrontal cortex, is a region thought to be involved in monitoring one's own thoughts. A second component, in the temporoparietal region of the superior temporal lobe, is known to be activated by eye gaze and biological motion. Patients with lesions in this area in the left hemisphere are unable to pass the Sally-Anne test. The third region is the amygdala, which is involved in the evaluation of social and nonsocial information for indications of danger in the environment. The fourth region is an inferior temporal region involved in the perception of faces.

Recent studies have used stimuli intended to capture more nuanced and naturalistic social content, for example, using movies of actual social encounters as opposed to static pictures of facial expressions. These studies have identified, among other things, the role of the orbital frontal cortex in social cognition.

Other Social Mechanisms Contribute to Autism Spectrum Disorder

From birth, normal infants prefer to attend to people rather than other stimuli. An absence of this preference could lead to an inability to understand and interact with others. Indeed, the absence of preferential attention to social stimuli and mutual attention are widely acknowledged as early signs of ASD. These deficits may not involve problems with mentalizing, given that mutual attention normally appears toward the end of the first year when signs of mentalizing are still sparse.

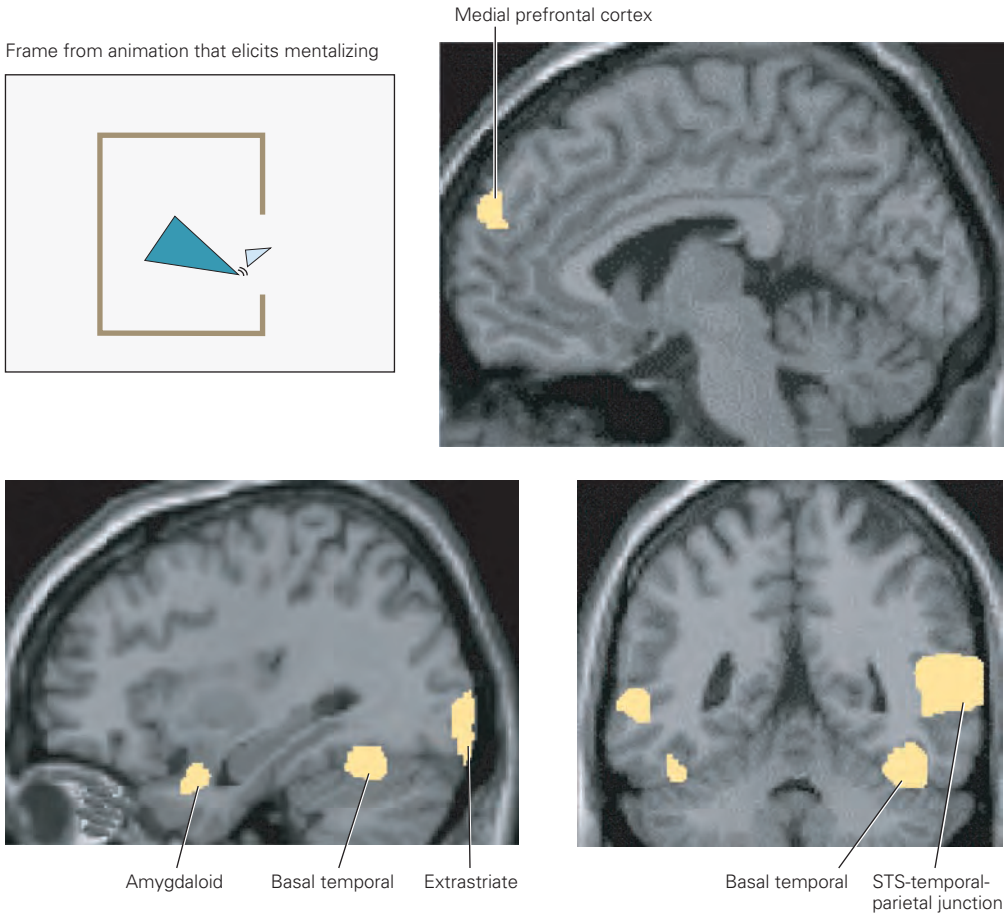

Figure 62–4 The mentalizing system of the brain. Healthy volunteers were presented with animated triangles that moved in such a way that viewers would attribute mental states to them. In the sample frame shown, the larger triangle was seen as encouraging the smaller triangle to leave the enclosure. They were also presented with animated triangles that moved in a more or less random fashion and thus would not elicit mentalizing. The highlighted areas show differences in the positron emission tomography scans of brain activation when these two viewing conditions were compared. (Abbreviation: STS, superior temporal sulcus.) Researchers have long considered the possibility that a specific neural mechanism underlies attention to social stimuli, such as faces, voices, and biological motion. In favor of this hypothesis, researchers found that the gaze of individuals with ASD is abnormal when watching social scenes. For example, multiple studies have found that individuals with ASD fixate on people's mouths instead of showing the normal preference for eyes (Figure 62–5).

People With Autism Show a Lack of Behavioral Flexibility

Repetitive and inflexible behavior in ASD may reflect abnormalities in frontal lobe executive functions, a wide array of higher cognitive processes that include the ability to disengage from a given task, inhibit inappropriate responses, stay on task (plan and manage sequences of deliberate actions), keep multiple task demands in working memory, monitor performance, and shift attention from one task to another.

Even ASD individuals with IQs in the normal range have problems in planning, organizing, and flexibly switching between behaviors. Irrespective of IQ, affected individuals have difficulties suggesting various different uses of a single object such as a handkerchief (used to block a sneeze, to wrap loose objects, etc.). Flexible thinking is also poor in patients with acquired damage to the frontal lobe.

Some Individuals With Autism Have Special Talents

A particularly fascinating feature of ASD in some individuals is "savant syndrome," defined by the presence

Figure 62–5 Individuals with autistic disorder often do not look into the eyes of others. Patterns of eye movements in individuals with autism were studied while the subjects watched clips from the film *Who's Afraid of Virginia Wolf?* When looking at human faces, the subjects tended to look at the mouth rather than the eyes, and in scenes of intense interaction between people, they tended to look at irrelevant places rather than at the faces of the actors. (Reproduced, with permission, from Klin et al. 2002. Copyright © 2002 American Psychiatric Association.)

of one or more exceptional skills that are in marked contrast to the individual's overall disability but also rare in the population at large. The most widely cited estimate is that 10% of individuals with ASD demonstrate such exceptional abilities compared to about 1 in 1,000 individuals with other forms of intellectual disability.

In the largest ASD cohort surveyed by self-reporting to date (about 5,000 families), 531 individuals were reported to have exceptional abilities in the following 10 areas (listed in descending frequency): music, memory, art, hyperlexia, mathematics, mechanical, coordination, directions, calendar calculating, and extrasensory perception. Subsequent small-scale studies have placed the prevalence of savant skills in ASD at between 13% and 28%.

A recently established savant syndrome registry now includes more than 400 people from 33 countries. Among a group of 319 individuals who met some criteria that earned them a savant diagnosis based on family or caregiver reports or self-reporting, 75% who showed savant skills in childhood were diagnosed with ASD. Approximately half reported a single exceptional skill and half reported multiple skills. Music was the most commonly reported exceptional skill, followed by art, memory, and mathematics. Calendar calculating, while present in many savants along with another skill, was the sole skill in only about 5% of the sample. Among this self- or family-selected group, the overall sex distribution mirrored that reported for ASD in general, with a male-to-female ratio of approximately 4:1.

One explanation for savant syndrome is that information processing is preferentially geared to tiny details at the cost of seeing the bigger picture. (For example, the drawing by the gifted artist with high-functioning autism in Figure 62–6 shows remarkably detailed cityscapes, as well as detailed numerical patterns and dates.) A similar hypothesis is that brain regions involved in perception are overfunctioning; another possibility is that there is a preference for manipulating the bits of information that fit within a strict framework such as calendar knowledge or a bus timetable. Neuropsychological data support both explanations, but decisive experiments to distinguish between them remain to be done.

Genetic Factors Increase Risk for Autism Spectrum Disorder

The earliest evidence that genes contribute to ASD arose from studies of twin pairs as well as familial aggregation. The former show from 60% to 90% concordance among monozygotic twin pairs; this wide range is due in part to previously used diagnostic criteria and classifications. For example, the highest estimates of monozygotic concordance are derived from observations of twins with any of three diagnoses that made up the social disability spectrum prior to the reformulations in the DSM-5. Only approximately 60% of monozygotic twins were found to be concordant for the "full diagnosis" of autism, which was defined at

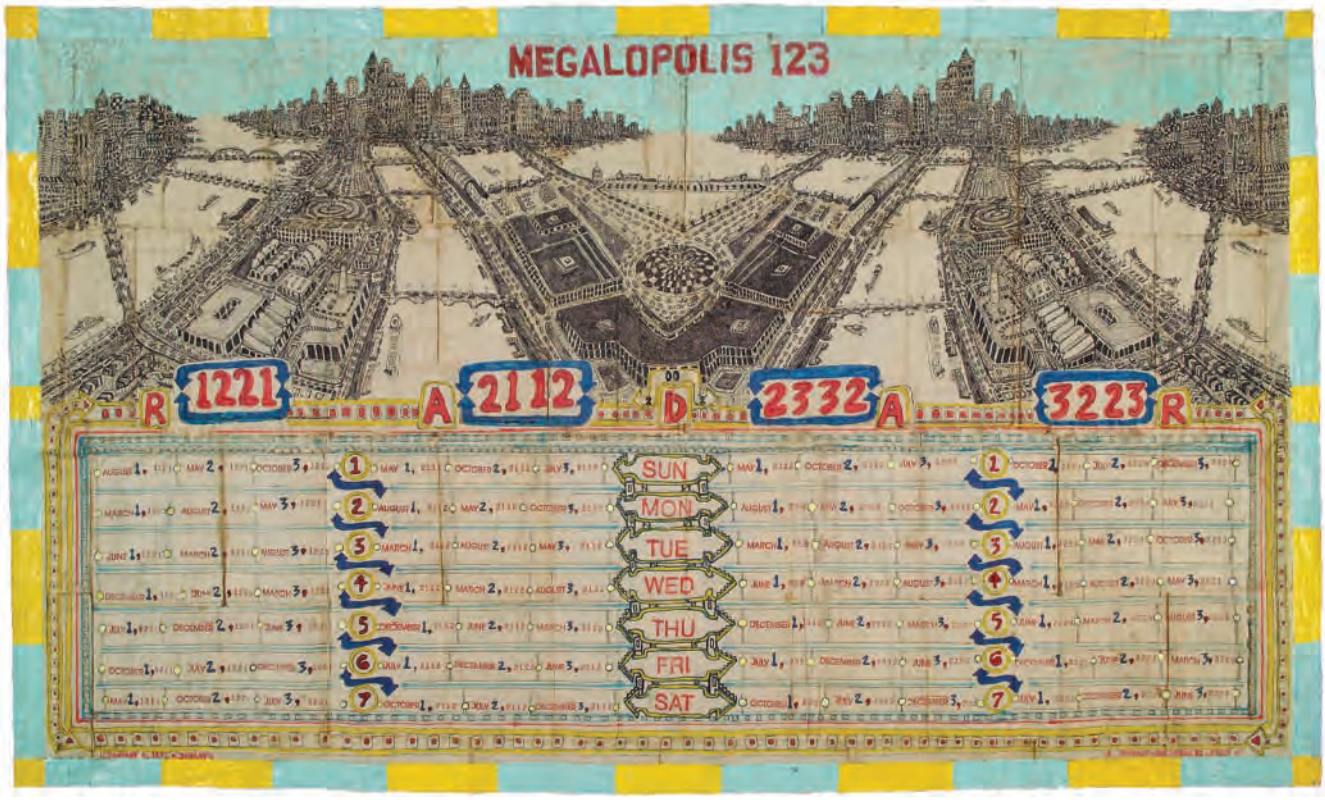

Figure 62–6 Strikingly beautiful art work by George Widener. George is a highly accomplished and much-admired outsider artist. In the attention to detail, this drawing resembles the drawings of other autistic savant artists. The intricate topographical detail of a symmetrically arranged city, with rivers, bridges, and tall buildings, is combined with minutely executed and seemingly abstruse calendar sequences. Mastery of the calendar and the ability to name the day of the week for any given date has often been described for autistic savants. The viewer of this drawing can partake in an otherwise very private world of space and time, numbers, and patterns. (Reproduced, with permission, from the Henry Boxer Gallery, London.)

the time as comprising fundamental impairments in each of three categories: social communication, language development, and restricted interests or repetitive behaviors. In contrast, dizygotic twins show 10% to 30% concordance—again with the lower number estimating concordance for the diagnosis of isolated autism, while the larger number encompasses any of three diagnoses on the autism spectrum.

This difference between the rates at which monozygotic and dizygotic twins share an ASD phenotype is attributed to differences in the amount of shared genetic material between the two types of twin pairs. Monozygotic siblings share all their DNA, whereas dizygotic twins share as much DNA as any sibling pair. In addition to these types of data, it has long been observed that ASD runs in families: Current estimates are that if parents have one child with ASD, the risk that a second child will be affected increases approximately 5- to 10-fold over the population base rate.

The most generous estimates of genetic contribution do not explain all risk for ASD in the population. Some contribution from the environment is a certainty. However, given the well-known public debate on the issue of whether immunization is a factor in ASD, it is important to note that there is no credible evidence that the increase in ASD prevalence is due to immunizations. The initial study that raised the issue of the contribution of the trivalent measles-mumps-rubella (MMR) vaccine has been retracted and thoroughly repudiated by the editors of the journal in which the article appeared, as well as by 10 of 12 of the original authors. A wide range of subsequent investigations, both of the MMR vaccine and of vaccines with the mercury-containing preservative thimerosal, has found no evidence for association with ASD risk.

The counter argument that certain rare individuals may be predisposed to a vulnerability to vaccines leading to ASD is nonfalsifiable. However, three lines of evidence suggest that such a contribution, if present, is

likely to be quite small. First, it is important to recall that the basis for the MMR hypothesis has been thoroughly debunked, and consequently, the prior probability that vaccines are major etiological factors is extremely low. Second, even in very large research cohorts, it has so far not been possible to detect a risk signal. Third, although there is a subset of children with ASD who show developmental regression in the second year of life, there is often evidence on careful examination of preexisting delay. In the final analysis, although the current level of understanding of pathophysiological mechanisms makes it impossible to definitively exclude any etiological contributor in a single individual, what is incontrovertible is that the risks to children of not receiving vaccinations are clear, measurable, and far greater overall than the role vaccines might play in ASD risk.

Although the evidence for a predominantly genetic contribution has been consistent, until recently, the search for risk genes contributing to nonsyndromic forms of ASD proved to be extremely challenging. Now, as will be discussed below, technological advances and changes in research culture have transformed the field. Moreover, critically important initial insights into both the genetics and neurobiology of ASD have emerged from the investigation of well-characterized genetic neurodevelopmental disorders, sometimes referred to as Mendelian syndromes (those with a single causative gene or genomic locus to the condition). These disorders typically manifest with intellectual disability, often with evidence of social impairment. Several of these syndromes, including fragile X, Rett, Williams, and Prader-Willi/Angelman syndromes, have been particularly important in beginning to elaborate the biology of ASD.

Rare Genetic Syndromes Have Provided Initial Insights Into the Biology of Autism Spectrum Disorders

Fragile X Syndrome

Fragile X syndrome is a common form of chromosome X–linked intellectual disability. Patients display a range of behavioral abnormalities including poor eye contact, social anxiety, and repetitive behaviors. In addition, approximately 30% of boys with fragile X meet the all diagnostic criteria for ASD. Moreover, in research with multiple cohorts, up to 1% of participants with apparently idiopathic ASD also carried fragile X mutations. The overall prevalence is approximately 1 in 4,000 boys and 1 in 8,000 girls.

The fragile X mutation is quite remarkable. The *FMR1* gene on the X chromosome includes the nucleotide triplet CGG. In normal individuals, this triplet is repeated in approximately 30 copies. In fragile X syndrome patients, the number of repeats is more than 200, with approximately 800 repeats being most common. This expansion of trinucleotide repeats has since been observed in other genes leading to neurological diseases, such as Huntington disease (Chapters 2 and 63). When the number of CGG repeats exceeds 200, the *FMR1* gene regulatory region becomes heavily methylated, and gene expression is shut off. Consequently, in these children, the fragile X mental retardation protein (FMRP) is lacking.

Lack of functional FMRP is considered responsible for fragile X syndrome. FMRP is a selective RNA-binding protein that blocks translation of messenger RNA until protein synthesis is required. It is found with ribosomes at the base of dendritic spines, where it regulates local dendritic protein synthesis that is needed for synaptogenesis and certain forms of long-lasting synaptic changes associated with learning and memory (Chapters 52 and 53). Interestingly, long-term depression of excitatory synaptic transmission, a form of long-lasting synaptic change that requires local protein synthesis, is enhanced in a mouse model of fragile X syndrome in which the gene encoding FMRP has been deleted. Loss of FMRP may enhance long-term depression by allowing excess translation of the messenger RNAs important for synaptic plasticity.

An exciting implication of these data is that antagonists of the type 5 metabotropic glutamate receptor (mGluR5), the activation of which is required for the enhanced protein synthesis underlying long-term depression, may lessen the excess protein translation. In fact, compounds with this activity have been found to rescue the mutant phenotype in mouse and fruit fly models. Thus far, clinical trials of mGluR5 antagonists for individuals with fragile X with ASD have not shown efficacy against the defined clinical end points. However, it is still too early to tell whether these initial forays into rational drug design for neurodevelopmental disorders may or may not be promising in the long run. A range of challenges have confronted these pioneering efforts, including measuring change in individuals with ASD, identifying ideal clinical end points, and determining the best age for evaluating interventions.

Rett Syndrome

Another single-gene disorder showing overlap with ASD is Rett syndrome, a devastating disorder that primarily affects girls. Affected females have normal

development from birth until 6 to 18 months of age, when they regress, losing speech and hand skills that they had acquired. Rett syndrome is progressive, and initial symptoms are followed by repetitive hand movements, loss of motor control, and intellectual disability. Often young girls will display symptoms indistinguishable from ASD early in the course of the syndrome, although social communication frequently improves later in childhood. Its prevalence is approximately 1 in 10,000 live female births.

Rett syndrome is an X-linked inherited disease caused by loss-of-function mutations in the *MECP2* gene, which encodes a transcriptional regulator that binds to methylated cytosine bases in DNA, regulating gene expression and chromatin remodeling. The gene product was initially thought to act predominantly as a transcriptional repressor, but studies of both the mouse model and human induced pluripotent stem cells have shown that overall gene expression is reduced when the gene is knocked out. Among the genes that have reduced expression in neurons is *BDNF*, encoding brain-derived neurotrophic factor. Studies in mouse models of Rett have found that overexpression of *BDNF* improves the knock-out phenotype. Other growth factors that increase gene expression but have more favorable neuropharmacological profiles, including insulin-like growth factor-1 (IGF-1), have also improved aspects of the mouse phenotype, leading to optimism about clinical trials of related compounds. Phase II human trials with both molecules are currently underway.

One might think that such a global abnormality in gene expression would lead to a very severe phenotype, but because females are mosaic, with approximately half of their brain cells expressing one normal copy of *MECP2* (due to random X-inactivation), they are viable but manifest the devastating Rett phenotype. Boys, who have a single X chromosome and thus a single copy of *MECP2*, typically die soon after birth or in infancy if they carry a loss-of-function mutation in *MECP2*.

The role of X-inactivation in the survival of female mutation carriers and the observation that favorable skewing (a shift toward preferential silencing of the mutant X) leads to a less severe clinical course have generated considerable interest in therapeutic strategies aimed at reactivating the normal but silenced X chromosomes in females with Rett syndrome. Although one can imagine considerable challenges resulting from the reactivation of many genes on a normally silenced chromosome, a recent study has reported a mouse mutation that leads to both alleles expressing MeCP2 without wholesale activation of genes on the X chromosome.

Interestingly, in 2005, duplications spanning *MECP2* were identified in males with severe intellectual disability. This condition, called *MECP2* duplication syndrome (MDS), includes autistic features, hypotonia, epilepsy, gait abnormalities, and recurrent infections. Like Rett syndrome, it has also been productively modeled in rodents. However, unlike Rett, the majority of identified cases are familial and not sporadic in nature. In these cases, female carriers are often healthy enough (due to favorable X-inactivation) to reproduce and transmit the duplication to boys with only a single X chromosome.

Williams Syndrome

Williams syndrome is caused by a segmental deletion of about 27 genes on the long arm of chromosome 7 and is characterized by mild to moderate intellectual disability, connective tissue abnormalities, cardiovascular defects, distinctive facies, and a behavioral phenotype characterized by increased sociability, preserved language abilities, affinity for music, and impaired visuospatial capabilities. The disorder occurs in 1 in 10,000 live births. The connective tissue and key cardiovascular symptoms have been attributed to the loss of the gene *ELN* (*elastin*), although no specific genes within the deleted interval have yet been definitively shown to result in the behavioral phenotype. Nonetheless, the social cognitive features of Williams syndrome are particularly intriguing: The degree of interest in social interaction is striking, leading to a nearly universal loss of reticence with strangers in children with the syndrome. In contrast to the almost complete absence of social anxiety, individuals with Williams syndrome have a high degree of general anxiety and isolated phobias. Finally, the affinity for and interest in music among a very large percentage of 7q11.23 deletion carriers, although less well characterized, are striking.

Conversely, duplication of the identical region of chromosome 7, including the same 26 to 28 genes, is a significant risk factor for ASD and other neurodevelopmental syndromes apart from Williams syndrome. The observation of contrasting social phenotypes depending on whether there is loss or gain of a small region of the genome is fascinating. Whether social functioning in William syndrome is truly the opposite of that seen in ASD, as is sometimes argued, seems less interesting than the conclusion that this region of the genome must contain one or more genes that modulate social affiliation. Consequently, the molecular characterization of these deletion and duplication syndromes and intensive investigation of their impact on the development of molecular, cellular, and circuit properties in the central nervous system are particularly important.

Angelman Syndrome and Prader-Willi Syndrome

Angelman and Prader-Willi syndromes are paradigmatic examples of genetic syndromes that result from mutations in genes subject to parental imprinting. To understand these conditions, one must not only know the associated DNA lesion but also its parental origin.

For example, both syndromes most often result from the loss of the identical region of chromosome 15 (15q11-q13) but have readily distinguishable phenotypes. Angelman syndrome is characterized by severe intellectual disability, epilepsy, absence of speech, hyperactivity, and inappropriate laughter. In contrast, Prader-Willi is characterized by infantile hypotonia, mild to moderate intellectual disability, obesity, highly perseverative behavior, social disability, and diminished or absent satiety.

How these contrasting phenotypes result from the loss of the identical set of genes confounded medical geneticists until about the year 2000. The mystery was solved by the discovery that the chromosomal interval is imprinted. Specifically, within this region, multiple genes are expressed only on the paternally inherited chromosome (*maternal* imprinting), whereas at least two genes, *UBE3A* and *ATP10C*, are expressed only on the maternally inherited chromosome (*paternal* imprinting) (Figure 62–7).

This discovery, along with a series of studies that allowed for fine mapping of the interval, provided a parsimonious explanation for the clinical observations. If the deletion of proximal chromosome 15 involved the maternal chromosome, the patient would suffer the loss of the protein product of *UBE3A*, a ubiquitin-protein ligase that stimulates the degradation and turnover of other proteins, leading to Angelman syndrome. Alternatively, if the paternal chromosome carried the deletion, *UBE3A* would be expressed normally, but a series of other genes, including several strongly implicated in Prader-Willi syndrome, would be lost.

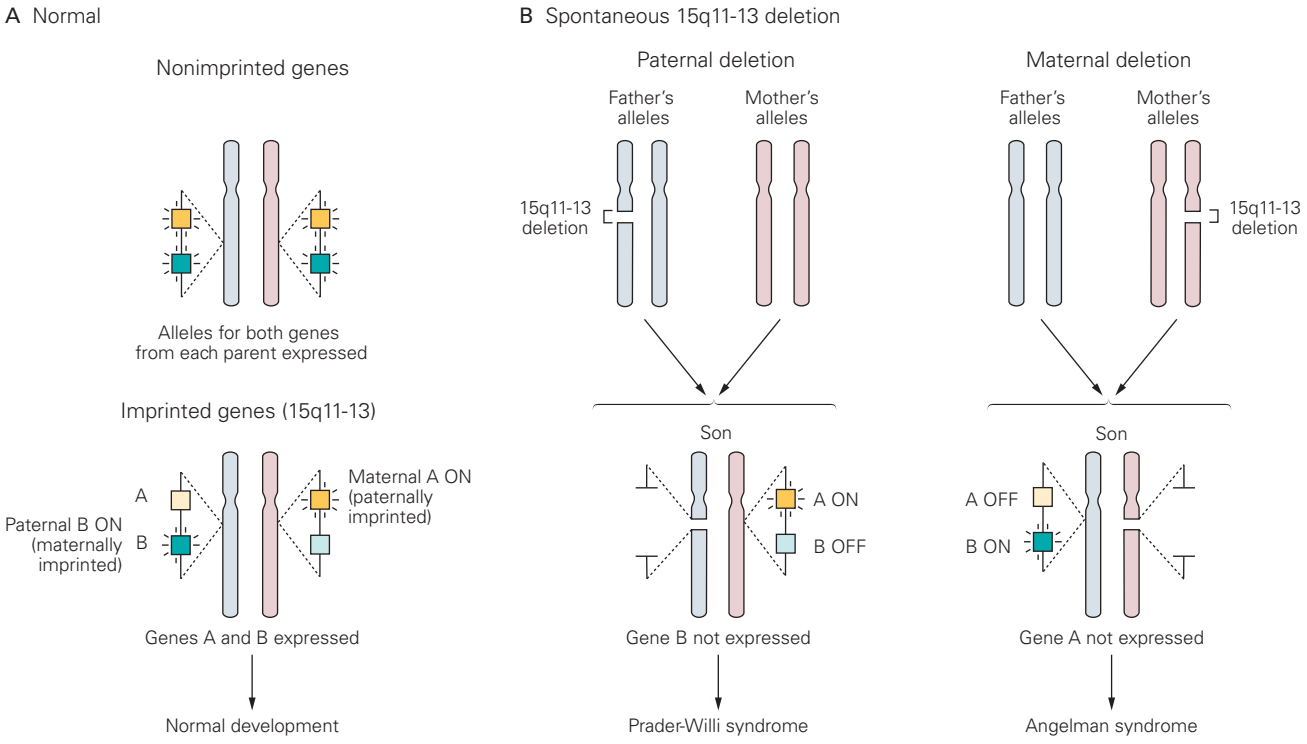

Figure 62–7 Imprinting in Prader-Willi and Angelman syndromes. Approximately 70% of Prader-Willi and Angelman syndrome patients inherit chromosome 15 from one parent with spontaneous (noninherited) deletions of the q11-13 interval. This interval contains imprinted genes with alleles that are either expressed or not depending on whether the chromosome was inherited from the father or mother. If the chromosome with the deletion is from the father, Prader-Willi syndrome occurs because maternally imprinted genes on the corresponding interval of the intact maternal chromosome (gene B, for example) are not expressed. If the chromosome with the deletion is from the mother, the gene for ubiquitin ligase (*UBE3A*) will not be expressed in offspring because of its normal inactivation on the paternal chromosome caused by imprinting; loss of expression of this gene leads to Angelman syndrome.

The solution to the phenotypic complexity seen in 15q11-13 deletion also led to a series of observations that revealed other previously unappreciated genetic mechanisms of behavioral pathology. For example, deletions on the maternal chromosome not directly involving the *UBE3A* gene were also observed in rare patients with Angelman syndrome, contributing to the identification of an Angelman syndrome *imprinting control* region mapping some distance from UBE3A but within the deletion interval. Similarly, the discovery of both Prader-Willi and Angelman syndromes in patients without deletions of any kind led to the recognition that in a small percentage of both conditions two copies of a chromosome from the same parent were present (with no representation from the other parent), a phenomenon called *uniparental disomy*.

Both syndromes have complex behavioral phenotypes. Social disability is characteristic of Prader-Willi; with Angelman syndrome, the overlap with ASD has been more difficult to establish because of the marked intellectual disability associated with the syndrome. Differentiating intellectual disability from ASD in individuals with very low IQ can be quite challenging. Nonetheless, there are multiple clear molecular and behavioral links with ASD. For example, duplications of the 15q11-13 region are a well-established risk factor for nonsyndromic ASD (see below), and functional de novo missense mutations in the gene *UBE3A* have been found in individuals with ASD without all of the features of Angelman syndrome.

Neurodevelopmental Syndromes Provide Insight Into the Mechanisms of Social Cognition

Although the fragile X, Rett, Williams, Angelman, and Prader-Willi syndromes collectively account for a small fraction of the burden of social disability in the population, studies of these disorders have contributed to major advances in the understanding of normal brain development, neurodevelopmental syndromes in general, and the mechanisms underlying social disability in particular. A number of biological processes identified in the study of these disorders—including the contribution of epigenetic mechanisms and chromatin dynamics, synaptic dysfunction, and the role of aberrant local protein synthesis—have all turned out to be important initial clues to the biological and developmental mechanisms underlying nonsyndromic forms of ASD. Moreover, characterization of the genetics underlying certain neurodevelopmental syndromes provided some of the earliest examples of a phenomenon that is now well accepted in ASD—either losses or gains of identical risk genes or regions may lead to neurodevelopmental disorders, sometimes with overlapping and sometimes contrasting phenotypes.

Importantly, in addition to the first clues regarding molecular mechanisms, recent studies of a number of Mendelian syndromes have challenged conventional wisdom by highlighting, in model systems, the potential reversibility of developmental phenotypes, even into adulthood. These observations, particularly with regard to Rett, Angelman, MDS, and fragile X syndromes, defied the long and generally held belief that the deficits associated with these types of severe syndromes are unchangeable. Moreover, the relevant studies have underscored the fact that a range of manipulations—from genetic, to pharmacological, to the more recent use of antisense oligonucleotides (in the case of *MEC2* duplication and Angelman syndromes)—have all been successful in reversing phenotype.

These findings provide not only an avenue forward for the development of rational therapies in humans but also a critical antidote to the penchant for nihilistic views of therapeutics development in neurodevelopmental disorders. In short, these findings have collectively, and now repeatedly, reinforced the notion that rationally designed therapies may reverse key symptoms long after initial pathology has begun to unfold in brain development. The question of how much of the core symptomatology seen in nonsyndromic ASD is a consequence of ongoing functional derangements, versus what would more traditionally be considered developmental pathology, remains to be clarified. One should note, however, that even with the limited treatments available, the observation that some children improve years after the onset of symptoms suggests that aspects of ASD pathology are not entirely static and may ultimately yield to the development of novel biologically driven treatment approaches.

The Complex Genetics of Common Forms of Autism Spectrum Disorder Are Being Clarified

The recent discovery of genes causing idiopathic ASD—once a scientific quagmire—has been among the most dramatic success stories in the field of human genetics. The combination of high-throughput genomic technologies—including the ability to assay common and rare variations in both the sequence and structure of DNA—the consolidation of large patient cohorts, and considerable investment in ASD research has transformed the field.

Initial breakthroughs can be traced to studies of the genes encoding the family of neuroligins—cell

adhesion molecules found at postsynaptic densities of glutaminergic synapses (Chapter 48). At the beginning of this century, the group led by Thomas Bourgeron, a geneticist at the Pasteur Institute, first identified putatively deleterious coding mutations in the genes coding for neuroligin 4X (loss-of-function) and neuroligin 3X (missense). About 6 months after the initial report on the loss-of-function mutation in *NLGN4X*, a nearly identical loss-of-function mutation in the same gene was found linked to both intellectual disability and ASD in a large pedigree. The relevance of the neuroligin 3X mutation to ASD has taken longer to clarify. Contemporary studies provide statistical evidence that *NLGN3X* is a probable, but not yet definitive, ASD risk gene. Additional studies of large cohorts will clarify this question.

In retrospect, these findings were prescient. The two papers on neuroligins pointed to the importance of loss-of-function heterozygous mutations leading not only to ASD but to a wide range of neurodevelopmental phenotypes and highlighted a role for synaptic proteins at the excitatory synapse. Moreover, in addition to being a harbinger of the contributions of both rare and de novo mutations (Chapter 2), the reported findings from Bourgeron's group also hinted, in retrospect, at a female protective effect as well as a paternal origin of de novo point mutations. In the initial report, the unaffected mother carried a de novo loss-of-function mutation on her paternally inherited X chromosome, which she passed to two affected sons.

Several years later, two key findings further ushered in the modern age of reliable and reproducible genetic studies in ASD. First, papers in 2006 and 2007 reported on the observation of rare de novo heterozygous copy number variations (Chapter 2) in children with ASD and intellectual disability. These studies focused specifically on idiopathic, nonsyndromic ASD and on families with only a single affected individual (simplex families). Both papers reported high rates of relatively large copy number variations among individuals with both intellectual and social disability. Second, it was not clear if individuals with ASD simply had more chromosomal abnormalities than those without. However, this question was soon answered by studies from multiple laboratories. De novo copy number variations did not appear to be distributed randomly throughout the genome but tended to cluster in distinct regions of the genome, suggesting that the increased rate in such cases was a consequence of an accumulation of specific risk events. Moreover, as higher-resolution genomic assays began to be applied, similar results emerged: Only certain subsets of mutations (eg, point mutations that disrupt gene function) proved to be elevated in individuals with autism, pointing to the aggregation of causal mutations in affected individuals, not hypermutability, as an explanation for the excess rate(s) of de novo events in affected individuals.

A considerable investment in studying copy number variations in simplex families has resulted in a steadily expanding list of copy number variations that clearly and dramatically increase the risk for ASD. At present, about a dozen genomic intervals reach genome-wide significance based on genome-wide screening of cases for de novo mutations (Figure 62–8). As a result, the American College of Medical Genetics now considers screening for copy number variations the standard of care for an individual presenting with ASD of unknown etiology.

Studies of de novo mutations have advanced throughout the second decade of this millennium, leading to the discovery that, similar to de novo copy number variations, de novo changes in the sequence of DNA—both single nucleotide variants and insertions or deletions (indels)—also contribute to ASD risk and can similarly be used to identify specific risk genes. Recent reports have now leveraged this approach to include more than 100 genes carrying large-effect single nucleotide variants and indel mutations that disrupt the function of the encoded protein (ie, likely gene-disruptive [LGD] mutations) (Chapter 2).

Several associated findings deserve mention here. First, although the contribution of de novo mutations to the risk for ASD in the total population is quite small (in the neighborhood of 3%), the proportion of individuals with large-effect de novo mutations who are seen in clinical settings and recruited for genetic studies is quite significant, as high as 40% of girls. The reason for this apparent contradiction is that most of the risk to the population writ large is carried in small-effect common variations that in most individuals are not sufficient to result in them crossing a diagnostic threshold for ASD. In short, most individuals carrying some degree of risk in the population never show overt social impairment and do not come to clinical attention. Conversely, individuals with large-effect de novo copy number variations, single nucleotide variants, and indels are much more likely to have significant clinical manifestations and seek medical attention.

Second, studies of de novo single nucleotide variants and indels in ASD using exome sequencing have found that the rate of de novo mutations increases with the father's age. Consistent with this observation is the finding that the vast majority of deleterious de novo sequence mutations in ASD cases are present on the paternally inherited chromosome. Although the

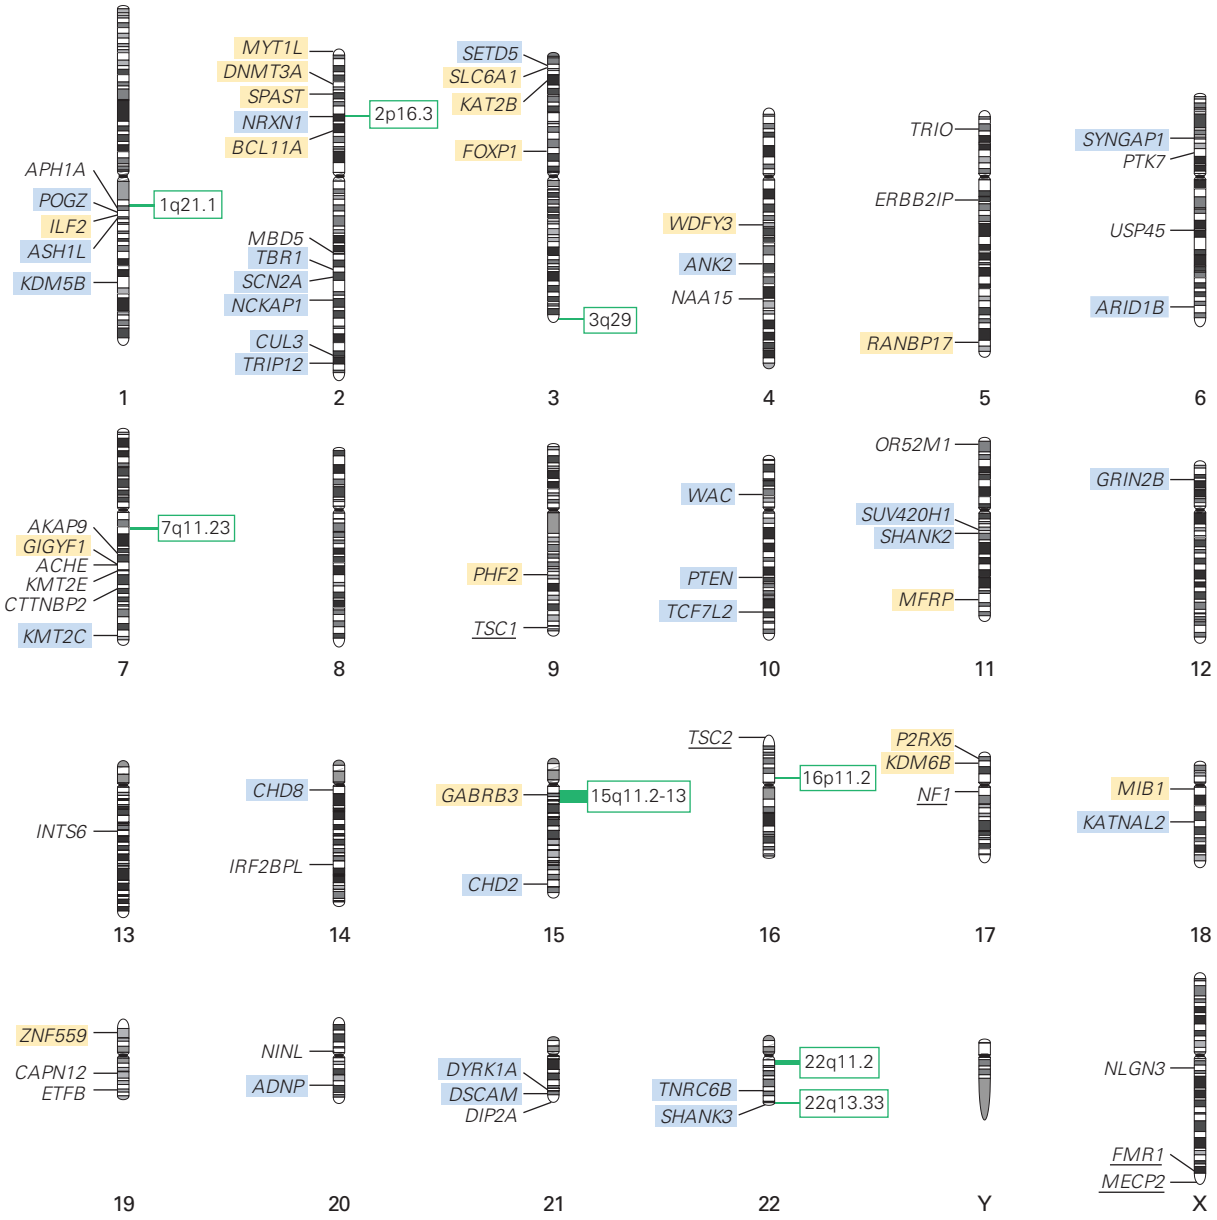

Figure 62–8 **Multiple genes and copy number variations that have been strongly associated with idiopathic risk for autism spectrum disorders (ASDs).** The figure identifies 71 genes and copy number variations (CNVs) associated with risk for ASDs based predominantly on the recurrence of de novo mutations. Abbreviations in **blue shading** denote genes with a false discovery rate (**FDR**) less than 0.01; abbreviations in **yellow shading** denote an FDR between 0.01 and 0.05; and abbreviations with **no shading** denote an FDR greater than 0.05 and less than 0.1. **Green bars** identify CNVs with an FDR less than 0.05. Data from Sanders et al. 2015. Statistical analysis was performed using the methods described in Sanders et al. 2015. Five additional genes with names underlined cause the syndromic forms of ASD discussed in the chapter text. Gene identification in ASD is continuing at a rapid pace. Up-to-date lists of associated genes and genomic regions can be found at https://gene.sfari.org.

absolute increase in risk with age is small, this observation nonetheless provides a conceptual framework for understanding secular increases in ASD prevalence. It also sets the stage for further studies of the impact of environmental factors in increasing de novo mutations and thereby potentially increasing the true incidence of clinical ASD cases.

The relationship of de novo large-effect mutations to intellectual disability has been the subject of considerable discussion, with some contending that de novo

large-effect mutations are typically seen in ASD with intellectual disability. Although it is the case that de novo mutations that are damaging (either copy number variations or single nucleotide variants) are more prevalent in ASD patients with lower IQ, it is also the case that mutations that confer ASD risk are found across the entire IQ spectrum, reinforcing the idea that domains of cognitive and social functioning are to some degree separable.

One notable difference between the genetics of ASD and other common disorders, including schizophrenia, has been the lack of progress using genome-wide association studies (Chapter 2). To date, only a handful of common genetic variants have been found that are significantly and reproducibly associated with ASD risk. Moreover, earlier conventional wisdom about the contribution of candidate genes such as *5-HTT*, *MTHFR*, or *OXT* polymorphisms is highly uncertain, based on the lack of findings from genome-wide association studies and the fact that these associations derived from an approach that has been shown empirically to be unreliable for gene discovery in complex common disorders. On the other hand, as noted, there is very strong evidence that common variation plays a substantial role in the population risk for ASD. Indeed, genome-wide association studies that have inferred the degree of contribution from this type of variation agree that the lion's share of vulnerability resides in common variation. One can reconcile these observations by noting that for those disorders, such as ASD, that markedly impair reproductive fitness, only common genetic variations carrying small effects remain in the human population over many generations. Those with larger effects would either be driven to low frequencies or removed entirely by natural selection. In addition, sample sizes for case-control genome-wide association studies of ASD to date have been more modest than those that have led to the marked success in identifying common polymorphisms associated with schizophrenia. In short, limited power is almost certainly a key limitation in identifying the common small-effect alleles contributing to ASD.

The relative success in identifying de novo mutations does not suggest that these are the only important mechanisms of ASD risk. Recent progress in this area is the result of a fortuitous combination of the large-effect size of the mutations, their location in the most easily interpreted portion of the genome (the coding region), and their low base rate in typically developing individuals. With regard to population risk, however, common noncoding, small-effect alleles are likely to collectively account for a greater overall proportion of the liability for ASD compared to rare high-effect variants. Moreover, there is evidence for recessive forms of ASD as well. These have initially been identified predominantly in consanguineous populations via the identification of homozygous loss-of-function mutations—that is, the identical damaging allele on both the paternally and the maternally inherited chromosomes—including in the genes *CNTNAP2*, *BCKDK*, and *NHE9*. Moreover, several recent studies have highlighted the contribution of compound heterozygote mutations to ASD risk—that is, different mutations mapping to the same gene on the maternally and paternally inherited chromosome—in populations with low rates of consanguinity.

A key point is that the pursuit and discovery of different types of mutations may help advance the science in different ways. For example, rare de novo high-effect mutations can be quickly studied in model systems. Also, common variants provide an opportunity to assess overall polygenic risk in research cohorts, an approach that may be highly useful for multimodal studies, such as those that integrate neuroimaging with genetic data, or other investigations linking human behaviors to genotypes. Finally, very rare homozygous/recessive variants mitigate some of the challenges of modeling haploinsufficiency.

Even though heritability—the proportion of the phenotypic variance due to genetic factors—is very high for ASD, environmental factors also play a role, although few specific environmental factors have been conclusively identified. Infections by viruses (eg, rubella, measles, influenza, herpes simplex, and cytomegalovirus) in utero may contribute to the etiology of ASD. There is substantial evidence that mediators of immune functions also play a role in brain development including synaptogenesis. Given the complexity of ASD and its various forms, it is likely that a variety of etiologies will ultimately be discovered—some purely genetic, others that depend on combinations of genetic risk factors and environmental factors, and some purely environmental causes.

Genetics and Neuropathology Are Illuminating the Neural Mechanisms of Autism Spectrum Disorder

Genetic Findings Can Be Interpreted Using Systems Biological Approaches

The recent advances in gene discovery are a particularly exciting development, offering many opportunities for biological analyses using an increasing armamentarium of in vitro and in vivo methods. In addition,

contemporary genomic approaches, examining large sections of the genome simultaneously, allow for unbiased approaches to be used in the study of groups of risk genes in an effort to identify points of convergence among disparate ASD genes.

To date, biological approaches that examine multiple systems have been divided roughly into two types of efforts: those that attempt to identify the types of biological processes reflected in the growing list of ASD genes and those that attempt to identify biological points of convergence at either the molecular or cellular level. The latter approach is based on the notion that multiple types of genetically driven perturbations in differing pathways may lead to a common phenotype due to their convergence on specific cell types, regions, or circuits at specific time points during the development of the human brain.

Biological processes or pathways in which ASD risk genes are present in a greater proportion than expected under the null hypothesis include chromatin modification, synaptic function, the WNT signaling pathway, and targets of FMRP. This list is clearly not exhaustive. For example, what we learned from genes involved in genetic syndromes as well as genes that cause nonsyndromic or idiopathic ASD implicates synaptic local protein synthesis as well as neurogenesis as points of potential biological convergence of disparate risk mutations.

Some variability in these findings is almost certainly attributable to different selection criteria for ASD risk genes as well as differences in the data used to annotate their function. This latter issue is important to keep in mind as numerous confounding factors are inherent in current efforts to annotate the biological processes assigned to a given gene or protein. These include the sources of data. For example, the assigned function of a gene can be markedly influenced by publication bias, whether in vitro or in vivo assays were employed, and what types of tissues and model systems were used to generate the data. Moreover, most functional annotations provide limited information on the time course of function for genes that may be developmentally regulated and biologically pleiotropic. Nonetheless, it is the increasing consistency in findings that is most striking. Despite the varying approaches, the biological processes noted above have been repeatedly identified among diverse rigorous studies.

As noted, an alternative approach to determining where multiple autism risk genes overlap involves examining not just their function but also their developmental expression pattern. Such studies are predicated on the notion that multiple risk genes may have different overt functions but share the ability to disrupt the same circuit, cellular, or developmental process. For example, a mutation in a gene encoding a protein known to mediate synaptic adhesion and a separate mutation in a gene encoding a chromatin modifier may both lead to identical abnormalities in the development of early cortical striatal connections. In such cases, the timing and location of the perturbation may be as relevant as a specific molecular pathway or the assigned molecular function of the individual gene(s). These studies have also tended to rely on assaying developmental expression trajectories genome-wide to minimize some of the confounding factors associated with other available annotation systems. For instance, it is now possible to assay essentially every gene in the genome simultaneously—eliminating the need to rely on prior research to assign a specific function to a gene. Moreover, such studies increasingly examine gene expression in human and/or nonhuman primate brain, mitigating some of the challenges of relying on in vitro data. Of course, such studies must still contend with the limits of resolution of expression analyses as well as a less than complete (and potentially biased) representation of different brain regions. Nonetheless, to date, the degree of agreement among varying studies is reassuring.

Despite differences in analytical and statistical approaches used in these types of studies, there has been general agreement to date that ASD risk genes point to vulnerability in human mid-fetal cortical development. There is also emerging evidence that these genes point to the involvement of both deep and upper layer projection neurons in cerebral cortex and of striatum and cerebellum (although the data on developmental expression in these regions remain limited in publicly accessible databases compared to cortical regions).

Autism Spectrum Disorder Genes Have Been Studied in a Variety of Model Systems

As a result of the tremendous progress of late, even a cursory description of the literature on the study of ASD in animal models is beyond the scope of this chapter. In part, this is a consequence of the sheer number of studies; in part, it is a product of the marked differences in the type of perturbation studied (eg, well-validated genetic models, "candidate gene" models, pharmacological models such as valproate exposure, or maternal immune activation). Moreover, differences in brain regions, cell types, developmental periods, and the biological processes assayed make summary generalizations problematic. In short, no consensus has yet been reached regarding the range of pathophysiological mechanisms relevant to ASD.

Nonetheless, given recent progress in human genetics, it is increasingly important to distinguish between models based on reproducible genetic findings, including those leading to syndromic ASD, and models based on unreliable candidate gene loci or solely on behaviors (ie, those that appear to reproduce human symptoms). Given the multiple options now available to study genetic variations that demonstrably increase the risk in humans for ASD in the phenotypes of interest, the study of models with more tenuous links to human pathophysiology is increasingly difficult to justify.

Many publications reporting rodent models of ASD, regardless of their origins, focus on phenotypes that resemble symptoms seen in the human syndrome, including changes in social interactions, vocalizations, and behaviors reminiscent of human anxiety or aggression. Even with a bias toward publishing positive findings, results vary dramatically. Of note, there has been a long-standing debate over the relevance of animal models for ASD, given the important differences in brain development, organization, and function between humans and the most commonly used experimental animals. Nevertheless, unbiased assessments of a wide range of animal behaviors—not necessarily prioritizing those that "look" like core ASD symptoms—may well provide a valuable window into pathophysiological mechanisms. For example, some of the most commonly observed phenotypes reported to date across various ASD genetic models (and by various laboratories) involve motor behavior. In this case, it seems far less important that the observed behaviors are reminiscent of core diagnostic features in humans than that the observations suggest an important point of biological convergence, providing clues to cell types, circuits, and processes involved in ASD.

Although rodent models continue to dominate the ASD literature, a wide range of other models have already provided important insights into biology. These include the fruit fly, worm, zebrafish, frogs, voles, nonhuman primates, induced pluripotent stem cells and brain organoids, and human postmortem samples. Given the complexity of the problems at hand, the differing strengths and limitations of various models, and the important differences in brain structure and development across species, continued progress will likely require integrating data across a wide range of existing models, from flies and worms to humans.

Postmortem and Brain Tissue Studies Provide Insight Into Autism Spectrum Disorder Pathology

The neuropathology of autism at a microscopic level is also not yet clear, but several studies provide evidence for the potential for multiple anatomical correlates. The multiple correlates may in part be due to the small number of brains available for pathological analysis. Moreover, only a small fraction of these have undergone quantitative analysis. Another problem is the frequent occurrence of epilepsy. Approximately 30% of individuals with autism also have seizure disorders, and seizures may damage the amygdala and many other brain regions implicated in ASD.

One of the earliest and most consistent anatomical findings in ASD has been the lower number of Purkinje cells in the cerebellum in some individuals. When neural stains are used to mark cell bodies, gaps in the orderly arrays of Purkinje cells are noticeable. Whether this reduction in cell number is because of ASD, epilepsy, or the co-occurrence of both disorders is not clear. It is also not clear whether the reduced number of Purkinje cells is characteristic of ASD in particular or neurodevelopmental disorders more generally. A wide variety of cerebellar changes were identified in cases of idiopathic intellectual disability, in Williams syndrome, and in other neurodevelopmental disorders. A few cases of alterations of brain stem nuclei that are connected to the cerebellum, such as the olivary complex, have also been reported. Finally, contemporary analyses have found considerable heterogeneity in cell number, with only a subset of samples showing a decrease in the number of Purkinje cells.

Microscopic abnormalities have also been observed in the autistic cerebral cortex, including defects in the migration of cells into the cortex, such as ectopias (nests of cells in white matter that failed to enter the cortex). It has also been proposed that the columnar organization of the autistic cortex is abnormal. These findings still await confirmation in larger studies using quantitative strategies. Finally, one study found fewer neurons in the mature amygdala of people with ASD without epilepsy.

In one of the few reported descriptions of live pathological tissue samples from patients with ASD (removed from three patients during surgery for intractable epilepsy), multiple cytoarchitectural abnormalities were identified in the temporal cortices. These individuals all carried rare recessive loss-of-function mutations in the gene *contactin associated protein-like 2*. Multiple histological abnormalities were observed in these patients, including areas of cortical thickening and blurring of the boundary between gray matter and white matter. Moreover, the authors described neurons in multiple cortical regions that were abnormally organized into tightly packed columns or clusters. In both the hippocampus and temporal cortex, the number of neurons was increased, and many of the

neurons had abnormal shapes instead of their pyramidal morphology. Given the presence of gross temporal lobe abnormalities visible on MRI in two of the three patients, the rare recessive genetic contribution, and the particularly severe seizure disorder, the generalizability of these findings to idiopathic ASD remains in question.

The notion overall that there are neuroanatomical changes in some ASD patients is supported by several other lines of evidence. A number of well-supported and well-characterized ASD risk genes (eg, *PTEN* mutations) are associated with increases in brain size ranging from modest (eg, *CHD8* loss-of-function mutations) to frank macrocephaly. In addition, ASD is often associated with microcephaly. Girls with Rett syndrome have acquired microcephaly, suggesting, not surprisingly, that multiple anatomical derangements may occur in social disability phenotypes.

Advances in Basic and Translational Science Provide a Path to Elucidate the Pathophysiology of Autism Spectrum Disorder

A full understanding of the neurobiological basis of the many neurodevelopmental disorders that lead to social and intellectual disability will require the convergence of neuroscience, other medical disciplines, computational biology, and genomics. A bottom-up approach—progressing from the identification of genes responsible for cognitive and behavioral disorders to an understanding of their effects on brain development—is already providing some key insights. At the same time, a top-down approach may also be highly productive by identifying and defining critical neural circuits involved in social function and dysfunction.

Fortunately, the tools available to pursue both approaches are increasingly accessible, from high-throughput whole-genome sequencing to rapidly advancing informatics pipelines, genome editing, optogenetics and other methods to study circuits in vivo, single cell technologies, improved neuroimaging methods and technologies, and the development of tractable human and nonhuman primate neural models, including brain organoids.

Although there has been great progress in elaborating the genetics and biology of ASD and other neurodevelopmental disorders, the findings from genomic studies have also pointed to some key challenges: At the most basic level, the translation of these discoveries to an understanding of pathophysiology is limited by the current state of knowledge regarding brain organization and development. It seems likely that without a detailed cellular understanding of the brains of humans, nonhuman primates, and other model systems, it will be challenging to interpret the wide variety of genetic perturbations and move from an understanding of the biology to any understanding of the pathogenesis. It is also reasonable to presume that to be most useful for the disorders of the type discussed in this chapter, this type of map will have to capture developmental dimensions. It is exciting and heartening, then, that the recent BRAIN Initiative, other large-scale governmental efforts, and the efforts of private foundations have all highlighted foundational knowledge as a key to success.

There is little doubt that the distance between our knowledge of clinical phenomenology, genetics, imaging, and neuropathology on the one hand and, on the other, the development of novel treatments that will profoundly improve the lives of severely affected individuals can seem daunting. At the same time, it is heartening to see the progress with Mendelian neurodevelopmental disorders, where some clinical trials of rational therapies have been completed and others are currently underway. Although some of the early results have been disappointing, the mere fact that the understanding of these syndromes has advanced to this point is cause for continued optimism. Along these lines, it is useful to consider the required extent of revision of this chapter from the prior volume to the current one. The ability to confidently assign large-effect genetic risk at nearly 100 genomic loci and genes, the emerging consensus regarding what types of molecular processes and pathways are involved, the first glimpses of the developmental characteristics, and the initiation of biologically driven therapeutic trials have all emerged over a relatively short period of time. It is exciting to speculate where the field could be by the publication of the next revision of this book.

Highlights

1. Neurodevelopmental syndromes can involve varying degrees of impairment in different cognitive domains. Syndromes that involve dysfunction in the social realm, with or without involvement of general cognition or perception, are the focus of this chapter.
2. Autism is the paradigmatic social disability syndrome, first described in the literature in 1943 by Leo Kanner. Today, autism is considered a spectrum of disorders with two defining diagnostic features: fundamentally impaired social communication and stereotyped behaviors and/

or highly restricted interests. The prevalence of autism spectrum disorder (ASD) is estimated to be at least 1.5% in developed countries and is much more frequent in males than females.

3. Both environmental factors and myriad genes contribute to ASD risk. This genetic complexity resulted for several decades in scant progress in efforts to map specific ASD risk genes and genomic regions (loci).
4. The earliest clues to both the genetics and neurobiology of ASD emerged from early investigations of neurodevelopmental syndromes that manifest both with intellectual disability and social impairment. These include, among others, fragile X syndrome, Rett syndrome, Williams syndrome, and Prader-Willi and Angelman syndromes.
5. High-throughput genomic technologies, the consolidation of large patient cohorts, and considerable investment in ASD research have transformed the field of gene discovery in idiopathic ASD. At present, dozens of specific genes and genomic regions have been reliably and reproducibly associated with risk for ASD.
6. Recent progress in the genetics of common forms of ASD has emerged from a focus on rare and sporadic (de novo) mutations in the coding portion of the genome. On average, these mutations carry much larger biological effects than have been identified in studies of other psychiatric disorders, such as schizophrenia, where many common genetic risk variants have been identified, each with a small effect.
7. Studies of both genetic syndromes and idiopathic ASD have begun to reveal processes, pathways, and developmental epochs involved in pathophysiology. These include epigenetic mechanisms and chromatin dynamics, synaptic dysfunction, and the role of aberrant local protein synthesis. Recent studies of genetically determined ASDs have also shown that human mid-fetal cortical development and glutamatergic neurons are particularly vulnerable.
8. The current availability of a significant number of confirmed ASD loci, both for syndromic as well as idiopathic forms of the disorder, provides a solid foundation for neurobiological studies. These advances provide a strong link to human pathophysiology, including potential traction on the question of cause versus effect, given that germline genetic changes are present prior to the earliest stages of brain development.
9. In addition to providing some of the first clues regarding molecular mechanisms of idiopathic ASD, studies of Mendelian syndromes have challenged conventional wisdom by highlighting the potential reversibility of developmental phenotypes. These observations, particularly with regard to Rett syndrome and fragile X syndrome, have generated renewed optimism about the opportunities for rational development of therapeutic treatments.
10. Multiple methods are now converging to elaborate the pathology underlying ASD, including gene discovery and systems biology, model systems approaches, neuroimaging studies, and neuropathological studies. The key challenge going forward will be to move from a general understanding of biology to an actionable understanding of pathophysiology.

Genetic Mechanisms in Neurodegenerative Diseases of the Nervous System

The major degenerative diseases of the nervous system—Alzheimer, Parkinson, and the triplet repeat diseases (Huntington disease and the spinocerebellar ataxias)—afflict more than six million people in the United States and more than 25 million throughout the world. Although this is a relatively small percentage of the population, these diseases bring a disproportionate amount of suffering and economic hardship, not only to their victims but also to the families and friends of the afflicted.

Most of these disorders strike in mid-life or later. Aging itself may contribute to susceptibility. The first symptoms to appear often involve loss of fine motor control. Huntington disease can first manifest itself in cognitive deficits, and this is certainly the case for Alzheimer disease. Nevertheless, the end result is the same: A period of slow deterioration, usually 10 to 20 years, robs afflicted patients of their abilities and eventually their lives.

The late-onset neurodegenerative diseases can be divided into two categories: inherited and sporadic (ie, of unknown etiology). Alzheimer and Parkinson diseases are predominantly sporadic; nevertheless, inherited forms, which afflict only a small number of patients, have provided some insight into the pathophysiology of these diseases. Huntington disease, the spinocerebellar ataxias, dentatorubropallidoluysian atrophy, and spinobulbar muscular atrophy are inherited, the result of polyglutamine or CAG triplet repeat diseases.

The triplet repeat diseases are notable for being caused by a "dynamic" mutation: The disease proteins contain a CAG repeat tract that codes for glutamine

and can undergo expansion during DNA replication. Unfortunately, the longer the CAG tract, the more likely it is to further expand, which accounts for the striking phenomenon of *anticipation*: Younger generations within a family have longer repeats and develop more severe symptoms at an earlier age than their parents. Identification of the molecular basis of these disorders has facilitated diagnosis and provides hope for eventual treatment.

Huntington Disease Involves Degeneration of the Striatum

Huntington disease usually strikes in early or middle adulthood and affects 5 to 10 people per 100,000. Symptoms include loss of motor control, cognitive impairment, and affective disturbance. Motor problems most commonly manifest first as chorea (involuntary, jerky movement that involves the small joints at first but then gradually affects the legs and trunk, making walking difficult). Fast, fluid movements are replaced by rigidity and bradykinesia (unusually slow movements).

Cognitive impairment—especially difficulty in planning and executing complex functions—may be detected by formal neuropsychological testing even prior to motor dysfunction. Affected individuals may also have disordered sleep and affective disturbances such as depression, irritability, and social withdrawal. About 10% of patients experience hypomania (increased energy), and a smaller percentage experience frank psychosis.

In adult patients, the disease progresses inexorably to death some 17 to 20 years after onset. Juvenile-onset patients suffer a more rapid course and typically develop bradykinesia, dystonia (spasms of the neck, shoulders, and trunk), rigidity (resistance to the passive motion of a limb), seizures, and severe dementia within only a few years.

The pathological hallmark of Huntington disease is degeneration of the striatum, which can show up in neuroimaging as much as a decade prior to the onset of symptoms. The caudate nucleus is more affected than the putamen. Loss of the medium spiny neurons, a class of inhibitory interneurons in the striatum, reduces inhibition of neurons in the external pallidum (Chapter 38). The resulting excessive activity of the pallidal neurons inhibits the subthalamic nucleus, which could account for the choreiform movements. As the disease progresses and striatal neurons projecting to the internal pallidum degenerate, rigidity replaces chorea. Disruption of the corticostriatal projections leads to thinning of the cortex. In addition to this central nervous system pathology, patients can suffer from immune system and metabolic disturbances, testicular atrophy, cardiac failure, osteoporosis, and skeletal muscle wasting. Cases of juvenile Huntington disease are more severe, and the pathology progresses more rapidly and broadly; for example, degeneration of cerebellar Purkinje cells can occur.

Huntington disease is an autosomal dominant disorder and one of the first human diseases whose gene was mapped using polymorphic DNA markers. It is caused by expansion of a translated CAG repeat that encodes a glutamine tract in the huntingtin protein. Normal or wild-type alleles have 6 to 34 repeats, whereas disease-causing alleles typically have 36 or more repeats that are quite unstable when transmitted from one generation to the next, especially through paternal germ cells. Disease severity, age of onset, and speed of progression correlate with repeat length; individuals with 36 to 39 repeats have later onset and milder disease, while those with more than 40 repeats will have earlier onset and a more severe course. Those carrying more than 75 repeats will develop the disease as juveniles.

The expanded glutamine tract causes a gain of function in huntingtin, a 348-kDa protein that is well conserved in nature from invertebrates to mammals. It is expressed throughout the brain as a soluble cytoplasmic protein, with a minor fraction present in cell nuclei. It is particularly abundant in somatodendritic regions and axons and has been found to associate with microtubules. Although its precise functions are not fully understood, huntingtin is essential for normal embryonic development. Based on a wide array of protein interactors that function in metabolism, protein turnover, cargo trafficking, and gene expression, it has been postulated that huntingtin functions as a molecular scaffold. Its large size, stability, and ability to switch between multiple conformations suggest it brings together multiple proteins into macromolecular complexes.

Huntingtin has multiple protein domains, the best studied of which is the N-terminal region, which contains the polyglutamine expansion and a nuclear localization signal. The N-terminal region consists of an amphipathic α-helix, which creates a structure critical for the protein's retention in the endoplasmic reticulum. The N-terminus undergoes extensive posttranslational modification by acetylation, ubiquitination, phosphorylation, and sumoylation, all of which affect huntingtin clearance and subcellular localization. Interestingly, the polyglutamine repeats in exon 1 are followed by a proline-rich domain, which, unlike the other exons, has been poorly conserved during evolution.

The remaining 66 exons outside the N-terminus, which account for about 98% of the protein, are far less well characterized. Several HEAT repeats are important for protein–protein interactions. These interactions allow the huntingtin protein to adopt a large number of three-dimensional conformations (up to 100 in vitro). Furthermore, the *HTT* gene produces two different mRNA transcripts, a short and long form. The long form contains an additional 3′ untranslated region and is enriched in the brain. Rare alternative splicing produces isoforms that skip exons 10, 12, 29, and 46 or include exon 41b or a fragment of intron 28, but their significance has not been determined. The diversity of these isoforms might be important during development and could expand the variety of protein interactions available to huntingtin.

Spinobulbar Muscular Atrophy Is Caused by Androgen Receptor Dysfunction

Spinobulbar muscular atrophy (SBMA, also known as Kennedy disease) is the only X-linked disorder among the neurodegenerative diseases discussed in this chapter. It is caused by expansion of a translated CAG repeat in the androgen receptor protein, a member of the steroid hormone receptor family. Only males manifest symptoms: The mutant androgen receptor is toxic only when localized to the nucleus, and this localization is dependent on the hormone androgen.

Proximal muscle weakness is usually the presenting symptom; eventually, the distal and facial muscles weaken as well. Muscle wasting is prominent, secondary to degeneration of motor neurons. Loss of androgen function typically leads to gynecomastia (growth of breast tissue in men), late hypogonadism, and sterility. Because individuals who lose androgen receptor function from other causes do not develop motor neuron degeneration, it seems that the glutamine expansion in SBMA causes both a partial loss of function that accounts for the secondary sexual characteristics and a partial gain of function that damages neurons and produces the neurological dysfunction.

Hereditary Spinocerebellar Ataxias Share Similar Symptoms but Have Distinct Etiologies

The spinocerebellar ataxias (SCAs) and dentatorubropallidoluysian atrophy (DRPLA) are characterized by dysfunction of the cerebellum, spinal tracts, and various brain stem nuclei. The basal ganglia, cerebral cortex, and peripheral nervous system can also be affected (Table 63–1).

Two clinical features common to all the SCAs, ataxia and dysarthria, are signs of cerebellar dysfunction. These typically appear in mid-adulthood and gradually worsen, eventually making walking impossible and speech incomprehensible. Brain stem dysfunction in advanced disease causes difficulties in keeping the airway clear; patients often die of aspiration pneumonia. Some SCAs are associated with additional symptoms such as chorea, retinopathy, or dementia, but these are too variable to support a differential diagnosis. Even individuals within the same family can present quite different clinical pictures. Thus, although the SCAs are single-gene Mendelian disorders, individual genetic makeup and environmental influences affect the clinical-pathological picture.

For example, Machado-Joseph disease and SCA type 3 (SCA3) had been regarded clinically as distinct diseases before it was discovered that they are caused by mutations in the same gene. The clinical confusion arose by historical accident. The most prominent features of the families of Azorean descent who were first studied were bulging eyes, faciolingual fasciculations, Parkinsonism, and dystonia; this syndrome was named Machado-Joseph disease. Subsequently, a group of European geneticists studied patients who had symptoms more reminiscent of SCA1—hypermetric saccades and brisk reflexes in addition to the characteristic ataxia and dysarthria. This constellation of symptoms was therefore called SCA3. It took several years before it became clear that the genetic locus of the two diseases was the same, but still both names (Machado-Joseph disease and SCA3) are used. We now know that the differences observed in the original two groups of patients are at least partially attributable to differences in length of the CAG repeats. Nonetheless, differences in the activity of other proteins caused by genetic variations are probably also at play.

The age of onset within each type of ataxia depends on the number of CAG repeats in the gene (Figure 63–1), although the toxicity of different repeat lengths depends on the protein context. For example, the CAG expansion in SCA6 is the shortest of all the SCAs: Normal alleles have fewer than 18 repeats, and pathological repeats have only 21 to 33 repeats. Yet, tracts of the very same length are completely nonpathogenic in other SCAs. In fact, the gene responsible for SCA7 normally tolerates a few dozen CAG repeats and, in the disease state, can undergo expansion to hundreds of CAGs, the largest expansions seen in any SCA.

Table 63–1 Pattern of Inheritance and Main Clinical Features of Neurodegenerative Diseases Caused by Unstable CAG Trinucleotide Repeats

Disease	Inheritance	Typical presenting features	Principal regions affected
SBMA	X-linked recessive	Muscle cramps, weakness, gynecomastia	Lower motor neurons and anterior horn cells
Huntington	AD	Cognitive impairment, chorea, depression, irritability	Striatum, cortex
Huntington-like 2	AD	Cognitive impairment, chorea, depression, irritability	Striatum, cortex
SCA1	AD	Hypermetric saccades, ataxia, dysarthria, balance, nystagmus	Purkinje cells, brain stem
SCA2	AD	Ataxia, hyporeflexia, slow saccades	Purkinje cells, granule cells, inferior olive
SCA3	AD	Ataxia, gaze-evoked nystagmus, bulging eyes, dystonia, spasticity	Pontine neurons, substantia nigra, anterior horn cells
SCA6	AD	Ataxia, late onset (>50 years of age)	Purkinje cells, granule cells
SCA7	AD	Ataxia, visual loss due to retinal degeneration, hearing loss	Purkinje cells, retina (cone-rod degeneration)
SCA8	AD	Scanning dysarthria, ataxia	Purkinje cells
SCA10	AD	Ataxia and seizures	Purkinje cells
SCA12	AD	Early arm tremor, hyperreflexia, ataxia	Purkinje cells, cortical and cerebellar atrophy
SCA17	AD	Dysphagia, intellectual deterioration, ataxia, absence seizures	Purkinje cells, granule layer, upper motor neurons
DRPLA	AD	Dementia, ataxia, choreoathetosis	Dentate nucleus, red nucleus, globus pallidus, subthalamic nucleus, cerebellar cortex, cortex

AD, autosomal dominant; DRPLA, dentatorubropallidoluysian atrophy; SBMA, spinobulbar muscular atrophy; SCA, spinocerebellar ataxia.

Besides tolerating different CAG repeat lengths, the gene products of mutated genes in polyglutamine diseases vary widely in function:

- The gene product in SCA1, ataxin-1 (ATXN1), is predominantly a nuclear protein that forms a complex with the transcriptional repressor Capicua (CIC). The expanded glutamine tract alters ATXN1's interaction with CIC in the cerebellum, which helps explain this region's vulnerability to SCA1 pathophysiology.
- SCA2 is caused by a CAG trinucleotide expansion in *ATXN2*. Genetic ablation of *Atxn2* increases global transcript abundance, indicating that it may work as an RNA-binding protein. More recent studies revealed that it interacts with TDP43, a protein involved in amyotrophic lateral sclerosis (ALS10), and mutations in *ATXN2* may contribute to amyotrophic lateral sclerosis.
- Impaired protein clearance is a theme among the SCAs, insofar as elevated levels of the disease-causing protein seem to drive pathogenesis. In the case of SCA3, the relationship is more direct in that ataxin-3 (ATXN3) is a deubiquitinating enzyme, and the expanded version cannot remove ubiquitin from proteins slated for clearance. More recently, ATXN3 has been linked to DNA damage repair.
- The affected gene product in SCA6, CACNA1A, is the α_{1A}-subunit of the voltage-gated Ca^{2+} channel; interestingly, loss-of-function mutations in the gene (not gain of function caused by CAG repeats) have been reported in patients with episodic ataxia and familial hemiplegic migraine.

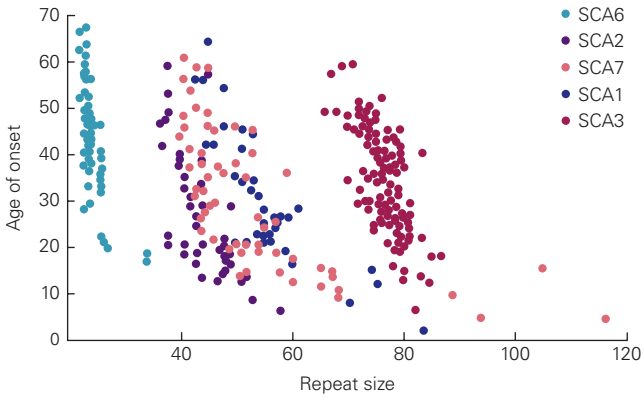

Figure 63–1 The length of the CAG repeat and age of onset in spinocerebellar ataxia (SCA) are inversely correlated. The longer the CAG tract, the earlier is the onset for a given disease. Specific repeat lengths, however, have different results depending on the host protein. For example, a 52-repeat of CAG causes juvenile onset of symptoms in spinocerebellar ataxia type 2 (**SCA2**), adult onset in spinocerebellar ataxia type 1 (**SCA1**), and no disease in spinocerebellar ataxia type 3 (**SCA3**).

- In SCA17, the affected gene product is the TATA box-binding protein, an essential transcription factor.
- Atrophin-1, the disease-causing protein in DRPLA, is thought to be a corepressor based on functional studies of its probable ortholog in *Drosophila*.

Despite these differences, some pathogenetic mechanisms may be common to the polyglutamine diseases, as discussed later in this chapter.

CAG repeats in coding regions are not the only dynamic mutations occurring in the SCAs (Table 63–2). SCA8 involves expansion of both a CAG tract and its complementary CTG repeat on the opposite strand in the 3′ untranslated region of a transcribed RNA with no open reading frame. The mutation responsible for SCA12 is a CAG repeat, but it occurs in a noncoding region 5′ upstream of a brain-specific regulatory subunit of the protein phosphatase 2A. SCA10 is caused by massive expansion of a pentanucleotide (ATTCT) repeat in the intron of a novel gene.

So far, a total of 33 SCAs have been identified. For the SCAs whose underlying pathogenesis is better understood, the most promising therapeutic approach seems to be to reduce the levels of the disease-driving protein. In the SCA7 mouse model, reducing the amount of both mutant and wild-type ATXN7 by RNA interference greatly improves the behavioral and pathological signs of disease. Likewise, in both *Drosophila* and mouse models of SCA1, genetic or pharmacological downregulation of several components of the RAS-MAPK-MSK1 pathway decreases ATXN1 levels and suppresses neurodegeneration.

Parkinson Disease Is a Common Degenerative Disorder of the Elderly

Parkinson disease, one of the more common neurodegenerative disorders, affects approximately 3% of the population older than age 65 years. Patients with Parkinson disease suffer from a resting tremor, bradykinesia, rigidity, and impairment in their ability to initiate and sustain movements. Affected individuals walk with a distinctive shuffling gait, and their balance is often precarious. Spontaneous facial movements are greatly diminished, creating a mask-like, expressionless appearance. The pathological hallmarks of Parkinson disease are the progressive loss of dopaminergic neurons, mainly in the substantia nigra pars compacta (Chapter 38), and the accumulation of proteinaceous aggregates termed Lewy bodies and Lewy neurites throughout the brain.

Although most cases of Parkinson disease are sporadic, studies of rare familial cases, which can be either autosomal dominant or recessive, have provided insight into the pathophysiology of this disorder and revealed novel risk factors for disease. To date, several genetic loci have been mapped (designated *PARK1–PARK22*), and the genes for all but four of these loci (*PARK3*, *PARK10*, *PARK12*, and *PARK16*) have been identified (Table 63–3). Of these mapped loci, the most studied and characterized are *PARK1/4*, *PARK2*, *PARK6*, and *PARK7*. Here, we focus on how the genetic basis of some forms of Parkinson disease provides insight into sporadic Parkinson disease.

Parkinson disease type 1/4 (4q2-22) is the locus for the dominantly inherited Parkinson disease caused by mutations in the gene *SNCA* encoding for α-synuclein. (As with Machado-Joseph disease and SCA3, Park1 and Park4 were initially thought to be two distinct variants.) Variants in the *SNCA* locus have been associated with increased risk of sporadic Parkinson disease, and several mutations in *SNCA* alter the conformation of the membrane-bound portion of the α-synuclein protein and cause it to aggregate. Duplications and triplications of *SNCA* have also been identified as causes of autosomal dominant Parkinson disease, indicating that elevated levels of even wild-type α-synuclein can cause disease. Patients with *SNCA* duplication have a disease course that resembles sporadic cases, but patients with triplication manifest an earlier-onset, more rapidly progressing disease with atypical features such as dementia and hallucinations.

Table 63–2 Hereditary Ataxias Caused by Expansion of Unstable CAG Trinucleotide Repeats

					Repeat lengths	
Disease	**Gene**	**Locus**	**Protein**	**Mutation**	**Normal**	**Disease**
SCA1	*SCA1*	6p23	Ataxin-1	CAG repeat in coding region	6–44[1]	39–121
SCA2	*SCA2*	12q24.1	Ataxin-2	CAG repeat in coding region	15–31	36–63
SCA3 (Machado-Joseph disease)	*SCA3, MJD1*	14q32.1	Ataxin-3	CAG repeat in coding region	12–40	55–84
SCA6	*SCA6*	19p13	α_{1A} subunit of voltage-dependent calcium channel	CAG repeat in coding region	4–18	21–33
SCA7	*SCA7*	3p12-13	Ataxin-7	CAG repeat in coding region	4–35	37–306
SCA8	*SCA8*	13q21	None	CTG repeat in the 3′ terminal exon (antisense)	16–37	110–250
SCA10	*SCA10*	22q13ter	Ataxin-10	Pentanucleotide (ATTCT) repeat in the intron	10–20	500–4,500
SCA12	*SCA12*	5q31-33	Protein phosphatase 2A	CAG repeat in 5′ UTR	7–28	66–78
SCA17	*TBP*	6qter	TATA-binding protein	CAG repeat in coding region	29–42	47–55
DRPLA	*DRPLA*	12q	Atrophin-1	CAG repeat in coding region	6–35	49–88
FXTAS	*FMR1*	Xq27.3	FMRP	CGG repeat in 5′ UTR	6–60	60–200

[1]Alleles with 21 or more repeats are interrupted by one to three CAT units; disease alleles contain pure CAG tracts.
DRPLA, dentatorubropallidoluysian atrophy; FXTA, fragile X–associated tremor ataxia; SCA, spinocerebellar ataxia.

Patients with *SNCA* mutations differ from those with sporadic Parkinson disease in that the age of onset is earlier (a mean of 45 years), and they exhibit fewer tremors and more rigidity, cognitive decline, myoclonus, central hypoventilation, orthostatic hypotension, and urinary incontinence.

Autosomal recessive juvenile parkinsonism is characterized by early-onset dystonia, brisk deep tendon reflexes, and cerebellar signs in addition to the classic signs of Parkinson disease, all as early as 3 years of age. Mutations in *PARK2*, *PARK6*, and *PARK7*—which encode parkin, PTEN-induced putative kinase 1 (PINK1), and protein deglycase DJ-1, respectively—have been confirmed as causes of this disease. Mutations in *PARK2* are much more frequent than mutations in *PARK6* and *PARK7*, and more than 60 different inactivating mutations have been identified; autosomal recessive juvenile Parkinsonism is thus caused by loss of function of the gene product rather than a gain of function. The pathology is also characterized by loss of dopaminergic neurons, but Lewy bodies are not as common as in sporadic or *PARK1/4* cases. Parkin is an E3 ubiquitin ligase of the RING finger family that transfers activated ubiquitin to lysine residues in proteins destined for degradation by proteasomes. Studies in the fruit fly *Drosophila melanogaster* revealed that parkin and PINK1 work together to promote healthy mitochondria. Interestingly, DJ-1, the third cause of autosomal recessive juvenile parkinsonism, is also involved in mitochondrial function, acting as an oxidative stress sensor.

Not all genetic causes of Parkinson disease exhibit complete penetrance. Such is the case with mutations in the gene encoding the leucine-rich repeat kinase 2 (*LRRK2*, *PARK8*). Interestingly, *LRRK2* mutations are a risk factor for sporadic Parkinson disease. Another genetic risk factor for Parkinson disease is the gene coding for glucocerebrosidase-1 (*GBA1*): Heterozygous carriers of *GBA1* mutations are at increased risk of developing Parkinson disease later in life, whereas homozygous carriers develop a recessive disorder known as Gaucher disease. There are undoubtedly additional genetic risk factors for Parkinson disease, and efforts to identify them are ongoing.

Table 63–3 Genetics and Main Clinical Features of Inherited Parkinson Disease

Disease	Locus map	Inheritance pattern	Gene	Main features
PARK1/4	4q21	AD	*SNCA*	Early onset, rigidity, and cognitive impairment
PARK2	6q26	AR	*PARKIN*	Juvenile onset and dystonia
PARK3	2p13	AD	Unknown	Adult onset, dementia
PARK5	4p13	AD	*UCHL1*	Adult onset
PARK6	1p36.12	AR	*PINK1*	Early onset, dystonia
PARK7	1p36.21	AR	*DJ1*	Early onset, behavioral disturbance, dystonia
PARK8	12q12	AD	*LRRK2*	Classic PD
PARK9	1p36.13	AR	*ATP13A2*	Juvenile or early onset, cognitive impairment
PARK10	1p32	AD	Unknown	Classic PD
PARK11	2q37.1	AD	*GIGYF2*	Adult onset, cognitive impairment
PARK12	Xq21-25	X-linked	Unknown	Unknown
PARK13	2p13.1	AD	*Omi/HtrA2*	Classic PD
PARK14	22q13.1	AR	*PLA2G6*	Early onset, cognitive impairment, dystonia.
PARK15	22q12.3	AR	*FBXO7*	Juvenile onset or early onset
PARK16	1q32	Unknown	Unknown	Unknown
PARK17	16q11.2	Unknown	*VPS35*	Adult onset, cognitive impairment, dystonia
PARK18	6p21.3	Unknown	*EIF4G1*	Classic PD
PARK19a/b	1p31.3	AR	*DNAJC6*	Juvenile or early onset, cognitive impairment
PARK20	21q22.11	AR	*SYNJ1*	Early onset, seizures
PARK21	3q22	AD	*DNAJC13*	Classic PD
PARK22	7p11.2	AD	*CHCHD2*	Classic PD

AD, autosomal dominant; AR, autosomal recessive; PARK, PD, Parkinson disease.

Selective Neuronal Loss Occurs After Damage to Ubiquitously Expressed Genes

One perplexing aspect of these neurodegenerative diseases is that the altered gene products are widely and abundantly expressed not only in the nervous system but also in other tissues, yet the phenotypes are predominantly neurological. Moreover, the phenotypes usually reflect dysfunction in only specific groups of neurons (Figure 63–2), a phenomenon referred to as neuronal selectivity.

Why are striatal neurons the most vulnerable in Huntington disease, whereas the Purkinje cells are targeted in the SCAs? Why are the dopaminergic neurons in the substantia nigra pars compacta primarily affected in Parkinson disease even though α-synuclein, parkin, DJ-1, PINK1, and LRRK2 are abundant in many other neuronal (and even nonneuronal) groups? Although definitive answers are not yet available, some hypotheses have been advanced. One possibility was suggested by the finding that the dopaminergic neurons that are vulnerable in Parkinson disease exhibit an unusual physiological characteristic: They depend on Ca^{2+} channels to fire in a rhythmic pattern. This dependence on Ca^{2+} influx in the neuron is thought to cause baseline mitochondrial stress, which could explain why these neurons are so vulnerable to direct insults to mitochondrial recycling, such as caused by parkin, DJ-1, and PINK1 dysfunction, as well as additional stress caused by LRRK2 dysfunction and α-synuclein accumulation.

In the polyglutamine diseases, the selectivity of the cellular pathology diminishes as the length of the glutamine tract increases: The more severe the mutation, the greater is the number of neuronal groups affected. This is especially evident in the early-onset forms

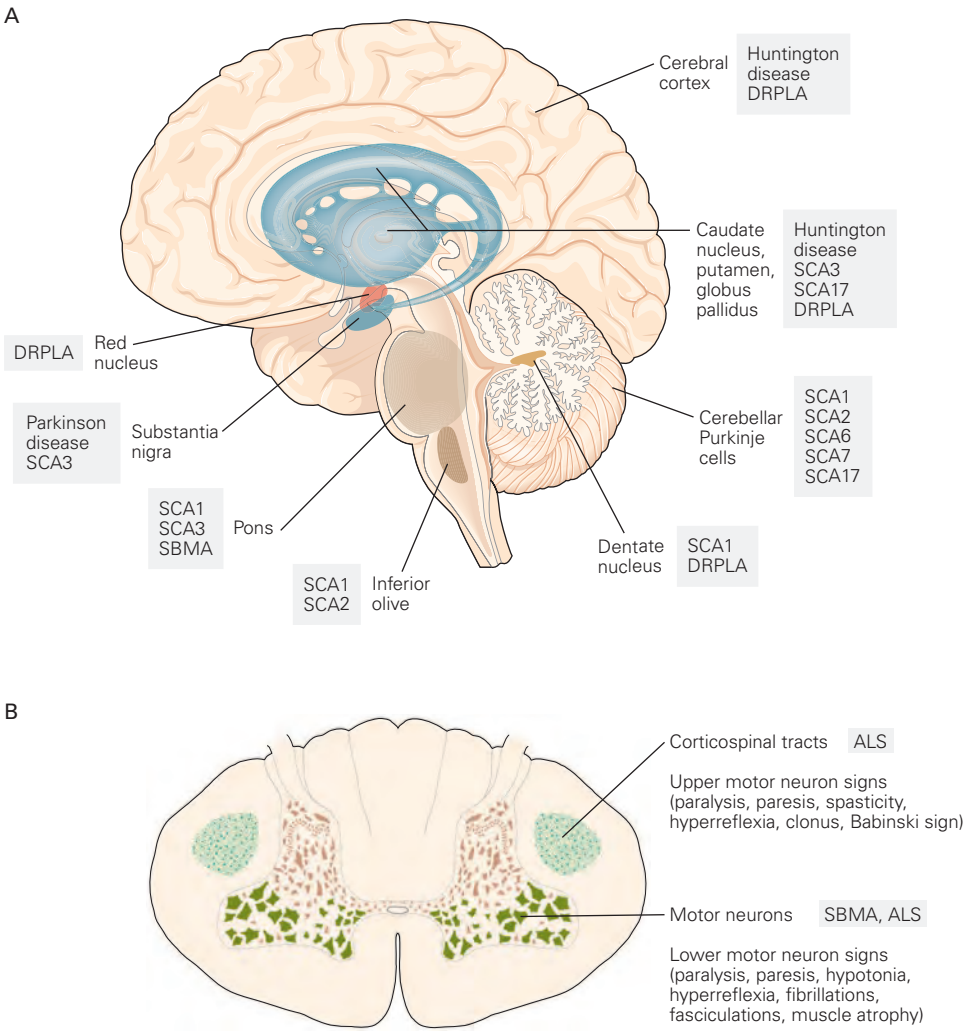

Figure 63–2 Neuronal selectivity illustrated by the primary sites of neuronal degeneration in the trinucleotide repeat diseases and Parkinson disease.

A. Brain regions most typically affected by adult-onset disease (see Table 63–1). (Abbreviations: **DRPLA**, dentatorubropallidoluysian atrophy; **SCA**, spinocerebellar ataxia.)

B. Comparison of neuropathology of amyotrophic lateral sclerosis (**ALS**) and spinobulbar muscular atrophy (**SBMA**).

characterized by extremely long repeats. Juvenile SCA1 can involve oculomotor abnormalities, for example, or cause dystonia, rigidity, and cognitive impairment, features that overlap with Huntington disease and DRPLA; death usually occurs within 4 to 8 years of symptom onset. Juvenile SCA7 patients can suffer seizures, delusions, and auditory hallucinations, and infantile disease also produces somatic features such as short stature and congestive heart failure. Infantile SCA7 causes progressive blindness by destroying both rods and cones; interestingly, infants with SCA2 can also suffer retinal degeneration. Such observations suggest that different cell types have different thresholds of vulnerability to toxic proteins with expanded glutamine tracts. Retinal cells, for example, seem more resistant to polyglutamine toxicity than cerebellar neurons, but more vulnerable than cardiac myocytes. Once the number of glutamines in the tract expands beyond a certain length—which varies from one protein to the next—no cell is safe.

Studies using mouse models suggest that protein misfolding is responsible for polyglutamine disorders. The longer the glutamine tract, the more severe the misfolding, and the more resistance there is to clearance; thus, the slow accumulation of higher-than-normal protein levels is a feature common to neurodegenerative diseases. As the tracts become very long, even cells with lower concentrations of disordered gene product

become vulnerable. Indeed, studies of animal models show that even a doubling in concentration can be the difference between phenotypic manifestation and apparent normality. It is therefore conceivable that the neurons affected in each disease have more dysfunctional protein than do the less vulnerable neurons. Although not detectable by current immunolabeling techniques, this incremental increase would nevertheless be sufficient to interfere with cellular function if the neuron was exposed to the toxic protein over decades.

Other major contributors to selective vulnerability might be variations in the levels of proteins that interact with or help dispose of the mutant proteins. Variations in the genes encoding such proteins could contribute to the clinical variability that is so prominent among ataxia families.

Why are neurons affected before other cells? As the organism ages, slight insults that have small detrimental effects could be exacerbated by the extra challenge the toxic protein presents to the protein-folding machinery. Because neurons are postmitotic, they might be especially sensitive to perturbations in the balance of intracellular factors. If the organism could survive the neurological assault long enough, other tissues might also eventually show signs of distress.

Animal Models Are Productive Tools for Studying Neurodegenerative Diseases

Animal models have proven extremely valuable for probing the pathogenesis of various neurodegenerative diseases and investigating therapies. The mouse has been the favored animal for modeling neurological disorders, but the *Drosophila* fly and the worm *Caenorhabditis elegans* have also proven useful in delineating genetic pathways.

Mouse Models Reproduce Many Features of Neurodegenerative Diseases

With the exception of the autosomal recessive juvenile forms of Parkinson disease, the neurodegenerative diseases discussed here primarily reflect gain-of-function mutations. Thus, most of the genetically engineered mice that model these diseases are created using one of two techniques. In the transgenic approach, an allele harboring the mutant gene is overexpressed, whereas in the knock-in approach, a human mutation, such as an expanded CAG tract, is inserted into an endogenous mouse locus to promote expression of the gene product at the correct time in development and in the right cells.

In some transgenic models, such as those generated for SCA types 1, 2, 3, and 7 and DRPLA, a full-length cDNA with either wild type or expanded alleles is overexpressed either in a particular class of neurons or in a larger population of cells (Figure 63–3). In other transgenic models of SCA3 and in models of SBMA, truncated versions of the coding regions are expressed. Both full-length and truncated huntingtin have been used in transgenic models.

Knock-in mice have been generated for Huntington disease, SBMA, and SCA types 1 and 7. These models confirm that sequences other than the expanded glutamine tract can produce toxic protein. Moreover, the same expansion in two different host proteins can affect cells differently. For example, in humans, 33 repeats cause SCA2, whereas 44 to 52 CAG repeats may or may not develop SCA3 (Figure 63–1 and Table 63–2). In mouse models, however, the relationship of the length of the tract to the rest of the protein is a good predictor of toxicity: Severe, widespread, nonselective neuronal dysfunction occurs in transgenic mice bearing a truncated protein with a relatively large glutamine tract. In contrast, mice that express full-length proteins containing the same CAG repeat length develop a milder neurological syndrome that progresses more slowly. Weakly expressing promoters also tend to produce more selective neuronal dysfunction. In some cases, expression of the full-length protein with even a moderately large expansion does not cause neurological dysfunction, but a truncated version bearing a similar repeat size does produce the disease phenotype. In sum, a glutamine tract of a certain length is more toxic when expressed in isolation or flanked by short peptide sequences, that is, when it occupies a larger proportion of the protein.

In SCA1 knock-in mice with 78 glutamine repeats, neurological dysfunction is barely detectable; only when the repeat length is expanded to approximately 154 glutamines does a neurological phenotype become apparent. Longer repeats are necessary to see a phenotype during the short life span of a mouse because polyglutamine toxicity takes time to exert its effects. In transgenic mice, however, massive overproduction of the mutant protein compensates for a moderate repeat length and brevity of exposure. Indeed, in mice, even overproduction of wild type ataxin-1 results in mild neurological dysfunction, and overexpression of wild type human α-synuclein is enough to cause parkinsonian symptoms.

Analysis of brain tissue from humans and various experimental mice reveals that misfolded proteins

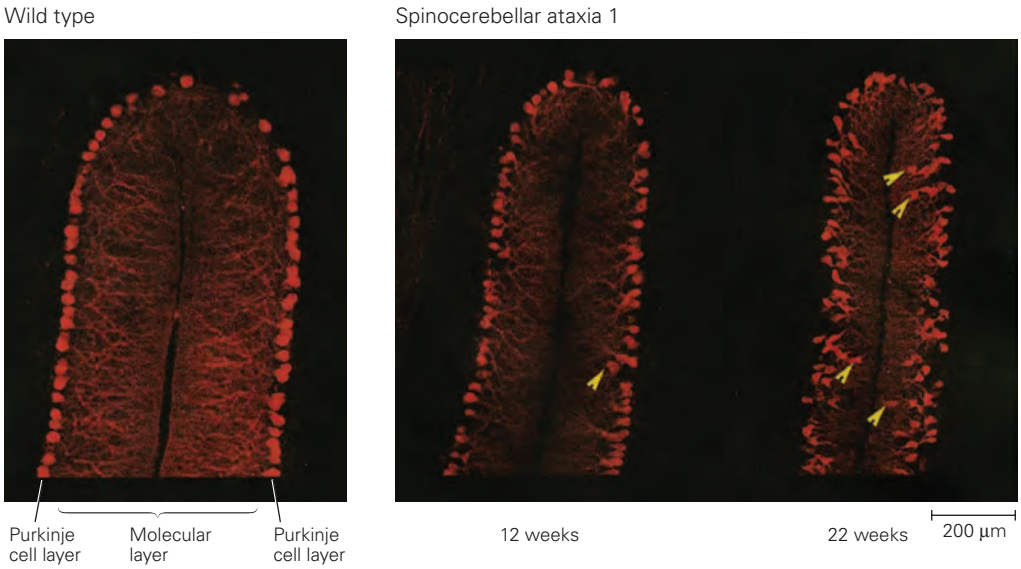

Figure 63–3 Progressive Purkinje cell pathology in spinocerebellar ataxia type 1 transgenic mice. Cerebellar sections from a wild type mouse and mice expressing a spinocerebellar ataxia type 1 (SCA1) transgene with 82 glutamines in Purkinje cells at 12 and 22 weeks of age. Calbindin immunofluorescence staining marks the Purkinje cells and their extensive dendritic arbors. In SCA1, there is progressive loss of dendrites, thinning of the molecular layer, and Purkinje cell displacement (**arrowheads**). (Images reproduced, with permission, from H.T. Orr.)

tend to accumulate in various neurons, often forming visible aggregates (Figure 63–4). Lewy bodies and abnormal accumulation of α-synuclein develop in mouse models of Parkinson disease, just as in humans. Although protein accumulation is common to all these neurodegenerative disorders, the location of the accumulated protein in the cell varies, and location within the cell is a factor in the protein's pathogenicity. For example, mutant ataxin-1 that accumulates in the cytoplasm instead of the nucleus (because its nuclear localization signal is disabled) exerts no detectable toxic effects.

The fact that mutant proteins accumulate both in mouse models that do not overproduce the proteins and in human patients who carry a single mutant allele suggests that neurons have difficulty clearing the proteins. This hypothesis is supported by the finding that ubiquitin and proteasome components, the machinery of protein degradation, are found with protein aggregates in both human and mouse tissues.

Invertebrate Models Manifest Progressive Neurodegeneration

Several invertebrate models have been used to study polyglutamine proteins, α-synuclein, parkin, and PINK1. The similarities in the pathogenic effects of these proteins across species are remarkable.

Flies with high levels of human α-synuclein develop progressive degeneration of dopaminergic neurons and have α-synuclein–immunoreactive cytoplasmic aggregates reminiscent of Lewy bodies. As in the mouse model, high levels of α-synuclein in flies carrying either the wild-type or mutant allele induce this phenotype. Additionally, flies with PINK1 or parkin mutations have dopaminergic neuron defects and motor abnormalities. Overexpression of wild type or mutant ataxin-1 in flies induces progressive neuronal degeneration that correlates with protein levels, but of course is more severe for flies with the mutant protein.

Polyglutamine toxicity has also been evaluated in the nematode *C. elegans* by expressing an amino terminal fragment of huntingtin containing glutamine tracts of different lengths. Neuronal dysfunction and cell death occur in worms expressing expanded tracts embedded within a truncated protein.

The Pathogenesis of Neurodegenerative Diseases Follows Several Pathways

Protein Misfolding and Degradation Contribute to Parkinson Disease

The gradual accumulation of neurodegenerative disease proteins along with chaperones and components

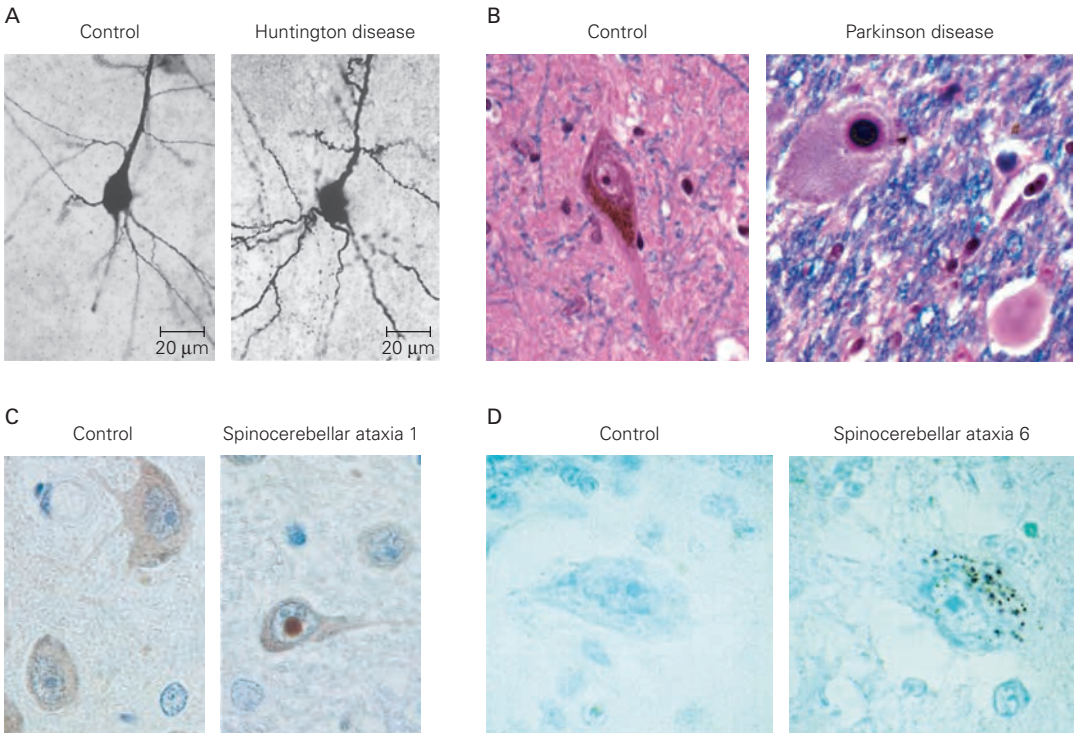

Figure 63–4 Neuropathological features of selected neurodegenerative disorders.

A. Comparison of a normal spiny neuron from the caudate nucleus and a spiny neuron affected by Huntington disease. Note the marked recurving of terminal dendritic branches in the diseased neuron. (Image of Huntington neuron reproduced, with permission, from Marian Di Figlia and J.-P. Vonsattel.)

B. A pigmented dopaminergic neuron in the substantia nigra with a classic cytoplasmic inclusion (Lewy body). The circular cytoplasmic inclusion is surrounded by a clear halo. Recent electron-microscopic and biochemical evidence indicates that the primary components of Lewy bodies are synuclein, ubiquitin, and abnormally phosphorylated neurofilaments that form a nonmembrane-bounded compacted skein in the cell body. Extracellular Lewy bodies occur following neuronal cell death and disintegration.

C. A neuron with a typical nuclear inclusion, almost as large as the nucleolus, and another Purkinje cell with a sizable vacuole and axonal swelling known as a torpedo.

D. Because spinocerebellar ataxia type 6 results from a repeat expansion in *CACNA1A*, which encodes a calcium channel, *CACNA1A* labeling occurs diffusely throughout the cytoplasm rather than in the nucleus.

of the ubiquitin-proteasome degradation pathway suggests that expansion of the glutamine tract alters the folding state of the native protein, which in turn recruits the activity of the protein-folding and degradation machinery. When that machinery cannot process the protein molecules, they accumulate, eventually forming aggregates. Evidence in support of this idea first came from observations in cell culture that overproduction of chaperones reduces protein aggregation and mitigates the toxicity of expanded glutamine tracts in proteins. In contrast, blocking the proteasome inhibits protein degradation and thus enhances aggregation and toxicity. Genetic studies in flies and mice provide even more compelling evidence. Overproduction of at least one chaperone, such as Hsp70, Hsp40, or tetratricopeptide protein 2, suppresses polyglutamine toxicity in *Drosophila* and reduces degeneration in mouse models of Parkinson disease and several types of ataxia. Conversely, loss of chaperone function worsens the neurodegenerative phenotypes (Figure 63–5).

The importance of the ubiquitin-proteasome pathway and protein degradation in the SCAs is further supported by genetic modification in animal models. In a *Drosophila* model of SCA1, haploinsufficiency for ubiquitin, ubiquitin carrier enzymes, or a ubiquitin carboxyl-terminal hydrolase worsens neurodegeneration. It appears that inclusions are part of the cell's attempt to sequester the mutant protein and thereby limit its toxic effects. Cells that are unable to form aggregates suffer the worst damage from polyglutamine toxicity. Indeed, the knock-in mouse models of SCA types 1 and 7 show conclusively that cells that

B. Ommatidia of a transgenic fly bearing a protein with expanded glutamine repeats.

C. Owing to the mitigating effect of over-producing a heat shock protein on the polyglutamine-induced phenotype, the ommatidia appear almost normal.

D. Absence of another heat shock protein aggravates the polyglutamine-induced phenotype.

form aggregates survive longer; cerebellar Purkinje cells, the prime targets in this disease, are the last to form nuclear aggregates.

In Huntington disease, the expanded huntingtin protein is readily cleaved by proteases, but the fragments are toxic to the cell, interfering with transcription and dysregulating the activity of dynamin-1. Expanded huntingtin activates the autophagy pathway via repression of mammalian target of rapamycin (mTOR) kinase, but the resulting autophagosomes are defective and cannot help the neurons degrade aggregated proteins. Finally, the expanded huntingtin protein forms aggregates. Some studies suggest these aggregates are harmful to the cell, while other studies have shown them to be protective because they reduce the circulating level of the soluble toxic protein. Their role in pathology might depend on the disease stage and which interacting proteins co-accumulate in the aggregates.

Studies of Parkinson disease further underscore the importance of the ubiquitin-proteasome pathway and reveal additional parallels with the polyglutamine diseases. First, studies focused on α-synuclein have shown that ubiquitinated forms of the protein accumulate in Lewy bodies and that ubiquitination regulates α-synuclein stability. Second, recent studies have identified NEDD4 as an E3 ubiquitin ligase that targets α-synuclein, and USP9X as a de-ubiquitinating enzyme that removes the modification. Other studies have identified parkin as an E3 ubiquitin ligase that targets many different mitochondrial proteins and is important for mitochondrial quality control.

How do misfolded α-synuclein or expanded glutamine tracts disrupt neuronal function? A protein that resists degradation might linger too long in the cell, performing its normal function longer than it should; the altered conformation might also cause it to favor certain protein interactions over others. This is what happens with glutamine-expanded ataxin-1: Part of the gain of toxic function involves prolonged binding with Capicua and subsequent alterations in its transcriptional activity.

Protein Misfolding Triggers Pathological Alterations in Gene Expression

One of the key consequences of misfolding as a result of expanded glutamine tracts is alteration in gene expression. This was first suspected when it was realized that most of the mutant proteins accumulate in the cell nucleus and that they interact with or affect the function of key transcriptional regulators. For example, huntingtin interacts with the transcription factors CREB-binding protein, NeuroD, specificity protein-1, nuclear factor-κB, and tumor suppressor protein 53 (p53), among others. Disruption of these interactions secondary to the polyglutamine expansion leads to myriad transcriptional changes seen in the disease state.

Alterations in gene expression are among the earliest events in pathogenesis, occurring within days of

expression of the mutant transgene in mouse models of SCA1 and Huntington disease. Many of the genes whose expression is altered are involved in Ca^{2+} homeostasis, apoptosis, cell-cycle control, DNA repair, synaptic transmission, and transduction of sensory events into neural signals. In fly models of SCA1, several modifiers of the neurodegenerative phenotype are transcriptional cofactors. Overproduction of polyglutamine proteins also can reduce levels of histone acetylation in cells, an effect that can be reversed by overproduction of CREB-binding protein. Finally, ataxin-1 is in a native complex with the transcriptional repressor Capicua; thus, some of the gain-of-function effects involve a gain of enhanced Capicua-mediated repression.

Mitochondrial Dysfunction Exacerbates Neurodegenerative Disease

Both morphological and functional studies provide evidence of mitochondrial dysfunction in polyglutamine disorders and Parkinson disease. Lymphoblast mitochondria from patients with Huntington disease as well as brain mitochondria from a transgenic mouse model for Huntington disease have a lower membrane potential and depolarize at lower Ca^{2+} loads than do control mitochondria.

Several proteins implicated in Parkinson disease affect mitochondrial function and integrity. For example, studies in *Drosophila* showed that the loss of PINK1 leads to mitochondrial dysfunction, dopaminergic neuron impairment, and motor abnormalities that can be rescued by parkin. These studies led to the finding that PINK1 and parkin regulate mitochondrial turnover in the cell in a process termed mitophagy. Thus, given the functions and interactions of these proteins, mitochondrial dysfunction is likely to be a key contributor to the Parkinson disease phenotype.

Apoptosis and Caspases Modify the Severity of Neurodegeneration

Although studies of most neurodegenerative diseases demonstrate that symptoms appear long before detectable cell death, loss of neurons is a hallmark of the end stage of all these disorders. Two major factors are implicated in the death of neurons: altered Ca^{2+} homeostasis and decreased induction of neuronal survival factors, such as brain-derived neurotrophic factor in Huntington disease. There is, however, specific evidence that the caspase activity critical for apoptosis is a contributing factor in neurodegenerative diseases. Some of the polyglutamine proteins, such as huntingtin, androgen receptor, ataxin-3, and atrophin-1, are substrates for caspases in vitro. This raises the possibility that caspase liberates the fragments of these proteins with expanded glutamine tracts. As noted above, such fragments are even more damaging than the full-length protein.

Intranuclear huntingtin increases production of caspase-1 in cells; this could lead to apoptosis and caspase-3 activation. Hip-1, a protein that interacts with huntingtin, forms a complex that activates caspase-8. This process might be enhanced by the glutamine expansion in huntingtin because Hip-1 binds less avidly to mutant huntingtin than to the wild type protein. In *Drosophila*, production of the antiapoptotic protein p35 results in partial rescue of the pigment loss induced by mutant ataxin-3.

In summary, expansions of polyglutamine tracts as well as several missense mutations in proteins implicated in neurodegenerative diseases alter the host protein, leading to its accumulation or abnormal interactions. The neuronal dysfunction results from the downstream effects of such abnormal interactions (Figure 63–6).

Understanding the Molecular Dynamics of Neurodegenerative Diseases Suggests Approaches to Therapeutic Intervention

The discovery of the genetic bases and pathogenic mechanisms of various neurodegenerative diseases offers us hope that therapies for these diseases will soon emerge. Dopamine replacement therapy has so far been the only pharmacological option for Parkinson disease, but it is not ideal. Patients tend to develop tolerance and require higher and higher doses of the drugs, which in turn cause a side effect known as levodopa-induced dyskinesias. The uncontrollable movements of dyskinesia soon become as disruptive as the motor symptoms originally being treated. Advancements in deep brain stimulation are promising, but the procedure is invasive and therefore reserved for medication-refractory Parkinson disease.

Patients with Huntington disease and SCA are worse off. No treatments that slow the progressive loss of motor coordination are currently available. However, several exciting therapeutic approaches that show great promise are under investigation. The most exciting therapeutic advances are those related to gene silencing of pathogenic products, including editing the genome, turning down transcription, or reducing expression of the protein. The most promising of these approaches in Huntington disease is the use of antisense oligonucleotides (ASOs). ASOs are small single-stranded molecules designed to bind to complementary sequences found within the mRNA product

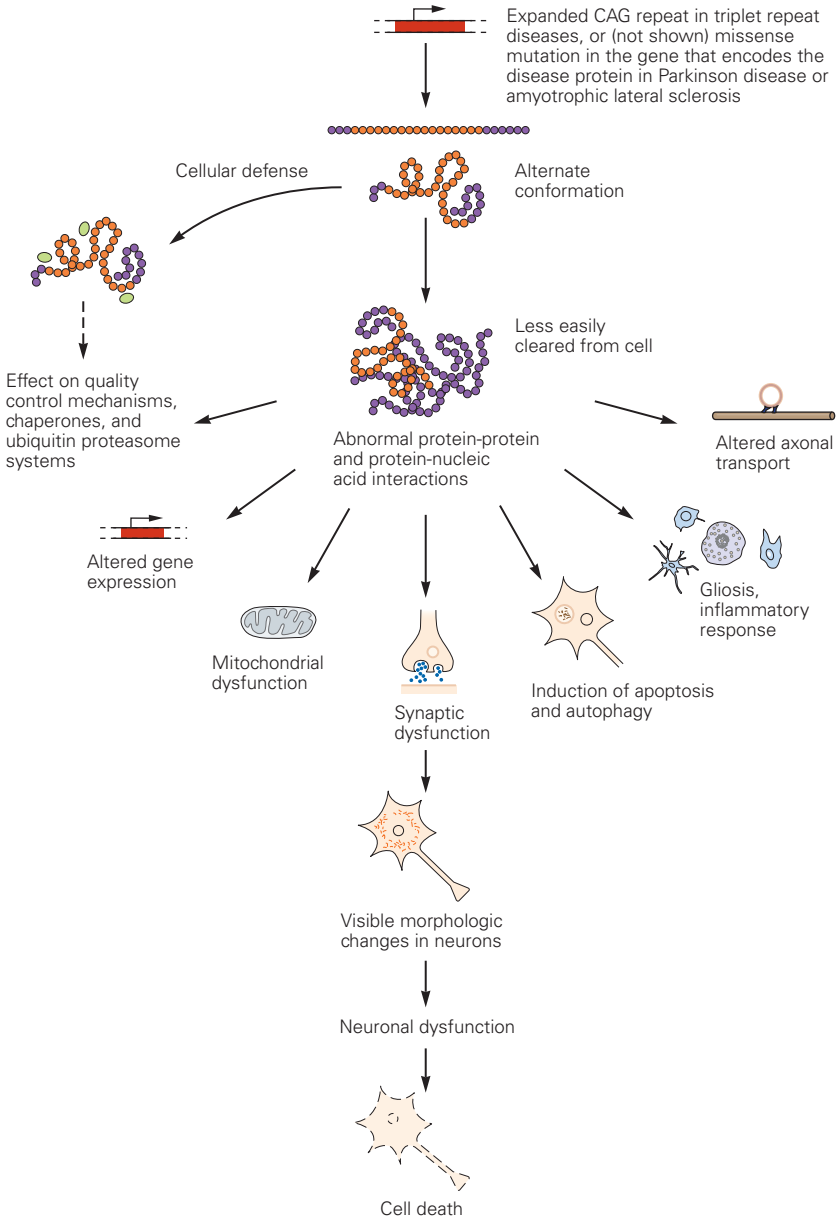

Figure 63–6 Current model for pathogenesis of the proteinopathies. The disease-causing protein adopts an alternative conformation that changes its interactions with other proteins, DNA, or RNA, altering gene expression and perhaps generating an inflammatory response. These early events in pathogenesis occur years before symptoms appear. Since this alternative conformation is more difficult for the cell to refold or degrade, steady-state levels of the mutant protein rise slowly over a period of decades. As levels of the mutant protein rise, the neuron attempts to sequester the mutant protein and forms aggregates. As disease progresses, these proteinaceous deposits themselves may affect protein interactions or compromise the protein quality-control system.

one wants to downregulate. When an ASO binds its mRNA target, it triggers degradation of the mRNA through RNAse H activity while at the same time sparing the ASO itself, thereby allowing it to bind to another mRNA molecule. In Huntington disease, several ASOs have been successfully used to reduce huntingtin protein levels. In fact, this approach is currently being utilized in clinical trials and holds promise for other diseases such as Parkinson disease.

Ideally, therapies should be targeted at some of the earliest pathogenic stages, when intervention could in theory halt the disease or even allow recovery of function. Indeed, studies of mouse models of Huntington disease and SCA1, in which expression of the mutant gene can be turned off, have shown that the neuronal dysfunction is reversible. When expression of the transgene is turned off, the neurons have a chance to clear the mutant polyglutamine protein and regain normal activity.

Because most neurodegenerative diseases progress over a period of decades, pharmacological interventions that even slightly modulate one or more of the pathways described above could delay disease progression or improve function, which would greatly enhance the quality of life for patients suffering from these devastating disorders.

Highlights

1. Late-onset neurodegenerative diseases collectively afflict more than 25 million people throughout the world, and it is anticipated that the prevalence of Alzheimer and Parkinson diseases will rise, given the increasing trend in life expectancy.
2. The identification of genes causing several forms of Parkinson disease and the various polyglutamine neurodegenerative diseases has allowed the accurate diagnosis and classification of these clinically heterogeneous disorders.
3. Although the gene product driving disease is widely expressed in the brain, there is selective neuronal vulnerability in all adult-onset neurodegenerative disorders. Perhaps a slight increase in abundance of the disease-driving protein and/or its interactors might explain such selective vulnerability.
4. Mitochondrial dysfunction is common in Parkinson disease; some of the genes mutated in Parkinson disease regulate mitochondrial turnover.
5. Studies in cell culture and model organisms have revealed a pathogenic mechanism common to adult-onset neurodegenerative diseases: protein misfolding. Mutations that cause the respective proteins to adopt an altered conformation gradually induce neuronal dysfunction either because of abnormal protein interactions or because of intracellular protein accumulation and altered activity.
6. The accumulation of polyglutamine-expanded proteins causes a variety of molecular changes in the cells, including alterations in gene expression, alterations in Ca^{2+} homeostasis, mitochondrial dysfunction, and activation of caspases.
7. The discovery that many adult neurodegenerative disorders are reversible in mouse models gives hope that some of the neuronal dysfunction can be rescued if a treatment is implemented early enough in the disease course before cell death occurs.
8. The identification of pathways that mediate some of the pathogenic effects is likely to lead to the discovery of drugs that can first be tested in animals and then applied in humans.
9. Lowering the levels of disease-driving proteins can ameliorate their toxic effects. This opens the way for therapeutic strategies that either employ antisense oligonucleotides that target the toxic RNA or that use small molecules to target regulators of the toxic protein.

The Aging Brain

The average life span in the United States in 1900 was about 50 years. By 2015, it was approximately 77 years for men and 82 for women (Figure 64–1). The average is even higher in 30 other countries. These increases result largely from a reduction in infant mortality, the development of vaccines and antibiotics, better nutrition, improved public health measures, and advances in the treatment and prevention of heart disease and stroke. Because of increased life expectancy, along with the large cohort of "baby boomers" born soon after World War II, the elderly are the most rapidly growing segment of the US population.

Increased longevity is a double-edged sword since age-related cognitive alterations are increasingly prevalent. The magnitude of the change varies widely among individuals. For many, the alterations are mild and have relatively little impact on the quality of life—the momentary lapses we jokingly call "senior moments." Other cognitive impairments, although not debilitating, are troubling enough to hinder our ability to manage life independently. The dementias, however, erode memory and reasoning and alter personality. Of these, Alzheimer disease is the most prevalent.

As the population ages, neuroscientists, neurologists, and psychologists have begun to devote more energy to understanding age-related changes in the brain. The primary motivation has been to find treatments for Alzheimer disease and other dementias, but it is also important to understand the normal process of cognitive decline with age. After all, age is the greatest risk factor for a wide variety of neurodegenerative disorders. Understanding what happens to our brains as we age may not only improve the quality of life for the general population but may also provide clues that will eventually help us vanquish seemingly unrelated pathological changes.

With this in mind, we begin this chapter with a consideration of the normal aging of the brain. We then turn to the broad range of pathological changes in cognition, and finally focus on Alzheimer disease.

The Structure and Function of the Brain Change With Age

As we grow old, our bodies change—our hair thins, our skin wrinkles, and our joints creak. It is no surprise then that our brain also changes. Indeed, the widespread behavioral alterations that occur with age are

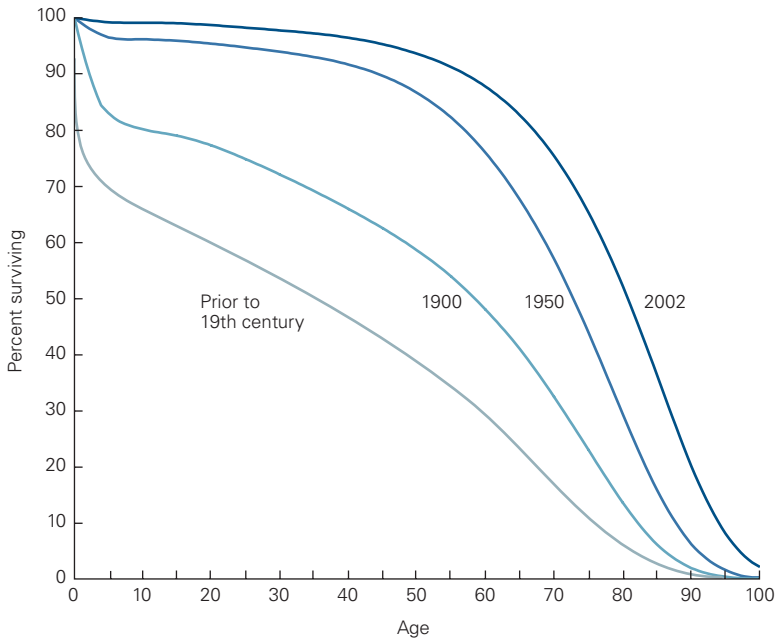

Figure 64–1 The human life span is increasing. The average life span in the United States has increased rapidly over the past 100 years. (Adapted from Strehler 1975; Arias 2004.)

signs of underlying alterations in the nervous system. For example, as motor skills decline, posture becomes less erect, gait is slower, stride length is shorter, and postural reflexes often become sluggish. Although muscles weaken and bones become more brittle, these motor abnormalities result in large part from subtle processes that involve the peripheral and central nervous systems. Sleep patterns also change with age; older people sleep less and wake more frequently. Mental functions ascribed to the forebrain, such as memory and problem-solving abilities, also decline.

Age-related declines in mental abilities are highly variable, in both rate and severity (Figure 64–2A). Although most people experience a gradual decline in mental agility, for some, the decline is rapid, whereas others retain their cognitive powers throughout life—Giuseppe Verdi, Eleanor Roosevelt, and Pablo Picasso are well-known examples of the latter category. Titian continued to paint masterpieces in his late 80s, and Sophocles is said to have written *Oedipus at Colonus* in his 92nd year. The fact that elderly people with completely preserved mental function are rare suggests that there may be special properties in the life experiences or genes of these people. Accordingly, there has been great interest in studying individuals who retain nearly intact cognition into their tenth or even eleventh decade. These centenarians may provide insight into environmental or genetic factors that protect against normal age-related cognitive decline or the more devastating pathological descent into dementia. One protective gene variant, discussed below, is the epsilon 2 allele of the apolipoprotein E gene.

An interesting finding that has emerged from studies of many individuals is that some cognitive capacities decline significantly with age while others are largely spared (Figure 64–2B). For example, working and long-term memories, visuospatial abilities (measured by arranging blocks into a design or drawing a three-dimensional figure), and verbal fluency (measured by rapid naming of objects or naming as many words as possible that start with a specific letter) usually decline with old age. On the other hand, measures of vocabulary, information, and comprehension often show minimal decline in normal individuals well into the 80s.

Age-related changes in memory, motor activity, mood, sleep pattern, appetite, and neuroendocrine function result from alterations in the structure and function of the brain. Even the healthiest 80-year-old brain does not look like it did at the age of 20. Elderly people exhibit mild shrinkage in the volume of the brain and a loss in brain weight, as well as enlargement of the cerebral ventricles (Figure 64–3A). The decreases in brain weight average 0.2% per year from college age onward, and about 0.5% per year in the 70s.

These changes could result from death of neurons. Indeed, some neurons are lost with age. For example, 25% or more of the motor neurons that innervate skeletal muscles die in generally healthy elderly individuals. As we will see, neurodegenerative diseases such as Alzheimer disease markedly accelerate the

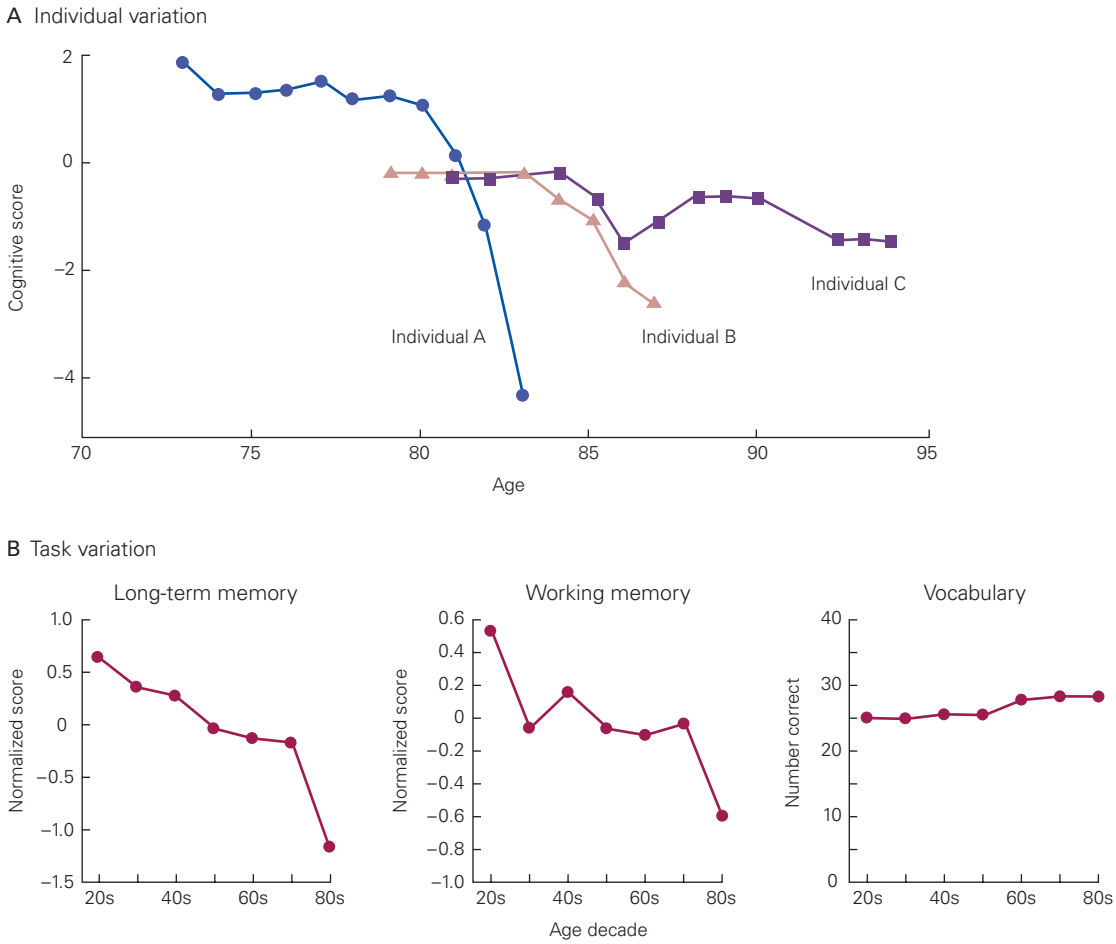

Figure 64–2 There is variation in age-related cognitive decline.

A. Scores of three people who were given a battery of cognitive tests annually for decades. Person A declined rapidly. Persons B and C showed similar cognitive performances into their 80s but then diverged. (Adapted from Rubin et al. 1998.)

B. Average scores on several cognitive tests administered to a large number of people. Long-term declarative memory and working memory decline throughout life and more so in advanced age. In contrast, knowledge of vocabulary is maintained. (Adapted from Park et al. 1996.)

death of neurons (Figure 64–3B). In most parts of the healthy brain, however, there is minimal to no neuronal loss simply because of age, so brain shrinkage must arise from other factors.

In fact, analysis of the brains of humans and experimental animals reveals structural alterations in both neurons and glia. Myelin is fragmented and lost, compromising the integrity of white matter. At the same time, the density of the dendritic arbors of cortical and other neurons decreases, resulting in shrinkage of neuropil. Levels of enzymes that synthesize some neurotransmitters, such as dopamine, norepinephrine, and acetylcholine, decrease with age, and this decline presumably results in functional defects in synapses that use these transmitters. Synapse structure is also altered, at least at the neuromuscular junction (Figure 64–4), raising the possibility that structural changes also lead to functional deficits at central synapses. Finally, the number of synapses in the neocortex and many other regions of the brain declines (Figure 64–5).

These cellular changes interfere with the integrity of the neural circuits that mediate our mental activities. Age-related loss of synapses along with impairment in function of remaining synapses are thought to be important contributors to cognitive decline. Changes in white matter are widespread but are especially notable in the prefrontal and temporal cortex. They may underlie alterations in executive functions

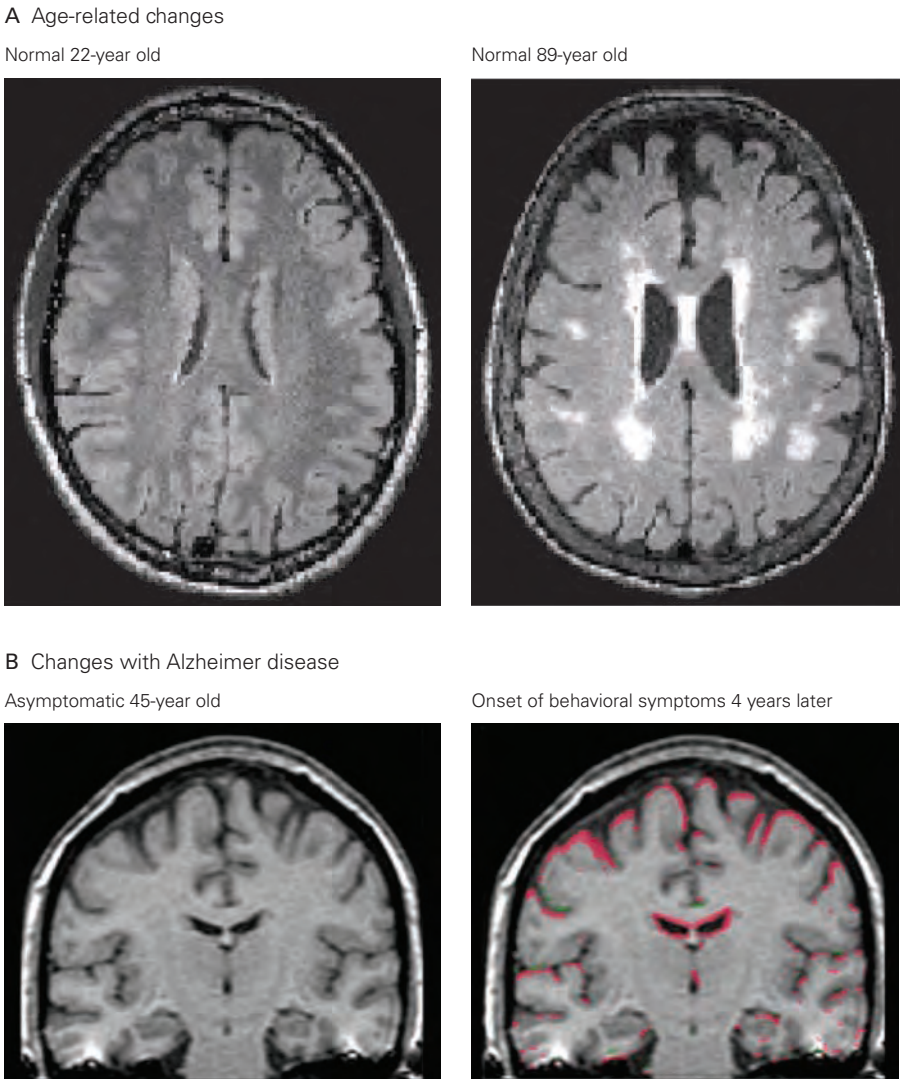

Figure 64–3 Changes in brain structure with age and at the onset of Alzheimer disease. (Also see Figure 64–8.)

A. Images of normal 22- and 89-year-old brains reveal changes in the structure of the living brain. (Reproduced, with permission, from R. Buckner.)

B. Images of the same individual over a 4-year period illustrate the progressive shrinking of cortical structures and the beginning of ventricular enlargement (**red**). These structural changes are evident prior to the onset of behavioral symptoms. (Reproduced, with permission, from N. Fox.)

and the ability to focus attention and encode and store memory, functions that are localized in frontal-striatal systems and the temporal lobes. The loss of white matter may also help explain the recent finding that the elderly brain is less able to support synchronization of activity in widely separated areas that normally work together to carry out complex mental activities. Disruption of these large-scale networks could be an important cause of cognitive decline.

It was long thought that aging resulted from progressive deterioration of cells and tissues due to accumulated genetic damage or toxic waste products. In support of this idea was the finding that mitotic cells removed from animals and placed in a tissue culture dish divide only for a limited number of times before they age and die. This view of "preordained" aging has changed radically over the past 10 to 20 years, primarily as a result of the discovery in model organisms of mutations that significantly extend life span (Figure 64–6).

Such dramatic discoveries established that the aging process is under active genetic control. One such regulatory pathway that has been characterized includes insulin and insulin-like growth factors, their receptors, and the signaling programs they activate. Disruption of these genes actually increases the resistance of cells to lethal oxidative damage. It is thought that the normal forms of these genes have been selected through evolution because they benefit the organism during the reproductive period. Their deleterious effects on longevity, once the animals are past reproductive age, may be an unfortunate side effect about which evolution cares little.

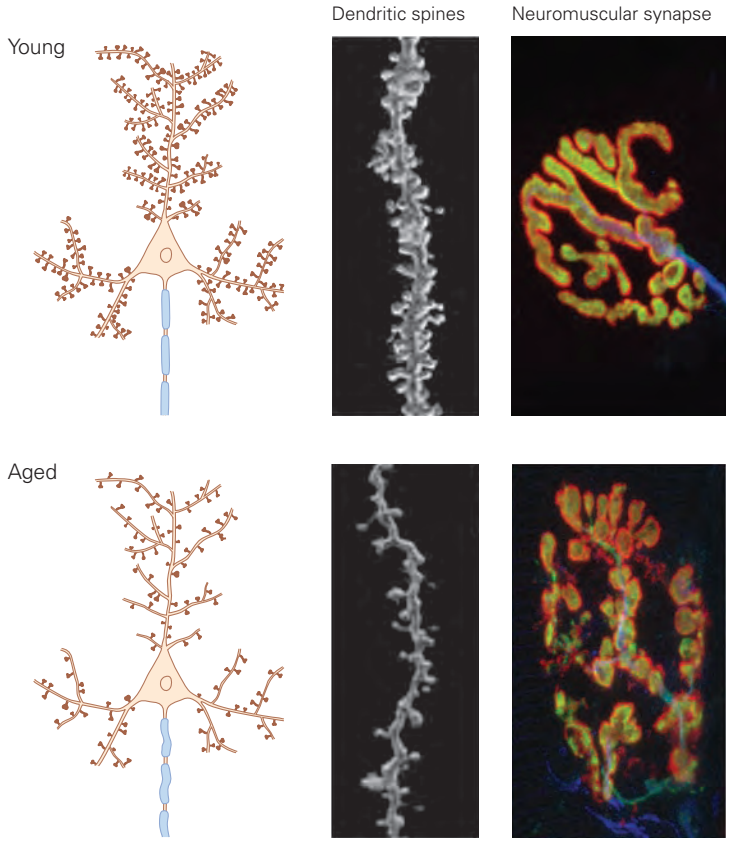

Figure 64–4 Age-related changes in dendritic and synaptic structure. Cortical pyramidal neurons in rodents lose dendritic spines with age. Neuromuscular synapses in rodents also exhibit age-related changes in structure. (Spine images reproduced, with permission, from J. Luebke; synapse images reproduced, with permission, from G. Valdez.)

These findings have two major implications for understanding how aging affects the nervous system. First, the biochemical mechanisms that lead to, or protect us from, the ravages of age are likely contributors to the changes in neurons that lead to age-related cognitive decline. Research to explore this link between cellular change and cognitive functioning is now underway in model organisms. Second, and perhaps more exciting, research on the pathways uncovered by genetic studies can identify pharmacological

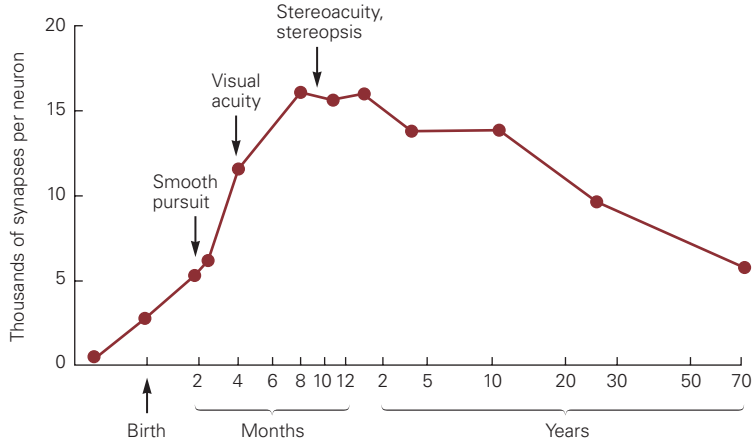

Figure 64–5 Age-related changes in synaptic density. Early cognitive development is accompanied by a marked increase in synapse density in different regions of the human cerebral cortex. Developmental landmarks through age 10 months are indicated. The density of cortical synapses declines with age. (Adapted from Huttenlocher 2002.)

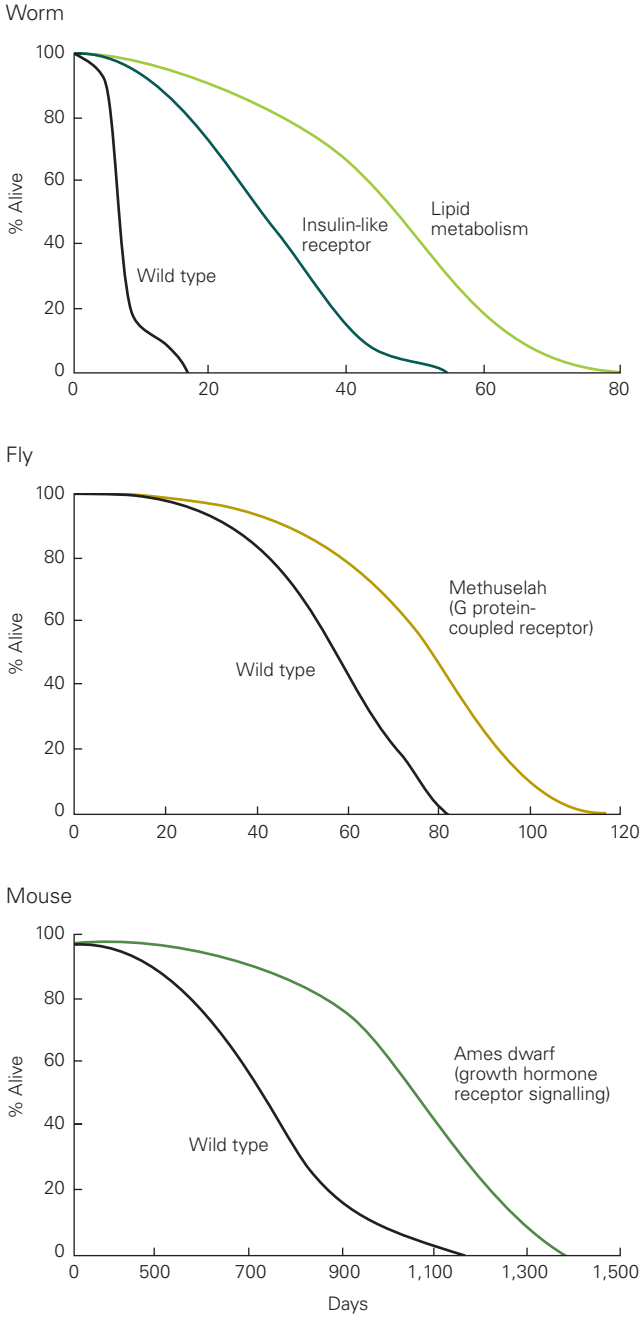

Figure 64–6 Life span can be increased through genetic mutation. Genetic mutations in specific receptors and signaling proteins markedly enhance life span in mutant strains of the worm, fly, and mouse, indicating that genetic regulatory mechanisms affect aging and life span. (Top adapted from Hekimi and Guarente 2003; middle reproduced, with permission, from Yi, Seroude, and Benzer 1998. Copyright © 1998 AAAS; bottom adapted from Brown-Borg et al. 1996.)

or environmental strategies for extending life span or health span (the period during which one remains generally healthy).

To date, the best-validated environmental strategy for extending life span (in organisms ranging from yeast to worms to primates) is caloric restriction. It appears that caloric restriction acts through genes in the insulin pathway mentioned above and may involve a set of enzymes called *sirtuins*. The sirtuins are activated by the compound *resveratrol*, originally isolated from red wine. Resveratrol, in turn, retards some aspects of aging, including cognitive decline, when administered to mice. While it is unlikely that resveratrol will serve as a fountain of youth in humans, it nevertheless exemplifies the new chemistries that are currently under consideration. These chemical strategies use model organisms to explore not only the positive factors that lead to aging but also the constraints that prevent model organisms, and presumably humans, from remaining generally healthy throughout their life span.

Cognitive Decline Is Significant and Debilitating in a Substantial Fraction of the Elderly

In most people, age-related cognitive changes do not seriously compromise the quality of life. In some elderly people, however, cognitive decline reaches a level that can be viewed as pathological. At the lower end of the abnormal range is a constellation of changes known as mild cognitive impairment (MCI). This syndrome is characterized by memory loss with or without other cognitive impairments that go beyond what is seen in normal aging. Individuals with MCI may be able to carry out most activities of daily living, although the impairments are noticeable to others and often influence the ability of the affected person to carry out certain activities that are important or pleasurable to them, such as managing finances or playing word games.

Importantly, MCI is a syndrome, not a diagnosis. Many underlying problems such as depression, overmedication, strokes, and neurodegenerative diseases can contribute to MCI. Approximately half of individuals with MCI have underlying Alzheimer disease, and more than 90% of this group will progress to full-blown dementia within 5 years from the time of diagnosis of MCI (Figure 64–7). As discussed below, there are now biomarkers that can suggest the presence of underlying Alzheimer disease pathology. As yet, however, there are no good biomarkers for predicting progression to dementia in people with MCI resulting from diseases other than Alzheimer.

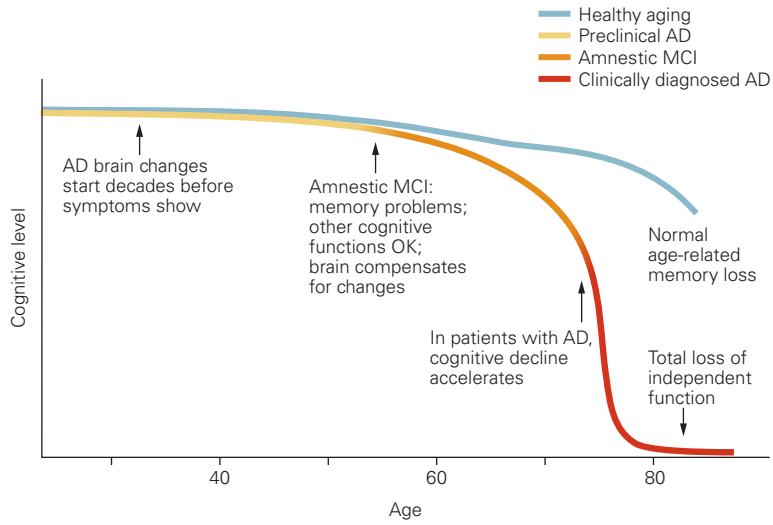

Figure 64–7 Cognitive performance can vary widely with age. The chart shows current thinking about the etiology of Alzheimer disease (**AD**). This gradual process, which results from a combination of biological, genetic, environmental, and lifestyle factors, eventually sets some people on a course to mild cognitive impairment (**MCI**) and then dementia. Other people, with a different genetic makeup or a different combination of factors over a lifetime, continue on a course of healthy cognitive aging. (From the National Institute on Aging: http://www.nia.nih.gov/alzheimers/publication/part-2-what-happens-brain-ad/changing-brain-ad.)

Like MCI, dementia is also a syndrome that involves progressive impairment of memory as well as other cognitive abilities such as language, problem solving, judgment, calculation, or attention. It is associated with a variety of diseases. The most common is Alzheimer disease, as discussed below. The second most common cause in the elderly is cerebrovascular disease, particularly strokes that lead to focal ischemia and consequent infarction in the brain.

Large lesions in the cortex are often associated with language disturbances (aphasia), hemiparesis, or neglect syndromes, depending on which portions of the brain are compromised. Small infarctions in white matter or deeper structures of the brain, termed *lacunes*, also occur as a consequence of hypertension and diabetes. In small numbers, these infarctions may be asymptomatic, or they may contribute to what appears to be normal age-associated cognitive decline or certain cases of MCI. As vascular lesions increase in number and size, however, their effects accumulate, and eventually, they can lead to dementia.

Numerous other conditions can lead to dementia, including Parkinson disease, Lewy body dementia, frontotemporal dementia, alcoholism, drug intoxications, infections such as HIV and syphilis, brain tumors, subdural hematomas, repeated brain trauma, vitamin deficiencies (notably lack of vitamin B_{12}), thyroid disease, and a variety of other metabolic disorders. Repeated brain trauma can result in what is termed chronic traumatic encephalopathy (CTE). Numerous cases of CTE in American professional athletes have recently been reported. In some patients, schizophrenia or depression may mimic a dementia syndrome. (Emil Kraepelin chose the term "dementia praecox" to describe the cognitive disease that we now call schizophrenia.) Because some dementias can be treated, it is important for the physician to probe differential diagnoses of dementia based on clinical history, physical examinations, and laboratory studies.

Alzheimer Disease Is the Most Common Cause of Dementia

In 1901, Alois Alzheimer examined a middle-aged woman who had developed a progressive loss of cognitive abilities. Her memory became increasingly impaired. She could no longer orient herself, even in her own home, and she hid objects in her apartment. At times, she believed that people intended to murder her.

She was institutionalized in a psychiatric hospital and died approximately 5 years after she was first seen by Dr. Alzheimer. After death, Alzheimer performed an autopsy that revealed specific alterations in the cerebral cortex, described below. The constellation of behavioral symptoms and physical alterations was subsequently given the name Alzheimer disease (AD).

This case caught Alzheimer's attention because it occurred in middle age; the initial clinical manifestations of AD (usually memory loss and decreased executive function) most commonly appear after age 65. The prevalence of AD at age 70 is about 2%, whereas after age 80, it is greater than 20%. Early-onset cases before age 65 are often familial (autosomal dominant AD), and gene mutations have been discovered in many of these patients, as we shall discuss below. In fact, new genetic tests on preserved brain samples from Alzheimer's first case recently showed that her disease resulted

from a mutation of a gene called presenilin-1, the most common cause of familial or dominantly inherited AD. Late-onset AD (onset at age 65 or greater) is more often sporadic, implying that there is no single causative gene as occurs in dominantly inherited AD. Nonetheless, it is clear that genetics contribute greatly to risk for even late-onset AD more likely through variants that affect susceptibility, along with environmental and other contributing factors that are just now being uncovered.

Both early-onset and late-onset varieties of AD usually present with a selective defect in episodic memory and executive function. At first, language, strength, reflexes, and sensory abilities and motor skills are nearly normal. Gradually, however, memory and attention are lost, along with cognitive abilities such as problem solving, language, calculation, and visuospatial perception. Unsurprisingly, these cognitive losses lead to behavioral alterations, and some patients develop psychotic symptoms such as hallucinations and delusions. All patients suffer progressive impairment of mental functions and activities of daily living; in the late stages, they become mute, incontinent, and bedridden.

Alzheimer disease affects approximately one-eighth of people older than 65 years. More than 5 million people in the United States now suffer from dementia due to AD. Because the elderly population is increasing rapidly, the population at risk for AD is growing rapidly. During the next 25 years, the number of people with AD in the United States is expected to triple, as will the cost of caring for patients no longer able to care for themselves. Thus, AD is one of society's major public health problems.

The Brain in Alzheimer Disease Is Altered by Atrophy, Amyloid Plaques, and Neurofibrillary Tangles

Three categories of brain abnormalities are found in AD. First, because of neuronal and synaptic loss, the brain is atrophied, with narrowed gyri, widened sulci, reduced brain weight, and enlarged ventricles (Figure 64–8). These changes are also seen in milder forms in cognitively intact elderly people who die from other causes. Thus, AD is a neurodegenerative disease.

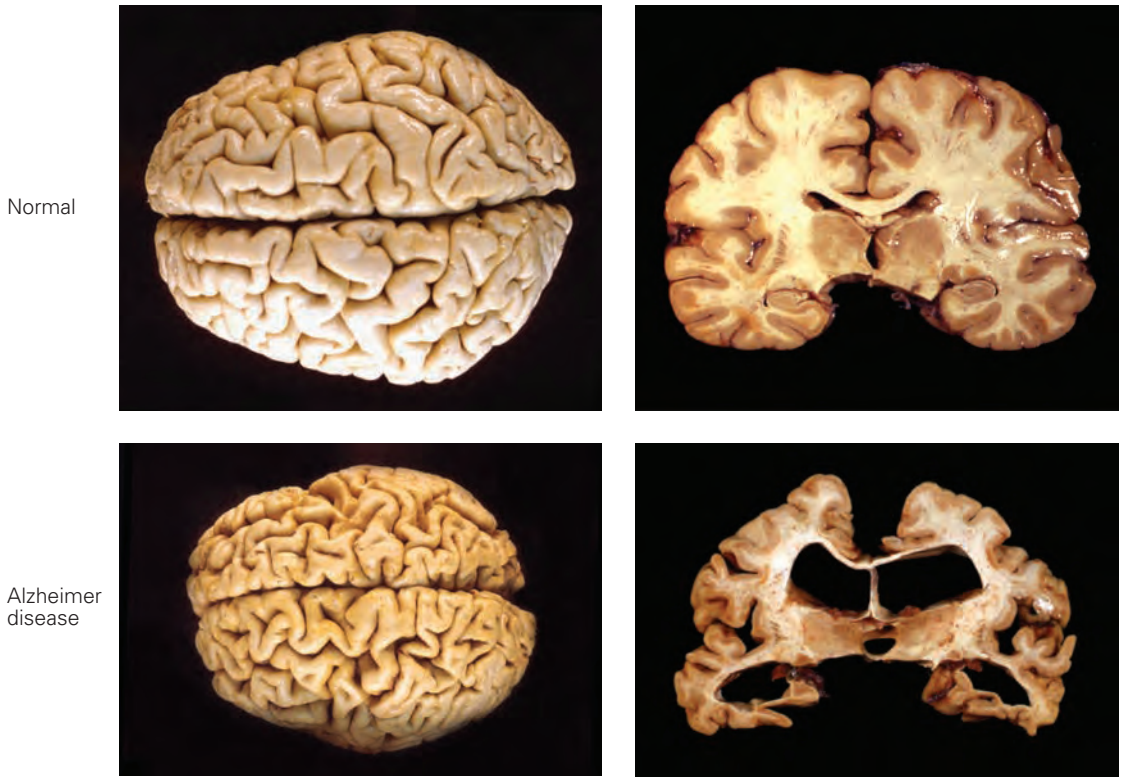

Figure 64–8 Overt pathological changes in the brain of individuals with Alzheimer disease. When compared to age-matched normal brains, the brain of an Alzheimer patient displays marked shrinkage and ventricular enlargement. (See also Figure 64–3.) (Whole brain photos reproduced, with permission, from University of Alabama at Birmingham Department of Pathology © PEIR Digital Library [http://peir.net]; brain slice photos reproduced, with permission, from A.C. McKee.)

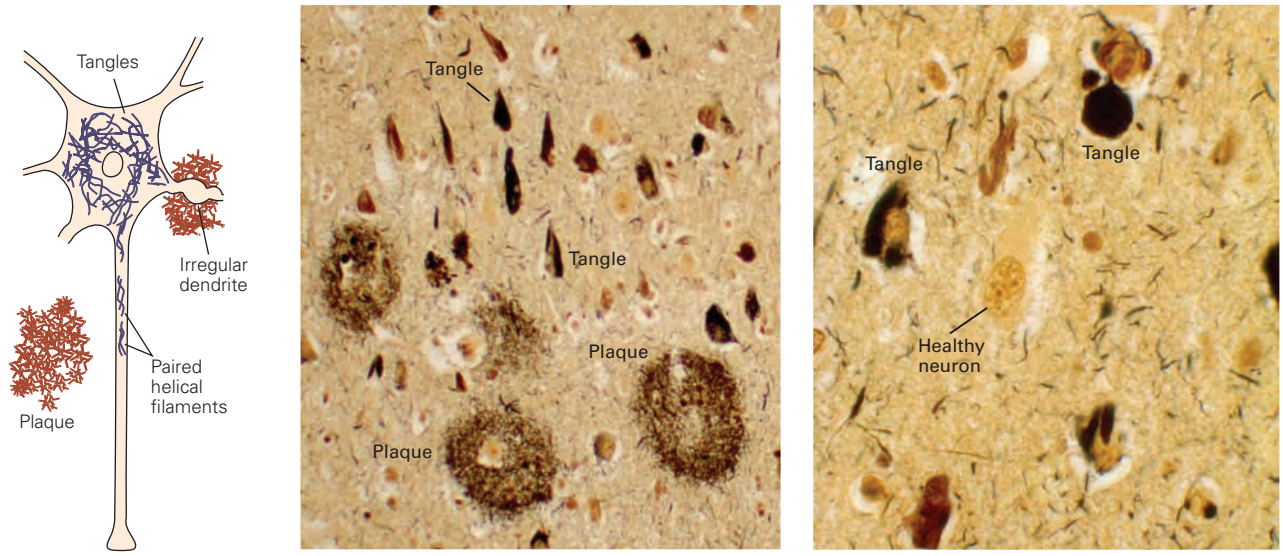

Figure 64–9 Plaques and tangles in the Alzheimer brain. A section of cerebral cortex from the brain of an individual with severe Alzheimer disease shows characteristic plaques and neurofibrillary tangles. (Images reproduced, with permission, from James Goldman.)

Left: The diagram shows a neuron containing neurofibrillary tangles in the cell body and axon. Amyloid plaques are shown in the neuropil; one of them surrounds a dendrite, which displays an altered, swollen shape. Tangles, composed of bundles of paired helical filaments, are comprised of abnormal polymers of hyperphosphorylated tau protein, and amyloid plaques are extracellular deposits of polymers of the amyloid-β (A4) peptide.

Middle: A section of neocortex from a patient with Alzheimer disease treated with a silver stain shows neuronal cell bodies containing neurofibrillary tangles and neuropil containing amyloid plaques.

Right: A higher magnification of the cortex shows neurofibrillary tangles in neuronal cell bodies and a healthy neuron without a tangle. Many thin silver-positive cell processes are seen in the neuropil.

Second, the brains of AD patients contain extracellular plaques composed predominantly of an aggregated form of a peptide called amyloid-β, or Aβ, which is cleaved from a normally produced protein. Aggregates of Aβ are called amyloid plaques. Much of the Aβ in plaques is fibrillar; aggregates of Aβ appear in a β-pleated sheet conformation along with other proteins that co-aggregate with Aβ (Figure 64–9). Amyloid can be detected when stained with dyes such as Congo red, and is refractive when viewed in polarized light or when stained with thioflavin S and viewed with fluorescence optics. The extracellular deposits of amyloid are surrounded by swollen axons and dendrites (neuritic dystrophy). These neuronal processes in turn are surrounded by the cell processes of activated astrocytes and microglia (inflammatory cells). Aβ can also form amyloid deposits in the walls of arterioles in the brain, producing what is known as cerebral amyloid angiopathy. This occurs to varying extents in up to 90% of patients who develop AD, but it can also occur independently of AD. Cerebral amyloid angiopathy can lead to ischemic stroke, and it is a common cause of hemorrhagic stroke in the elderly.

Third, many neurons that are affected by Alzheimer pathology but still alive have cytoskeletal abnormalities, the most dramatic of which is the accumulation of neurofibrillary tangles and neuropil threads (Figure 64–9). The tangles are filamentous inclusions in the cell bodies and dendrites that contain paired helical filaments and 15-nm straight filaments. These filaments are made up of an aggregated form of the normal microtubule-associated protein tau.

In AD, tangles do not occur uniformly throughout the brain, but rather affect specific regions. The entorhinal cortex, the hippocampus, parts of the neocortex, and the nucleus basalis are especially vulnerable (Figure 64–10). Alterations in the entorhinal cortex and hippocampus likely underlie the problems with episodic memory that are among the first symptoms of AD. Abnormalities in the basal forebrain cholinergic systems may contribute to cognitive difficulties and attention deficits. These cholinergic abnormalities contrast with those in frontostriatal circuits that correlate with age-related cognitive decline in normal subjects. The combination of anatomical differences, pathological changes, widespread neuronal death, and genetic

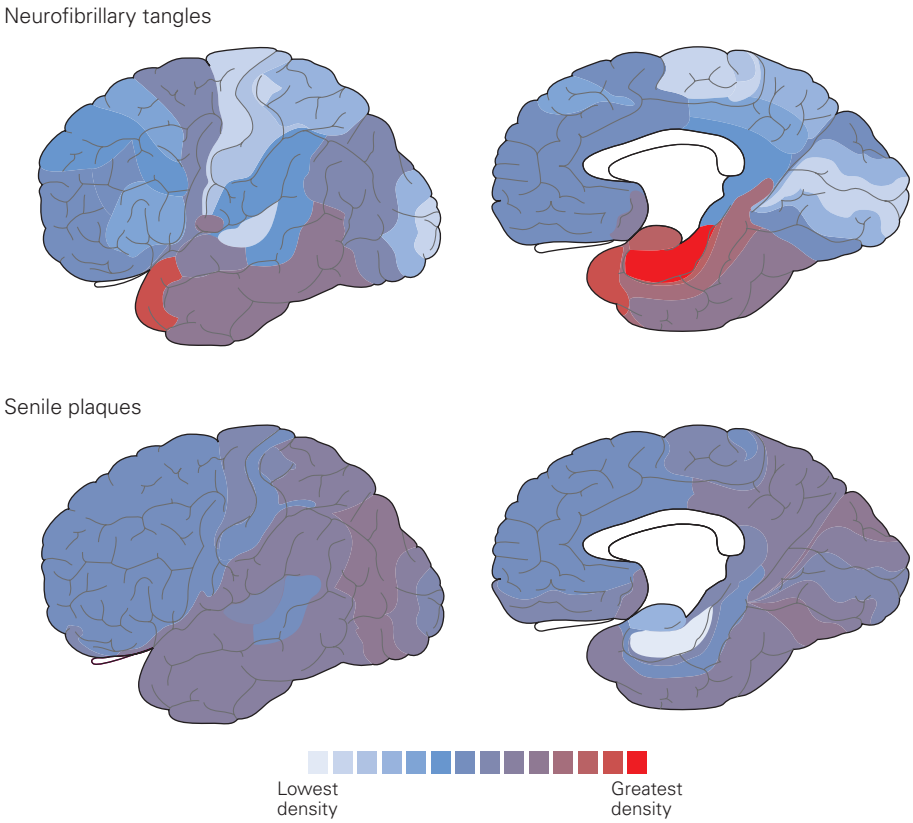

Figure 64–10 Neurofibrillary tangles and senile plaques are concentrated in different regions of the Alzheimer brain. (Adapted, with permission, from Arnold et al. 1991. Copyright © 1991, Oxford University Press.)

mutations (see below) argue against the idea, once prevalent, that AD is an aberrant form of normal aging processes.

Amyloid Plaques Contain Toxic Peptides That Contribute to Alzheimer Pathology

The main constituent of amyloid plaques, aggregates of Aβ peptides, were first isolated in the early 1980s by centrifugation, based on their low solubility. The predominant peptides were 40 and 42 amino acids in length (the 40 residues plus two additional amino acids at the carboxy terminal end). Biochemical studies showed that the Aβ42 peptide nucleates more rapidly than Aβ40 into amyloid fibrils.

Considerable experimental evidence indicates that Aβ42 drives the initial aggregation, although Aβ40 also accumulates to a significant extent, especially in cerebral amyloid angiopathy. For neurons in culture, the forms of the Aβ42 peptide that are larger than a monomer are generally more toxic than aggregated forms of Aβ40. These results implicate Aβ42 as a key driver of amyloid formation as well as Aβ toxicity.

Once it was discovered that Aβ peptides 38 to 43 amino acids in length are formed by cleavage of a precursor protein, researchers set out to isolate the precursor. The precursor was found in the mid-1980s, molecularly cloned, and named the *amyloid precursor protein* (APP). It is a large transmembrane glycoprotein that is present in all types of cells but is expressed at its highest levels in neurons. The normal functions of APP in the brain are not understood.

How is APP processed to form Aβ peptides? The answer has turned out to be complex. Three enzymes, α-, β-, and γ-secretase, cut APP into pieces. The β- and γ-secretases cleave APP to generate soluble extracellular fragments that are released into the interstitial fluid. These are the Aβ peptides, which include part of the transmembrane segment of APP (Figure 64–11). The cleavage by γ-secretase is unusual in that it occurs in a membrane-spanning portion of APP, a region long thought to be immune from hydrolysis because it is surrounded by lipids rather than water. Cleavage by α-secretase in the middle of the Aβ sequence prevents the formation of Aβ peptides.

The enzymes that account for α-, β-, and γ-secretases have been isolated and characterized. The enzyme α-secretase is a member of a large family of extracellular proteases called ADAM (a disintegrin and metalloproteinase) that are responsible

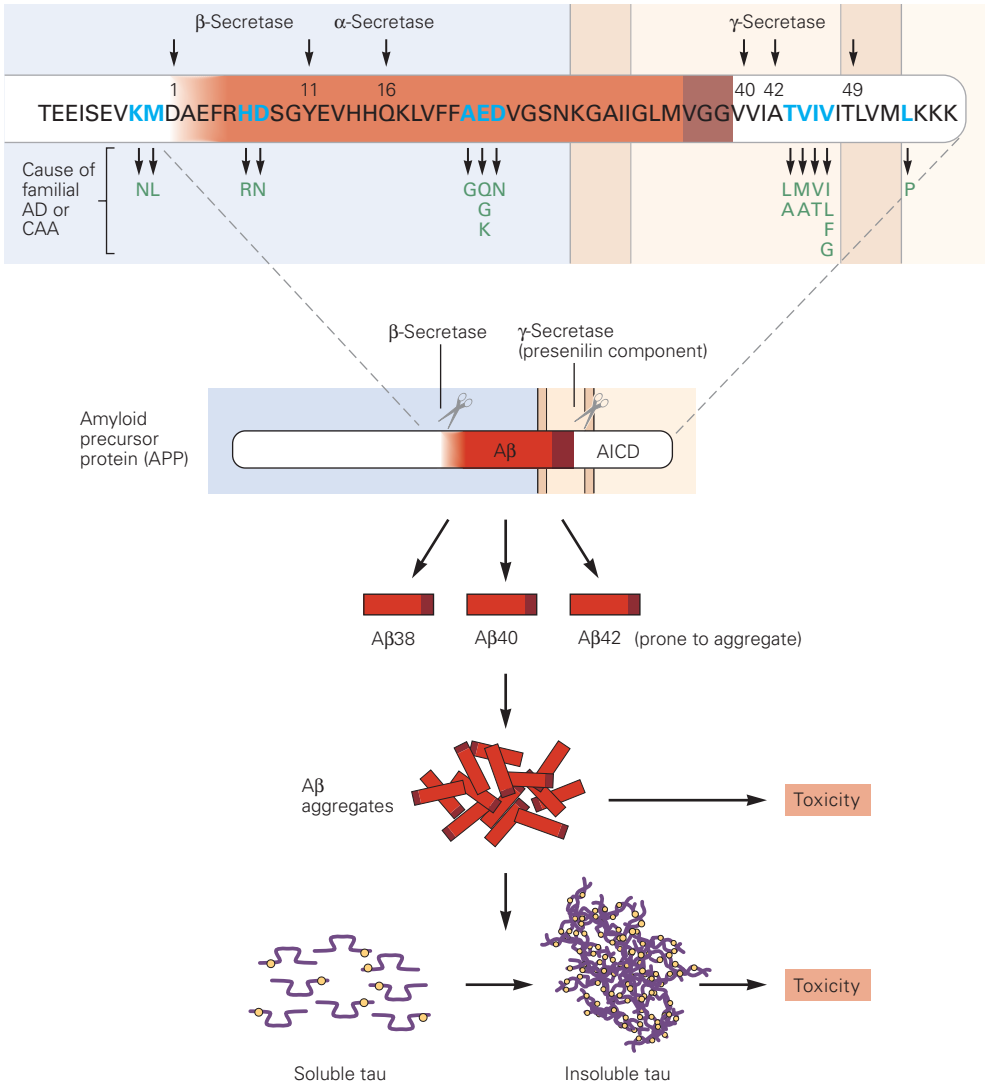

Figure 64–11 Processing of the amyloid precursor protein, generation of the Aβ peptide, and downstream effects on tau aggregation. The Aβ peptide is produced from the amyloid precursor protein (**APP**), a transmembrane protein, via cleavage by two enzymes, β-secretase and γ-secretase. (Cleavage by α-secretase prevents Aβ production.) Presenilin is the active enzymatic component of the γ-secretase complex and cleaves APP at several sites within the membrane to produce Aβ peptides of different lengths such as Aβ38, Aβ40, and Aβ42. Several mutations in APP that are just outside of the Aβ region or within the coding sequence of Aβ cause forms of autosomal dominant Alzheimer disease (**AD**). The amino acids (**blue**) in the APP/Aβ amino acid sequence represent the normal amino acids in APP; amino acids in **green** (below the normal sequence) are those that cause familial AD or cerebral amyloid angiopathy (**CAA**). Aβ is predominantly produced from APP within endosomes. A variety of molecules and synaptic activity regulate Aβ levels. There is evidence that Aβ aggregation is influenced by the Aβ-binding molecules ApoE and clusterin, which likely interact in the extracellular space of the brain. A variety of molecules and processes affect Aβ clearance from the interstitial fluid (ISF) that is present in the extracellular space of the brain, including neprilysin and insulin-degrading enzyme (IDE), as well as cerebral spinal fluid and interstitial fluid bulk flow. LRP1 and RAGE (receptor for advanced glycation end products) appear to influence Aβ transport across the blood–brain barrier. The concentration and type of Aβ influence aggregation (Aβ42 is more fibrillogenic). Once it aggregates into oligomers and fibrils, it can be directly toxic to cells, induce inflammation, and exacerbate the conversion of soluble tau to aggregated tau through mechanisms that remain unclear. In addition to Aβ, a variety of factors influence tau aggregation and toxicity, including tau levels, sequence, and phosphorylation state. (Abbreviation: **AICD**, APP intracellular domain.)

for degrading many components of the extracellular matrix. β-Secretase, called BACE1 (β-site APP cleaving enzyme 1), is a transmembrane protein in central neurons that is concentrated in synapses. Brain cells derived from mutant mice lacking BACE1 do not produce Aβ peptides, proving that BACE1 is indeed the neuronal β-secretase. γ-Secretase, the most complicated of the three, is actually a multiprotein complex that cleaves several different transmembrane proteins. As would be expected, given its peculiar ability to act within the membrane, γ-secretase itself includes several transmembrane proteins. Two of these are called presenilin-1 and presenilin-2, reflecting their association with AD. Other components of the complex include the transmembrane proteins nicastrin, Aph-1, and Pen-2.

Although the biochemical properties of Aβ and APP are interesting, the critical question is whether they have a part in the debilitating symptoms of AD. The disease might be caused by Aβ accumulation, but Aβ might itself be a result of another pathological process or even be an innocuous correlate. Genetic evidence in humans and experimental animals has been critical in demonstrating that APP and, specifically, Aβ play a central role in AD.

The first clue came from the observation that the APP gene lies on chromosome 21, which is present in three copies rather than the normal two in people with Down syndrome (also known as trisomy 21). All people with Down syndrome who live to middle age develop AD pathology and dementia, with onset around 50 years. This association is consistent with the idea that APP predisposes to AD by overproducing APP and Aβ by 50% throughout life. Nevertheless, copies of many genes are present in three copies in individuals with trisomy 21, and initially, it was not clear that triplication of APP in Down syndrome was responsible for AD in this population. Subsequently, rare families were found in which both AD and cerebral amyloid angiopathy developed in the absence of Down syndrome due to duplication of just the APP locus on human chromosome 21. This is strong evidence that overexpression of APP alone is enough to lead to AD and cerebral amyloid angiopathy.

More direct genetic evidence came from analysis of the rare patients with dominantly inherited AD, in whom the onset of symptoms is usually between 30 and 50 years of age. In the late 1980s, several research groups began using methods of molecular cloning to identify the genes mutated in dominantly inherited AD. Remarkably, the first three genes identified were those encoding the proteins APP, presenilin-1, and presenilin-2 (Figure 64–12). Many different mutations in these three genes have been found, and the majority influence cleavage of APP, increasing the production of Aβ peptides or specifically the proportion of the more aggregation-prone Aβ42 species. Interestingly, some APP mutations occur within the Aβ sequence itself and do not affect Aβ production but do affect Aβ aggregation and clearance from the brain.

Some APP mutations are amino acid substitutions flanking the Aβ region. Cells that express a double mutation at the β-secretase cleavage site (the so-called Swedish mutation), which is required for Aβ formation, secrete several-fold more Aβ peptide than cells expressing wild type APP. Interestingly, another mutation in APP adjacent to the β-secretase site was recently discovered. This mutation appears to protect against AD by decreasing Aβ production. Yet another APP mutation causes γ-secretase to generate a greater proportion of longer Aβ species, such as Aβ42, in relation to shorter species such as Aβ40. Likewise, in most presenilin mutants the mutant γ-secretase has higher than normal activity or generates peptides with an increased ratio of Aβ42 to Aβ40.

These human genetic studies offer compelling evidence that (1) cleavage of APP to generate Aβ and the propensity of Aβ to aggregate play key instigating roles in some cases of dominantly inherited early-onset AD and (2) less Aβ production decreases the risk for late-onset AD. Genetic studies in mice have also strengthened the case that APP cleavage and specifically Aβ aggregation contribute to AD. Transgenic expression or knock-in of mutant APP forms identical to those found in autosomal dominant AD leads to the appearance of amyloid plaques in the hippocampus and cortex, dystrophic neurites in proximity to Aβ deposits, decreased density of synaptic terminals around amyloid plaques, and impairments in synaptic transmission. Several mouse models develop functional abnormalities such as deficits in spatial and episodic-like memory. Alterations are more severe in transgenic mice that express altered forms of both APP and presenilin-1. It is important to note that although these mice do not develop tau aggregation or neurofibrillary tangles, lesions believed to be important in the cognitive decline seen in AD, they remain invaluable models for addressing the mechanistic role of Aβ and related pathology in the pathogenesis of AD, especially the role of Aβ, and for testing potential therapies.

Given the strong evidence that APP cleavage is involved in the pathogenesis of AD, the next question is: How does the accumulation of cleavage products contribute to symptoms and ultimately dementia? There are three sets of cleavage products: the secreted extracellular region (ectodomain), the Aβ peptide, and

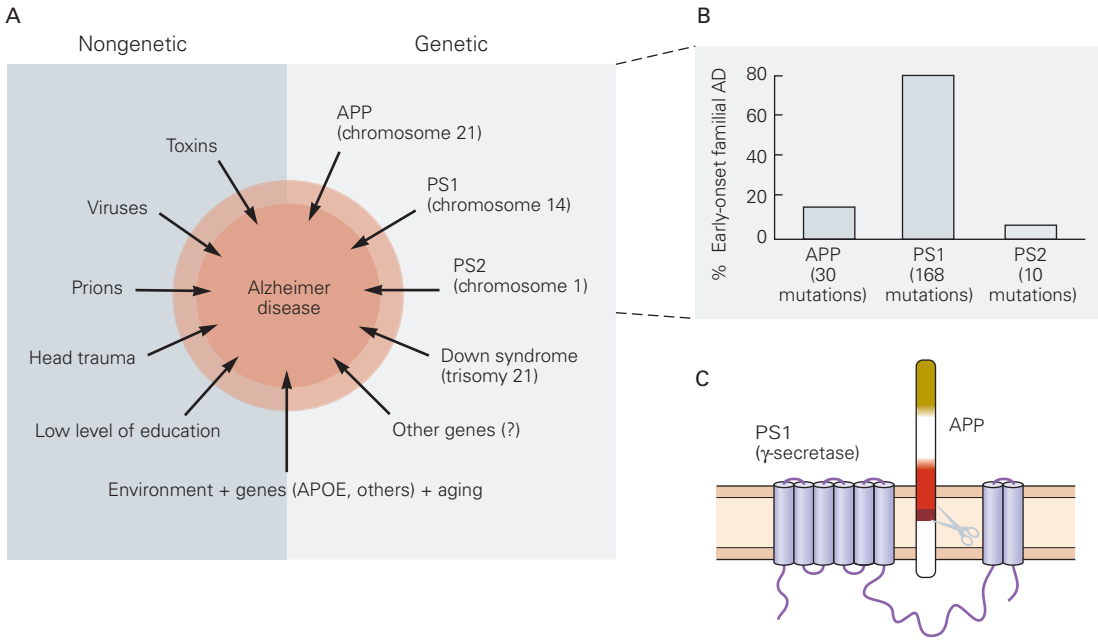

Figure 64–12 Environmental and genetic factors play a role in Alzheimer disease.

B. Specific genes involved in early-onset Alzheimer disease (**AD**).

C. Presenilin-1 (a component of the gamma secretase enzyme complex) is associated with the APP protein within the plasma membrane.

cytoplasmic fragment. Although all three fragments can have deleterious effects on neurons in experimental animals, the Aβ peptides have received the most attention, and evidence for their involvement is strongest. There is evidence that different aggregated forms of Aβ such as oligomers, protofibrils, and fibrils can lead to synaptic and neuronal damage that might contribute to AD.

Neurofibrillary Tangles Contain Microtubule-Associated Proteins

Until around 2005, most research on the molecular and cellular basis of AD focused on Aβ peptides and amyloid plaques, but tau aggregation in neurofibrillary tangles appears to play a key role in the progression of AD (Figure 64–9). Molecular analysis revealed that these abnormal inclusions in cell bodies and proximal dendrites contain aggregates of hyperphosphorylated isoforms of tau, a microtubule-binding protein that is normally soluble (Figure 64–13). The tau protein plays a key role in intracellular transport, particularly in axons, by binding to and stabilizing microtubules. Impairments in axonal transport compromise synaptic stability and trophic support. While the mechanism by which aggregation and hyperphosphorylation of tau lead to toxicity is still not understood, tau accumulation is clearly associated with neuronal degeneration.

Although tangles are a defining feature of AD, it was initially unclear what role tangles and hyperphosphorylated forms of tau play in the pathogenesis of the disease. Whereas mutations of APP and presenilin genes can lead to AD, no mutations of the tau gene have been found in familial AD. Nevertheless, there is now a great deal of evidence indicating that tau aggregation is a key factor in the neurodegeneration that occurs in AD.

First, filamentous deposits of hyperphosphorylated tau are seen in a variety of neurodegenerative disorders, including AD, forms of frontotemporal dementia, progressive supranuclear palsy, corticobasal degeneration, and CTE. Second, mutations in the tau gene have been found to underlie another form of autosomal dominant neurodegenerative disease: frontotemporal dementia with Parkinson disease type 17 (FTPD17). These patients develop tau aggregation together with brain atrophy in specific brain regions in the absence of Aβ deposition. Third, progressive symptoms of AD correlate much better with the number and distribution of tangles than with the amyloid plaques

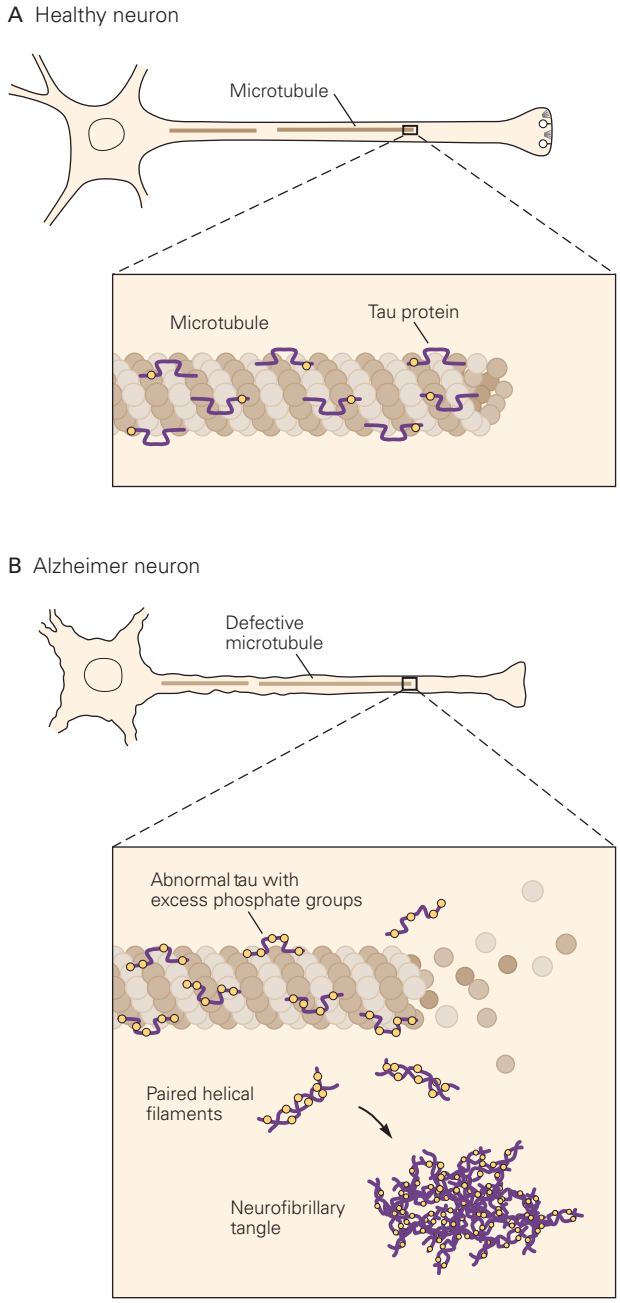

Figure 64–13 Formulation of neurofibrillary tangles.

A. In healthy neurons, tau protein associates with normal microtubules but not as paired helical filaments, and contributes to the structural integrity of the neuron.

B. In a diseased neuron, the tau protein becomes hyperphosphorylated and loses its association with normal microtubules, which begin to disassemble. It then forms paired helical filaments, which become sequestered in neurofibrillary tangles.

seen in autopsy. For example, tangles are usually first evident in neurons of the entorhinal cortex and hippocampus, the likely site of early memory disturbance, before plaques appear in this area (see Figure 64–16).

For many years, controversy raged between those who believe that Aβ is the main causal agent of AD and those who believe that tau-rich tangles play a major role. These partisans have been called "Baptists" and "Tauists," respectively. Baptists pointed to the fact that during the development of AD pathology, which begins about 15 years before symptom onset, accumulation of neocortical Aβ precedes the development of neocortical tau pathology. More recent evidence suggests, however, that Aβ accumulation appears to somehow drive tau aggregation and spreading in the brain. Thus, Aβ aggregation probably instigates the disease and tau aggregation and spreading likely contribute in a major way to neurodegeneration. For example, transgenic mice that express both mutant APP and mutant tau develop much worse tau pathology.

There appears to be interplay between plaques and tangles. Injection of Aβ42 into specific brain regions of transgenic mice that express a mutant tau protein increases the number of tangles in nearby neurons. Further, a manipulation that reduces the number and size of plaques leads to a decrease in levels of hyperphosphorylated tau. Importantly, recent experiments suggest that Aβ deposition in some way promotes spreading of tau aggregates from one brain region to another, possibly transsynaptically in a prion-like fashion. The details of this process remain to be worked out and are likely to be extremely important.

There is now abundant evidence from cell culture and studies in animal models that several proteins that aggregate in neurodegenerative diseases, including tau and synuclein, can spread from cell to cell in a prion-like manner. This is particularly important as a potential disease mechanism. For example, if the cell-to-cell spreading of misfolded proteins occurs in the extracellular space, this process might be interrupted with antibodies directed against the appropriate disease-associated protein. In fact, this now serves as the basis of several clinical trials in humans targeting tau and synuclein.

Risk Factors for Alzheimer Disease Have Been Identified

Very few individuals develop AD because they bear autosomal dominant mutant alleles of the APP or presenilin genes, and these are generally of the early-onset variety. Hardly any cases of late-onset AD are due to mutations in APP or presenilin genes. Can we, then, predict AD in such individuals?

The major risk factor is age. The disease is present in a vanishingly small fraction of people younger than age 60 (many of those being autosomal dominant cases), 1% to 3% of those between ages 60 and 70, 3% to 12% of those between ages 70 and 80, and 25% to 40% of those older than age 85. Knowing that elderly people are prime candidates for AD is of little therapeutic use, however, because modern medicine can do nothing to slow the passage of time. Therefore, there has been intense interest in other factors that affect the incidence of AD.

To date, the most significant genetic risk factors discovered for late-onset AD are the alleles of the gene *APOE*. The ApoE protein is an apolipoprotein. In the blood, it plays an important role in plasma cholesterol metabolism. It is also expressed at high levels in the brain, most prominently by astrocytes and to some extent by microglia. In the brain, where its normal function has not been clarified, it is secreted as a component of high density-like lipoproteins. In humans, there are three alleles of the *APOE* gene, *APOE2*, *APOE3*, and *APOE4*, which differ from each other by at most two amino acids. People with the *APOE4* allele are at risk for AD, whereas those with the *APOE2* allele are protected against AD relative to people who have the most common *APOE3/APOE3* genotype. The *APOE4* allele is present in about 25% of the general population but present in as many as 60% of those with AD. One copy of the *APOE4* allele increases the risk of AD by about 3.7-fold, and two copies by about 12-fold, relative to someone who is *ApoE3/E3* (Figure 64–14). One copy of the *APOE2* allele decreases the risk for AD by about 40% relative to being *APOE3/APOE3*.

The mechanism by which *APOE4* predisposes to AD and *APOE2* protects against AD is uncertain, but ApoE4 clearly promotes Aβ aggregation by diminishing Aβ clearance and promoting fibrillization (ApoE4 > ApoE3 > ApoE2). It may also act through additional mechanisms such as influencing tau, the innate immune system, cholesterol metabolism, or synaptic plasticity, although these pathways remain to be worked out.

A number of other genes and genetic loci influence risk for late-onset AD. Some are common variants that alter risk only slightly, whereas other rarer variants increase risk to a greater extent (Figure 64–14). For example, relatively rare mutations in the gene *TREM2* double or triple the risk for AD, similar to having one copy of the *APOE4* allele. This is interesting because *TREM2* as well as another gene associated with risk

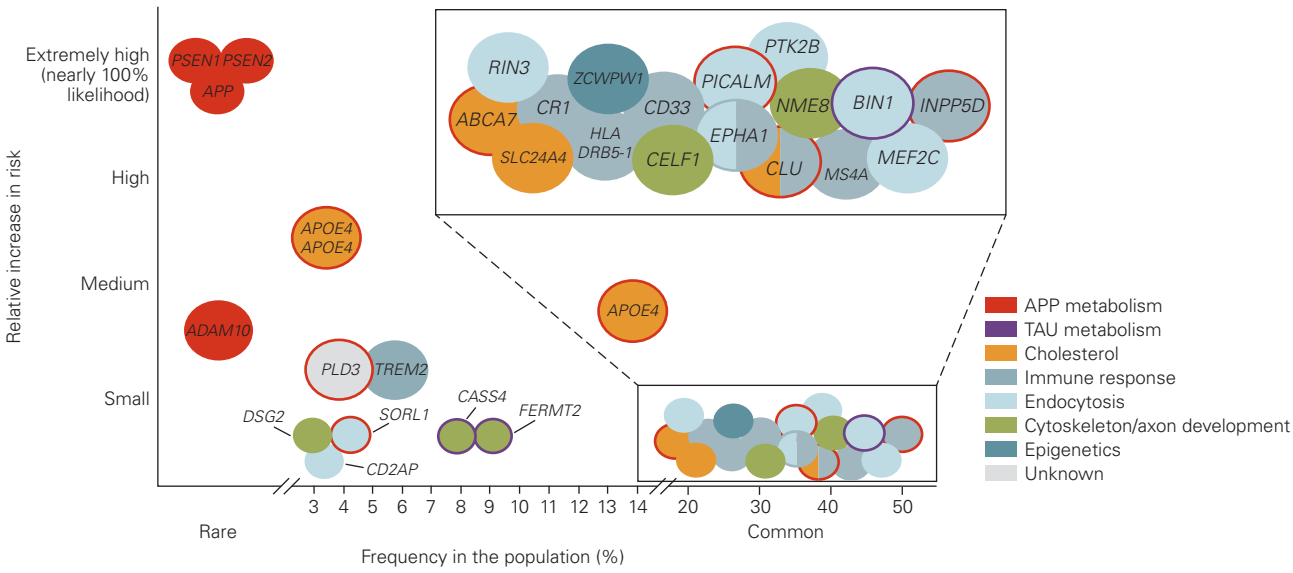

Figure 64–14 The risk for Alzheimer disease due to rare and common genetic variants. Data are from genome-wide association studies (GWAS). Mutations in the three genes that cause early-onset familial Alzheimer disease (*PSEN1*, *PSEN2*, and *APP*) are rare but result in Alzheimer disease in virtually 100% of people with these mutations if they live to middle age. There have been a number of common genetic changes found located in regions around or in genes that are relatively frequent in the population (eg, *ABCA7*, *CLU*, *BIN1*) that affect risk for Alzheimer disease but to a very small degree. The one common and strong genetic risk factor for Alzheimer disease that is present in about 20% to 25% of the population (allele frequency ~15%) is *APOE4*. One copy of *APOE4* increases risk approximately 3.7-fold and two copies increase risk approximately 12-fold relative to people who are homozygous for *APOE3*. (Adapted, with permission, from Karch and Goate 2015.)

for AD, *CD33*, are expressed only in microglia. Along with other emerging cellular and animal model data, this finding suggests that the innate immune system is involved in AD pathogenesis. A number of other rare variants that increase risk to varying degrees are under investigation. It seems likely that these developments will ultimately result in a more personalized clinical approach to determining risk for AD, especially as treatments for the disease emerge.

Alzheimer Disease Can Now Be Diagnosed Well but Available Treatments Are Unsatisfactory

Diagnosing AD at its earliest stages in the absence of biomarkers can be challenging, as its initial symptoms can be similar to those of normal age-related cognitive decline or of other related diseases. Nevertheless, diagnosis of mild to moderate dementia due to AD is usually fairly accurate. In fact, during the past few decades, the ability to accurately diagnose the disease has improved, largely because of three factors.

First, protocols for physical, neurological, and neuropsychological examination have become more sophisticated and standardized. Second, increased knowledge of the structural changes revealed by magnetic resonance imaging (MRI) have helped in diagnosing AD at early stages. For example, it is now possible to predict, with approximately 80% accuracy, which patients with MCI will develop AD based on the cortical thinning and ventricular enlargement visible by MRI. These imaging and diagnostic methods also assist in distinguishing dementia syndromes from each other and relating structural to functional defects. For example, patients with the disease known as *behavioral variant of frontotemporal dementia* experience personality changes early on, and MRI at that stage reveals atrophy of the frontal and/or temporal lobes. Likewise, initial difficulties in AD usually center on memory and attention, and MRI reveals initial alterations in the medial temporal cortex and hippocampus.

Third, and perhaps most promising, amyloid plaques and neurofibrillary tangles can be visualized by positron emission tomography (PET) using compounds that avidly bind fibrillar forms of Aβ or aggregated forms of tau. The first of these, Pittsburgh compound B (PIB), binds with high affinity to fibrillar Aβ; its radioactive form, labeled with short-lived isotopes of carbon or fluorine, is readily detected by PET (Figure 64–15). The US Food and Drug Administration (FDA) has approved three amyloid imaging agents: florbetapir (Amyvid), flutemetamol (Vizamyl), and florbetaben (Neuraceq).

The availability of safe molecular markers of AD allows early stages of the disease to be identified before clinical symptoms are present. Of equal importance, it allows for improved selection of patients for clinical trials and keener selection of subjects for detailed analyses of normal aging. It is important to note that these changes can also be detected in the cerebrospinal fluid, where the level of Aβ42 drops when amyloid deposition is present and total tau and phosphorylated forms of tau increase with neurodegeneration and tau aggregation.

Of course, improved diagnosis of AD is most useful if treatments are available that can halt or slow its progression at an early stage. While we still do not

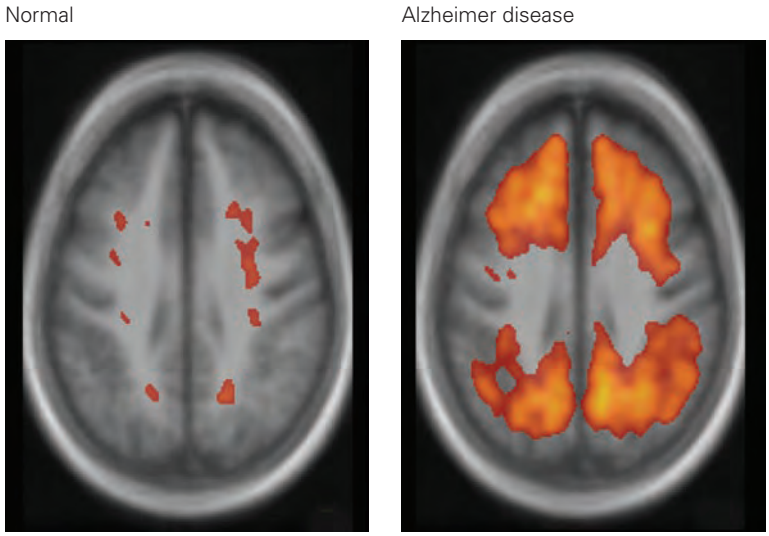

Figure 64–15 Positron emission tomography scans can visualize amyloid plaques in the living brain. The density of Aβ plaques is indicated by the red regions in these images made after administration of Pittsburgh compound B (PIB), a fluorescent analog of thioflavin T. (Images reproduced, with permission, from R. Buckner.)

have a treatment that delays the onset or slows the progression of AD, there is hope that we are not too far off from being able to mitigate symptoms. Although there is no definitive proof, there is good evidence that a variety of lifestyle factors decrease risk for AD. These include high levels of education, cognitive stimulation, staying socially engaged, regular exercise, not being overweight, and getting appropriate amounts of sleep. Present-day therapies focus on treating associated symptoms such as depression, agitation, sleep disorders, hallucinations, and delusions.

One of the principal therapeutic targets to date has been the cholinergic system in the basal forebrain, a region of the brain that is damaged in AD and that contributes to attention. Acetylcholinesterase inhibitors increase levels of acetylcholine by inhibiting its breakdown and represent one of the few drug classes approved by the FDA for treatment of AD. Another drug, the *N*-methyl-D-aspartate (NMDA) receptor antagonist memantine, also improves symptoms in individuals with mild to moderate dementia due to AD. It is believed that memantine's action modulates glutamate-mediated neurotransmission. Nevertheless, these drugs exert only a modest effect on cognitive functions and the activities of daily living.

Recent advances in our understanding of the cell-biological basis of AD have produced several promising new therapeutic targets, all of which are being explored intensively. One approach is to develop drugs that reduce or modulate the activity of the β- and γ-secretases that cleave APP to generate Aβ peptides and the associated soluble extracellular and intracellular fragments. In fact, decreasing either β- or γ-secretase levels in transgenic mice that overexpress mutant APP decreases Aβ deposition and, in some cases, functional abnormalities.

Accordingly, pharmaceutical companies have developed drugs that decrease or modulate levels of β- and γ-secretases in humans. An obstacle to this approach is that the secretases also act on substrates other than APP, so decreasing their levels can have deleterious side effects. This is especially true for γ-secretase, whose inhibition has led to toxicity in human trials for AD. There are now several β-secretase inhibitors in clinical trials for AD, and it is likely such drugs will also move into trials for what is called preclinical AD, when AD pathology is accumulating but there is no sign yet of cognitive decline (Figure 64–16). The goal of this therapy would be to delay or prevent the onset of cognitive decline and dementia.

Another approach is to decrease levels of Aβ through immunological means. Both immunization with Aβ, which leads to generation of antibodies to Aβ, and passive transfer of Aβ antibodies have been

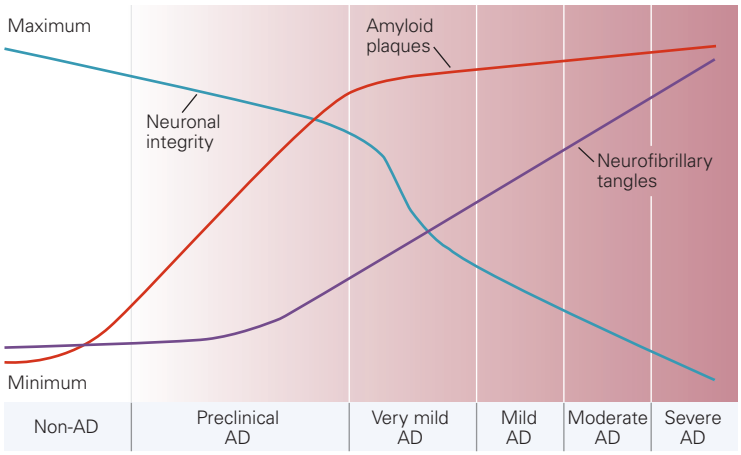

Figure 64–16 Relationship of biomarker changes to cognitive and clinical changes in Alzheimer disease (AD). In cognitively normal people who are going to develop AD dementia, one of the first physical signs is the initiation of Aβ aggregation in the brain in the form of amyloid plaques. While people are still cognitively normal, amyloid plaques continue to accumulate. At some point, about 5 years before any clear-cut cognitive decline, tau accumulation begins to increase in the neocortex, inflammation and oxidative stress increase, and brain network connections and metabolism begin to decline. Neuronal and synaptic loss and brain atrophy also begin. This period—when the patient remains cognitively normal but AD-type pathology is building up—is termed preclinical AD. Once there is enough neuronal and synaptic dysfunction as well as cell loss, very mild dementia and mild cognitive impairment become detectable. At that time, amyloid deposition has almost reached its peak. As dementia worsens to mild, moderate, and severe stages, neurofibrillary tangles form, and neuronal and synaptic dysfunction, inflammation, cell death, and brain atrophy worsen. (Adapted, with permission, from Perrin, Fagan, and Holtzman 2009.)

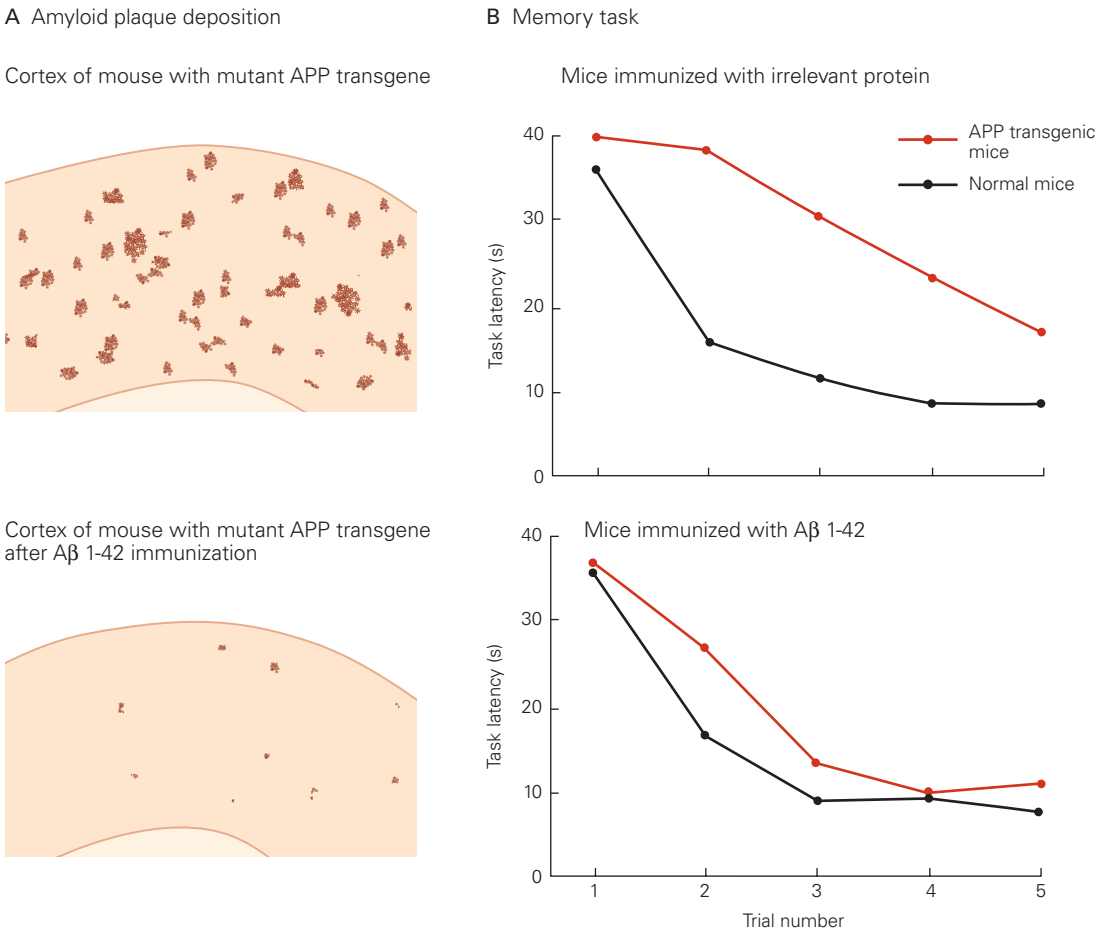

Figure 64–17 Immunization with antibodies to the Aβ peptide clears amyloid plaques and preserves cognitive performance in mice expressing the peptide. Mice that develop Aβ deposition in the form of amyloid plaques were immunized with the Aβ peptide. This led to production of antibodies against Aβ.

A. Comparison of amyloid plaque deposition in the cerebral cortex of mice overexpressing a mutant APP transgene (APP transgenic mice) that develop amyloid plaques. The mice that were immunized with the Aβ peptide have substantially reduced amyloid plaque deposition. (Adapted from Brody and Holtzman 2008.)

B. Cognitive performance (a memory test) in two groups of APP transgenic mice. One group was immunized with an irrelevant protein, the other with the Aβ peptide. The mice vaccinated with Aβ performed at levels close to normal animals, whereas mice immunized with the irrelevant protein showed severe impairment in memory. (Adapted, with permission, from Janus et al. 2000.)

tested in transgenic mouse models of AD. Both treatments have been shown to reduce levels of Aβ, Aβ toxicity, and plaques (Figure 64–17). The mechanisms of enhanced Aβ clearance are not completely clear. Serum antibodies likely serve as a "sink," resulting in Aβ peptides with low molecular weight being cleared more extensively from the brain into the circulation, thus changing the equilibrium of Aβ in different compartments and promoting removal of Aβ from the brain.

It is also clear that in the brain several anti-Aβ antibodies bind either soluble or fibrillar Aβ, or both. Those that bind to aggregated forms of Aβ can stimulate microglia-mediated phagocytosis to remove Aβ, although there is also plaque removal that is not dependent on microglial-mediated phagocytosis. Antibodies to soluble Aβ that enter the brain may decrease soluble Aβ toxicity. These findings suggest that immunotherapeutic strategies may be successful in AD patients, especially if they are given early enough in the disease course, prior to significant neuronal damage and loss. There are multiple human trials underway using active and passive immunotherapies against Aβ both in preclinical and mild AD.

In addition to targeting Aβ, clinical trials have also begun targeting tau. This is being done with active and passive immunization against tau as well as with small molecules that, in cell culture and animal models, can decrease tau aggregation. A number of studies in animal models have shown that certain anti-tau antibodies can decrease the amount of aggregated, hyperphosphorylated tau in the central nervous system and in some cases improve function. Although tau is predominantly a cytoplasmic protein, one of the reasons that anti-tau antibodies may be having an effect is that, as discussed above, tau aggregates may spread from cell to cell in the extracellular space in a prion-like fashion. It is in this space that an antibody may be able to interact with tau and block this process.

Highlights

1. It is only in the past 50 years that a large percentage of the population has lived into the eighth to tenth decades of life. With this increase, neuroscientists have been able to study changes in the brain that occur with normal aging as well as in individuals who develop age-related brain disorders.
2. Subtle changes in a variety of brain functions occur with age, including declines in speed of processing and memory storage and changes in sleep. The underlying basis for these changes is likely brain atrophy and loss of white matter integrity. In general, however, there is not a significant decrease in neuronal number that accounts for changes in brain function that occur with normal aging.
3. The changes in cognition that occur in normal aging are not disabling. When memory and often other areas of cognitive function decline more than is expected with age such that it is noticeable to others and mildly affects one's day-to-day life, this syndrome is called mild cognitive impairment (MCI).
4. MCI is not a disease, it is a syndrome. About 50% of individuals with MCI have Alzheimer disease (AD) as the underlying cause of the MCI. Other conditions that can cause MCI include depression, cerebrovascular disease, Lewy body disease, metabolic disorders, and drugs, prescribed for other diseases, that cause central nervous system side effects.
5. AD is the most common cause of dementia and manifests as loss of memory and other cognitive abilities sufficient to impair social and occupational functions. AD accounts for about 70% of cases of dementia in the United States, with the remainder caused primarily by cerebrovascular disease, Parkinson and Lewy body dementia, and frontotemporal dementia.
6. The pathology of AD is characterized by the accumulation of aggregated forms of two proteins in the brain, the Aβ peptide and tau. Aβ accumulates in a fibrillar form in extracellular structures called amyloid plaques in the brain parenchyma as well as in the walls of arterioles (where it is called cerebral amyloid angiopathy). Tau accumulates in neurofibrillary tangles in cell bodies and dendrites.
7. In addition to the accumulation of protein aggregates in the Alzheimer brain, marked brain atrophy as well as synaptic and neuronal loss occurs as the disease progresses. There is also a strong neuroinflammatory response, especially around amyloid plaques, which involves microglia and astrocytes.
8. The pathology of AD begins about 15 years prior to the onset of cognitive decline or the MCI phase of the disease. Aβ accumulation in the neocortex appears to initiate the disease with markedly abnormal levels, followed by the spread of tau aggregates from the medial temporal lobe to other regions of the neocortex. This phase of Alzheimer pathology prior to symptom onset is known as preclinical AD.
9. Significant data suggest that certain aggregated forms of the Aβ peptide lead to synaptic and neuronal damage in the Alzheimer brain, but a much better correlate of the cognitive decline is the presence and accumulation of aggregated forms of the tau protein.
10. There are two major forms of AD. The first is a dominantly inherited AD, which accounts for less than 1% of Alzheimer patients and is caused by mutations in one of three genes encoding the proteins APP, PS1, and PS2; this form leads to clinical disease onset between the ages of 30 and 50. Genetic, biochemical, and other studies have shown that the genes that cause autosomal dominant AD do so through early accumulation of the Aβ peptide in the brain. The second form, late-onset AD, with an age of onset of 65 years or later, accounts for more than 99% of cases. Although age is the greatest risk factor for late-onset AD, genetics also contribute. The *APOE* gene is by far the biggest genetic contributor to AD, with the *APOE4* variant increasing risk and the *APOE2* variant decreasing risk. There are a number of

other common genetic variants in other genes that influence risk. There are also rare variants in other genes such as *TREM2* that increase risk to a level similar to that associated with one copy of *APOE4*. Nonetheless, there is general agreement that major features of pathogenesis are similar in sporadic and familial AD.

11. Besides clinical symptoms and signs of AD, amyloid and tau imaging and cerebrospinal fluid markers can determine that Alzheimer pathology is present in a living person with or without cognitive decline.
12. There are currently only symptomatic therapies for AD that have modest benefit at best. A number of potential disease-modifying therapies that influence the production, clearance, and aggregation of either Aβ or tau are being tested in humans. Although none of these therapies is yet approved, there is hope that over the next several years one or more of these therapies will begin to show a clear benefit.

Symbols

C Capacitance (measured in farads).

c_m Capacitance per unit length of membrane cylinder.

C_m Membrane capacitance: either total input capacitance of a cell (measured in units of F) or capacitance of a unit area of membrane ($F \cdot cm^{-2}$), depending on context.

E Equilibrium (or Nernst) potential of an ion species, e.g., E_{Na}, or reversal potential for current through an ion channel.

F Faraday's constant (9.65×10^4 coulombs per mole).

G Conductance (measured in siemens).

g Conductance of a population of ion channels to one or more ion species, e.g., g_{Na}.

g_l Resting (leakage) conductance; total conductance of a population of resting (leakage) ion channels.

I Current (measured in amperes). The flow of charge per unit time, $\Delta Q/\Delta t$. Ohm's law, $I = V \cdot G$, states that current flowing through a conductor (G) is directly proportional to the potential difference (V) imposed across it.

I_c Capacitive current; the current that changes the charge distribution on the lipid bilayer.

I_i Ionic current; the resistive current that flows through ion channels.

I_l Leakage current; the current flowing through a population of resting ion channels.

I_m Total current crossing the cell membrane.

i Current flowing through a single ion channel.

Q Excess positive or negative charge on each side of a capacitor (measured in coulombs).

R Gas constant ($1.99\ cal \cdot °K^{-1} \cdot mol^{-1}$).

R Resistance (measured in ohms). The reciprocal of conductance, $1/G$.

R_{in} Total input resistance of a cell.

R_m Specific resistance of a unit area of membrane (measured in $\Omega \cdot cm^2$).

r Resistance of a single ion channel.

r_a Axial resistance of the cytoplasmic core of an axon, per unit length (measured in Ω/cm).

r_m Membrane resistance, per unit length (measured in $\Omega \cdot cm$).

V_m Membrane potential, $V_m = Q/C_{in}$ (measured in volts).

V_r Resting membrane potential.

V_t Threshold of membrane potential above which the neuron generates an action potential.

V_{in} Potential on the inside of the cell membrane.

V_{out} Potential on the outside of the cell membrane.

Z Valence.

γ Conductance of a single ion channel, e.g., γ_{Na}

λ Cell membrane length constant (typical values 0.1–1.0 mm). $\lambda = \sqrt{r_m/r_a}$

τ Cell membrane time constant; the product of resistance and capacitance of the membrane (typical values 1–20 ms). $\tau = R_m \cdot C_m$

Units of Measurement

A Ampere, measure of electric current (SI base unit). One ampere of current represents the movement of 1 coulomb of charge per second.

Å Ångström, measure of length (10^{-10} m, non-SI unit).

C Coulomb, measure of quantity of electricity, electric charge (expressed in SI base units $s \cdot A$).

F Farad, measure of capacitance (expressed in SI base units $m^2 \cdot kg^{-1} \cdot s^4 \cdot A^2$).

Hz Hertz, measure of frequency (expressed in s^{-1}).

M Molar measure of concentration of a solution (moles of solute per liter of solution).

mol Mole, measure of amount of substance (Sl base unit).

mol wt Molecular weight.

S Siemens, measure of conductance (expressed in SI base units $m^{-2} \cdot kg^{-1}. s^3 \cdot A^2$).

V Volt, measure of electric potential, electromotive force (expressed in SI base units $m^2 \cdot kg \cdot s^{-3} \cdot A^{-1}$). One volt is the energy required to move 1 coulomb a distance of 1 meter against a force of 1 newton. Measurements in cells are in the range of millivolts (mV).

Ω Ohm, measure of electric resistance (expressed in SI base units $m^2 \cdot kg \cdot s^{-3} \cdot A^{-2}$).
